These streams are regular `text files` like those returned by the `open()` function. Their parameters are chosen as follows:

- The encoding and error handling are initialized from `PyConfig.stdio_encoding` and `PyConfig.stdio_errors`.

On Windows, UTF-8 is used for the console device. Non-character devices such as disk files and pipes use the system locale encoding (i.e. the ANSI codepage). Non-console character devices such as NUL (i.e. where `isatty()` returns `True`) use the value of the console input and output codepages at startup, respectively for `stdin` and `stdout/stderr`. This defaults to the system `locale encoding` if the process is not initially attached to a console.

The special behaviour of the console can be overridden by setting the environment variable `PYTHONLEGACYWINDOWSSTDIO` before starting Python. In that case, the console codepages are used as for any other character device.

Under all platforms, you can override the character encoding by setting the `PYTHONIOENCODING` environment variable before starting Python or by using the new `-X utf8` command line option and `PYTHONUTF8` environment variable. However, for the Windows console, this only applies when `PYTHONLEGACYWINDOWSSTDIO` is also set.

- When interactive, the `stdout` stream is line-buffered. Otherwise, it is block-buffered like regular text files. The `stderr` stream is line-buffered in both cases. You can make both streams unbuffered by passing the `-u`

command-line option or setting the `PYTHONUNBUFFERED` environment variable.

*Changed in version 3.9:* Non-interactive `stderr` is now line-buffered instead of fully buffered.

### Note

To write or read binary data from/to the standard streams, use the underlying binary `buffer` object. For example, to write bytes to `stdout`, use

```
sys.stdout.buffer.write(b'abc').
```

However, if you are writing a library (and do not control in which context its code will be executed), be aware that the standard streams may be replaced with file-like objects like `io.StringIO` which do not support the `buffer` attribute.

```
sys.__stdin__  
sys.__stdout__  
sys.__stderr__
```

These objects contain the original values of `stdin`, `stderr` and `stdout` at the start of the program. They are used during finalization, and could be useful to print to the actual standard stream no matter if the `sys.std*` object has been redirected.

It can also be used to restore the actual files to known working file objects in case they have been overwritten with a broken object. However, the preferred way to do this is to explicitly save the previous stream before replacing it, and restore the saved object.

### Note

Under some conditions `stdin`, `stdout` and `stderr` as well as the original values `__stdin__`, `__stdout__` and `__stderr__` can be `None`. It is usually the case for

Windows GUI apps that aren't connected to a console and Python apps started with **pythonw**.

### `sys.stdlib_module_names`

A frozenset of strings containing the names of standard library modules.

It is the same on all platforms. Modules which are not available on some platforms and modules disabled at Python build are also listed. All module kinds are listed: pure Python, built-in, frozen and extension modules. Test modules are excluded.

For packages, only the main package is listed: sub-packages and sub-modules are not listed. For example, the `email` package is listed, but the `email.mime` sub-package and the `email.message` sub-module are not listed.

See also the [`sys.builtin\_module\_names`](#) list.

*New in version 3.10.*

### `sys.thread_info`

A [`named tuple`](#) holding information about the thread implementation.

#### **Explanation**

---

**Name** of the thread implementation:

- `'nt'`: Windows threads
- `'pthread'`: POSIX threads
- `'pthread-stubs'`: stub POSIX threads (on WebAssembly platforms without threading support)
- `'solaris'`: Solaris threads

---

**Name** of the lock implementation:

- `'semaphore'`: a lock uses a semaphore
  - `'mutex+cond'`: a lock uses a mutex and a condition variable
-

- None if this information is unknown

`Name` and version of the thread library. It is a string, or None if this information is unknown.

---

*New in version 3.3.*

## `sys.tracebacklimit`

When this variable is set to an integer value, it determines the maximum number of levels of traceback information printed when an unhandled exception occurs. The default is 1000. When set to 0 or less, all traceback information is suppressed and only the exception type and value are printed.

## `sys.unraisablehook(unraisable, /)`

Handle an unraisable exception.

Called when an exception has occurred but there is no way for Python to handle it. For example, when a destructor raises an exception or during garbage collection (`gc.collect()`).

The *unraisable* argument has the following attributes:

- *exc\_type*: Exception type.
- *exc\_value*: Exception value, can be None.
- *exc\_traceback*: Exception traceback, can be None.
- *err\_msg*: Error message, can be None.
- *object*: Object causing the exception, can be None.

The default hook formats *err\_msg* and *object* as:

```
f'{err_msg}: {object!r}'; use "Exception ignored in" error message if err_msg is None.
```

`sys.unraisablehook()` can be overridden to control how unraisable exceptions are handled.

Storing *exc\_value* using a custom hook can create a reference cycle. It should be cleared explicitly to break the reference cycle when the exception is no longer needed.

Storing *object* using a custom hook can resurrect it if it is set to an object which is being finalized. Avoid storing *object*

after the custom hook completes to avoid resurrecting objects.

See also `excepthook()` which handles uncaught exceptions.

Raise an auditing event `sys.unraisablehook` with arguments `hook`, `unraisable` when an exception that cannot be handled occurs. The `unraisable` object is the same as what will be passed to the hook. If no hook has been set, `hook` may be `None`.

*New in version 3.8.*

### `sys.version`

A string containing the version number of the Python interpreter plus additional information on the build number and compiler used. This string is displayed when the interactive interpreter is started. Do not extract version information out of it, rather, use `version_info` and the functions provided by the `platform` module.

### `sys.api_version`

The C API version for this interpreter. Programmers may find this useful when debugging version conflicts between Python and extension modules.

### `sys.version_info`

A tuple containing the five components of the version number: *major*, *minor*, *micro*, *releaselevel*, and *serial*. All values except *releaselevel* are integers; the release level is 'alpha', 'beta', 'candidate', or 'final'. The `version_info` value corresponding to the Python version 2.0 is `(2, 0, 0, 'final', 0)`. The components can also be accessed by name, so `sys.version_info[0]` is equivalent to `sys.version_info.major` and so on.

*Changed in version 3.1:* Added named component attributes.

### `sys.warnoptions`

This is an implementation detail of the warnings framework; do not modify this value. Refer to the [warnings](#) module for more information on the warnings framework.

### `sys.winver`

The version number used to form registry keys on Windows platforms. This is stored as string resource 1000 in the Python DLL. The value is normally the major and minor versions of the running Python interpreter. It is provided in the [sys](#) module for informational purposes; modifying this value has no effect on the registry keys used by Python.

[Availability](#): Windows.

### `sys._xoptions`

A dictionary of the various implementation-specific flags passed through the [-X](#) command-line option. Option names are either mapped to their values, if given explicitly, or to [True](#). Example:

```
$ ./python -Xa=b -Xc
Python 3.2a3+ (py3k, Oct 16 2010, 20:14:50)
[GCC 4.4.3] on linux2
Type "help", "copyright", "credits" or "license" fo
>>> import sys
>>> sys._xoptions
{'a': 'b', 'c': True}
```

**CPython implementation detail:** This is a CPython-specific way of accessing options passed through [-X](#). Other implementations may export them through other means, or not at all.

*New in version 3.2.*

## Citations

ISO/IEC 9899:1999. “Programming languages – C.” A public draft of this standard is available at <https://www.open-std.org/jtc1/sc22/wg14/www/docs/n1256.pdf>.

# **sysconfig** — Provide access to Python's configuration information

*New in version 3.2.*

**Source code:** [Lib/sysconfig.py](https://github.com/python/cpython/tree/3.11/Lib/sysconfig.py) [https://github.com/python/cpython/tree/3.11/Lib/sysconfig.py]

---

The **sysconfig** module provides access to Python's configuration information like the list of installation paths and the configuration variables relevant for the current platform.

## Configuration variables

A Python distribution contains a `Makefile` and a `pyconfig.h` header file that are necessary to build both the Python binary itself and third-party C extensions compiled using **distutils**.

**sysconfig** puts all variables found in these files in a dictionary that can be accessed using `get_config_vars()` or `get_config_var()`.

Notice that on Windows, it's a much smaller set.

`sysconfig.get_config_vars(*args)`

With no arguments, return a dictionary of all configuration variables relevant for the current platform.

With arguments, return a list of values that result from looking up each argument in the configuration variable dictionary.

For each argument, if the value is not found, return `None`.

`sysconfig.get_config_var(name)`

Return the value of a single variable *name*. Equivalent to `get_config_vars().get(name)`.

If *name* is not found, return `None`.

Example of usage:

```
>>> import sysconfig
>>> sysconfig.get_config_var('Py_ENABLE_SHARED')
0
>>> sysconfig.get_config_var('LIBDIR')
'/usr/local/lib'
>>> sysconfig.get_config_vars('AR', 'CXX')
['ar', 'g++']
```

## Installation paths

Python uses an installation scheme that differs depending on the platform and on the installation options. These schemes are stored in `sysconfig` under unique identifiers based on the value returned by `os.name`.

Every new component that is installed using `distutils` or a Distutils-based system will follow the same scheme to copy its file in the right places.

Python currently supports nine schemes:

- *posix\_prefix*: scheme for POSIX platforms like Linux or macOS. This is the default scheme used when Python or a component is installed.
- *posix\_home*: scheme for POSIX platforms used when a *home* option is used upon installation. This scheme is used when a component is installed through Distutils with a specific home prefix.
- *posix\_user*: scheme for POSIX platforms used when a

component is installed through Distutils and the *user* option is used. This scheme defines paths located under the user home directory.

- *posix\_venv*: scheme for **Python virtual environments** on POSIX platforms; by default it is the same as *posix\_prefix* .
- *nt*: scheme for NT platforms like Windows.
- *nt\_user*: scheme for NT platforms, when the *user* option is used.
- *nt\_venv*: scheme for **Python virtual environments** on NT platforms; by default it is the same as *nt* .
- *venv*: a scheme with values from either *posix\_venv* or *nt\_venv* depending on the platform Python runs on
- *osx\_framework\_user*: scheme for macOS, when the *user* option is used.

Each scheme is itself composed of a series of paths and each path has a unique identifier. Python currently uses eight paths:

- *stdlib*: directory containing the standard Python library files that are not platform-specific.
- *platstdlib*: directory containing the standard Python library files that are platform-specific.
- *platlib*: directory for site-specific, platform-specific files.
- *purelib*: directory for site-specific, non-platform-specific files.
- *include*: directory for non-platform-specific header files for the Python C-API.
- *platinclude*: directory for platform-specific header files for the Python C-API.
- *scripts*: directory for script files.
- *data*: directory for data files.

**sysconfig** provides some functions to determine these paths.

`sysconfig.get_scheme_names()`

Return a tuple containing all schemes currently supported in **sysconfig**.

`sysconfig.get_default_scheme()`

Return the default scheme name for the current platform.

*New in version 3.10:* This function was previously named `_get_default_scheme()` and considered an implementation detail.

*Changed in version 3.11:* When Python runs from a virtual environment, the *venv* scheme is returned.

`sysconfig.get_preferred_scheme(key)`

Return a preferred scheme name for an installation layout specified by *key*.

*key* must be either "prefix", "home", or "user".

The return value is a scheme name listed in `get_scheme_names()`. It can be passed to `sysconfig` functions that take a *scheme* argument, such as `get_paths()`.

*New in version 3.10.*

*Changed in version 3.11:* When Python runs from a virtual environment and `key="prefix"`, the *venv* scheme is returned.

`sysconfig._get_preferred_schemes()`

Return a dict containing preferred scheme names on the current platform. Python implementers and redistributors may add their preferred schemes to the `_INSTALL_SCHEMES` module-level global value, and modify this function to return those scheme names, to e.g. provide different schemes for system and language package managers to use, so packages installed by either do not mix with those by the other.

End users should not use this function, but `get_default_scheme()` and `get_preferred_scheme()` instead.

*New in version 3.10.*

`sysconfig.get_path_names()`

Return a tuple containing all path names currently supported in `sysconfig`.

```
sysconfig.get_path(name[, scheme[, vars[, expand]]])
```

Return an installation path corresponding to the path *name*, from the install scheme named *scheme*.

*name* has to be a value from the list returned by `get_path_names()`.

`sysconfig` stores installation paths corresponding to each path name, for each platform, with variables to be expanded. For instance the *stdlib* path for the *nt* scheme is: `{base}/Lib`.

`get_path()` will use the variables returned by `get_config_vars()` to expand the path. All variables have default values for each platform so one may call this function and get the default value.

If *scheme* is provided, it must be a value from the list returned by `get_scheme_names()`. Otherwise, the default scheme for the current platform is used.

If *vars* is provided, it must be a dictionary of variables that will update the dictionary return by `get_config_vars()`.

If *expand* is set to `False`, the path will not be expanded using the variables.

If *name* is not found, raise a `KeyError`.

```
sysconfig.get_paths([scheme[, vars[, expand]]])
```

Return a dictionary containing all installation paths corresponding to an installation scheme. See `get_path()` for more information.

If *scheme* is not provided, will use the default scheme for the current platform.

If *vars* is provided, it must be a dictionary of variables that will update the dictionary used to expand the paths.

If *expand* is set to false, the paths will not be expanded.

If *scheme* is not an existing scheme, `get_paths()` will raise a `KeyError`.

## Other functions

`sysconfig.get_python_version()`

Return the MAJOR.MINOR Python version number as a string. Similar to `'%d.%d' % sys.version_info[:2]`.

`sysconfig.get_platform()`

Return a string that identifies the current platform.

This is used mainly to distinguish platform-specific build directories and platform-specific build distributions. Typically includes the OS name and version and the architecture (as supplied by `'os.uname()'`), although the exact information included depends on the OS; e.g., on Linux, the kernel version isn't particularly important.

Examples of returned values:

- linux-i586
- linux-alpha (?)
- solaris-2.6-sun4u

Windows will return one of:

- win-amd64 (64bit Windows on AMD64, aka x86\_64, Intel64, and EM64T)
- win32 (all others - specifically, `sys.platform` is returned)

macOS can return:

- macosx-10.6-ppc
- macosx-10.4-ppc64

- macosx-10.3-i386
- macosx-10.4-fat

For other non-POSIX platforms, currently just returns `sys.platform`.

`sysconfig.is_python_build()`

Return `True` if the running Python interpreter was built from source and is being run from its built location, and not from a location resulting from e.g. running `make install` or installing via a binary installer.

`sysconfig.parse_config_h(fp[, vars])`

Parse a `config.h`-style file.

*fp* is a file-like object pointing to the `config.h`-like file.

A dictionary containing name/value pairs is returned. If an optional dictionary is passed in as the second argument, it is used instead of a new dictionary, and updated with the values read in the file.

`sysconfig.get_config_h_filename()`

Return the path of `pyconfig.h`.

`sysconfig.get_makefile_filename()`

Return the path of `Makefile`.

## Using `sysconfig` as a script

You can use `sysconfig` as a script with Python's `-m` option:

```
$ python -m sysconfig
Platform: "macosx-10.4-i386"
Python version: "3.2"
Current installation scheme: "posix_prefix"
```

Paths:

```
data = "/usr/local"
include = "/Users/tarek/Dev/svn.python.org/py3k/"
platinclude = "."
platlib = "/usr/local/lib/python3.2/site-packages"
platstdlib = "/usr/local/lib/python3.2"
purelib = "/usr/local/lib/python3.2/site-packages"
scripts = "/usr/local/bin"
stdlib = "/usr/local/lib/python3.2"
```

Variables:

```
AC_APPLE_UNIVERSAL_BUILD = "0"
AIX_GENUINE_CPLUSPLUS = "0"
AR = "ar"
ARFLAGS = "rc"
...
```

This call will print in the standard output the information returned by `get_platform()`, `get_python_version()`, `get_path()` and `get_config_vars()`.

# `builtins` — Built-in objects

---

This module provides direct access to all ‘built-in’ identifiers of Python; for example, `builtins.open` is the full name for the built-in function `open()`. See [Built-in Functions](#) and [Built-in Constants](#) for documentation.

This module is not normally accessed explicitly by most applications, but can be useful in modules that provide objects with the same name as a built-in value, but in which the built-in of that name is also needed. For example, in a module that wants to implement an `open()` function that wraps the built-in `open()`, this module can be used directly:

```
import builtins

def open(path):
    f = builtins.open(path, 'r')
    return UpperCaser(f)

class UpperCaser:
    '''Wrapper around a file that converts output to upper case'''

    def __init__(self, f):
        self._f = f

    def read(self, count=-1):
        return self._f.read(count).upper()

    # ...
```

As an implementation detail, most modules have the name `__builtins__` made available as part of their globals. The value of `__builtins__` is normally either this module or the value of this module’s `__dict__` attribute. Since this is an implementation

detail, it may not be used by alternate implementations of Python.

# `__main__` — Top-level code environment

---

In Python, the special name `__main__` is used for two important constructs:

1. the name of the top-level environment of the program, which can be checked using the `__name__ == '__main__'` expression; and
2. the `__main__.py` file in Python packages.

Both of these mechanisms are related to Python modules; how users interact with them and how they interact with each other. They are explained in detail below. If you're new to Python modules, see the tutorial section [Modules](#) for an introduction.

## `__name__ == '__main__'`

When a Python module or package is imported, `__name__` is set to the module's name. Usually, this is the name of the Python file itself without the `.py` extension:

```
>>> import configparser
>>> configparser.__name__
'configparser'
```

If the file is part of a package, `__name__` will also include the parent package's path:

```
>>> from concurrent.futures import process
>>> process.__name__
'concurrent.futures.process'
```

However, if the module is executed in the top-level code

environment, its `__name__` is set to the string `'__main__'`.

## What is the “top-level code environment”?

`__main__` is the name of the environment where top-level code is run. “Top-level code” is the first user-specified Python module that starts running. It’s “top-level” because it imports all other modules that the program needs. Sometimes “top-level code” is called an *entry point* to the application.

The top-level code environment can be:

- the scope of an interactive prompt:

```
>>> __name__  
'__main__'
```

- the Python module passed to the Python interpreter as a file argument:

```
$ python3 helloworld.py  
Hello, world!
```

- the Python module or package passed to the Python interpreter with the `-m` argument:

```
$ python3 -m tarfile  
usage: tarfile.py [-h] [-v] (...)
```

- Python code read by the Python interpreter from standard input:

```
$ echo "import this" | python3  
The Zen of Python, by Tim Peters  
  
Beautiful is better than ugly.  
Explicit is better than implicit.  
...
```

- Python code passed to the Python interpreter with the `-c` argument:

```
$ python3 -c "import this"
The Zen of Python, by Tim Peters

Beautiful is better than ugly.
Explicit is better than implicit.
...
```

In each of these situations, the top-level module's `__name__` is set to `'__main__'`.

As a result, a module can discover whether or not it is running in the top-level environment by checking its own `__name__`, which allows a common idiom for conditionally executing code when the module is not initialized from an import statement:

```
if __name__ == '__main__':
    # Execute when the module is not initialized from an
    ...
```

## See also

For a more detailed look at how `__name__` is set in all situations, see the tutorial section [Modules](#).

## Idiomatic Usage

Some modules contain code that is intended for script use only, like parsing command-line arguments or fetching data from standard input. If a module like this was imported from a different module, for example to unit test it, the script code would unintentionally execute as well.

This is where using the `if __name__ == '__main__':` code block comes in handy. Code within this block won't run unless the module is executed in the top-level environment.

Putting as few statements as possible in the block below `if __name__ == '__main__':` can improve code clarity and correctness. Most often, a function named `main` encapsulates the program's primary behavior:

```
# echo.py

import shlex
import sys

def echo(phrase: str) -> None:
    """A dummy wrapper around print."""
    # for demonstration purposes, you can imagine that the
    # valuable and reusable logic inside this function
    print(phrase)

def main() -> int:
    """Echo the input arguments to standard output"""
    phrase = shlex.join(sys.argv)
    echo(phrase)
    return 0

if __name__ == '__main__':
    sys.exit(main()) # next section explains the use of
```

Note that if the module didn't encapsulate code inside the `main` function but instead put it directly within the `if __name__ == '__main__':` block, the `phrase` variable would be global to the entire module. This is error-prone as other functions within the module could be unintentionally using the global variable instead of a local name. A `main` function solves this problem.

Using a `main` function has the added benefit of the `echo` function itself being isolated and importable elsewhere. When `echo.py` is imported, the `echo` and `main` functions will be defined, but neither of them will be called, because `__name__ != '__main__'`.

## Packaging Considerations

`main` functions are often used to create command-line tools by specifying them as entry points for console scripts. When this is done, [pip](https://pip.pypa.io/) [https://pip.pypa.io/] inserts the function call into a template script, where the return value of `main` is passed into

`sys.exit()`. For example:

```
sys.exit(main())
```

Since the call to `main` is wrapped in `sys.exit()`, the expectation is that your function will return some value acceptable as an input to `sys.exit()`; typically, an integer or `None` (which is implicitly returned if your function does not have a return statement).

By proactively following this convention ourselves, our module will have the same behavior when run directly (i.e. `python3 echo.py`) as it will have if we later package it as a console script entry-point in a pip-installable package.

In particular, be careful about returning strings from your `main` function. `sys.exit()` will interpret a string argument as a failure message, so your program will have an exit code of `1`, indicating failure, and the string will be written to `sys.stderr`. The `echo.py` example from earlier exemplifies using the `sys.exit(main())` convention.

### See also

[Python Packaging User Guide](https://packaging.python.org/) [https://packaging.python.org/] contains a collection of tutorials and references on how to distribute and install Python packages with modern tools.

## `__main__.py` in Python Packages

If you are not familiar with Python packages, see section [Packages](#) of the tutorial. Most commonly, the `__main__.py` file is used to provide a command-line interface for a package. Consider the following hypothetical package, “bandclass”:

```
bandclass
  __init__.py
  __main__.py
  student.py
```

`__main__.py` will be executed when the package itself is invoked directly from the command line using the `-m` flag. For example:

```
$ python3 -m bandclass
```

This command will cause `__main__.py` to run. How you utilize this mechanism will depend on the nature of the package you are writing, but in this hypothetical case, it might make sense to allow the teacher to search for students:

```
# bandclass/__main__.py
```

```
import sys
```

```
from .student import search_students
```

```
student_name = sys.argv[2] if len(sys.argv) >= 2 else ''
print(f'Found student: {search_students(student_name)}')
```

Note that `from .student import search_students` is an example of a relative import. This import style can be used when referencing modules within a package. For more details, see [Intra-package References](#) in the [Modules](#) section of the tutorial.

## Idiomatic Usage

The contents of `__main__.py` typically isn't fenced with `if __name__ == '__main__':` blocks. Instead, those files are kept short, functions to execute from other modules. Those other modules can then be easily unit-tested and are properly reusable.

If used, an `if __name__ == '__main__':` block will still work as expected for a `__main__.py` file within a package, because its `__name__` attribute will include the package's path if imported:

```
>>> import asyncio.__main__
>>> asyncio.__main__.__name__
'asyncio.__main__'
```

This won't work for `__main__.py` files in the root directory of a `.zip` file though. Hence, for consistency, minimal `__main__.py` like the [venv](#) one mentioned below are preferred.

## See also

See [venv](#) for an example of a package with a minimal `__main__.py` in the standard library. It doesn't contain a `if __name__ == '__main__':` block. You can invoke it with `python -m venv [directory]`.

See [runpy](#) for more details on the `-m` flag to the interpreter executable.

See [zipapp](#) for how to run applications packaged as `.zip` files. In this case Python looks for a `__main__.py` file in the root directory of the archive.

## `import __main__`

Regardless of which module a Python program was started with, other modules running within that same program can import the top-level environment's scope ([namespace](#)) by importing the `__main__` module. This doesn't import a `__main__.py` file but rather whichever module that received the special name `'__main__'`.

Here is an example module that consumes the `__main__` namespace:

```
# namely.py
```

```
import __main__
```

```
def did_user_define_their_name():
    return 'my_name' in dir(__main__)
```

```
def print_user_name():
    if not did_user_define_their_name():
        raise ValueError('Define the variable `my_name`!')

    if '__file__' in dir(__main__):
        print(__main__.my_name, "found in file", __main_
```

```
else:
    print(__main__.my_name)
```

Example usage of this module could be as follows:

```
# start.py

import sys

from namely import print_user_name

# my_name = "Dinsdale"

def main():
    try:
        print_user_name()
    except ValueError as ve:
        return str(ve)

if __name__ == "__main__":
    sys.exit(main())
```

Now, if we started our program, the result would look like this:

```
$ python3 start.py
Define the variable `my_name`!
```

The exit code of the program would be 1, indicating an error. Uncommenting the line with `my_name = "Dinsdale"` fixes the program and now it exits with status code 0, indicating success:

```
$ python3 start.py
Dinsdale found in file /path/to/start.py
```

Note that importing `__main__` doesn't cause any issues with unintentionally running top-level code meant for script use which is put in the `if __name__ == "__main__"` block of the `start` module. Why does this work?

Python inserts an empty `__main__` module in [sys.modules](#) at

interpreter startup, and populates it by running top-level code. In our example this is the `start` module which runs line by line and imports `namely`. In turn, `namely` imports `__main__` (which is really `start`). That's an import cycle! Fortunately, since the partially populated `__main__` module is present in [sys.modules](#), Python passes that to `namely`. See [Special considerations for `\_\_main\_\_`](#) in the import system's reference for details on how this works.

The Python REPL is another example of a “top-level environment”, so anything defined in the REPL becomes part of the `__main__` scope:

```
>>> import namely
>>> namely.did_user_define_their_name()
False
>>> namely.print_user_name()
Traceback (most recent call last):
...
ValueError: Define the variable `my_name`!
>>> my_name = 'Jabberwocky'
>>> namely.did_user_define_their_name()
True
>>> namely.print_user_name()
Jabberwocky
```

Note that in this case the `__main__` scope doesn't contain a `__file__` attribute as it's interactive.

The `__main__` scope is used in the implementation of [pdb](#) and [rlcompleter](#).

# warnings — Warning control

**Source code:** [Lib/warnings.py](https://github.com/python/cpython/tree/3.11/Lib/warnings.py) [https://github.com/python/cpython/tree/3.11/Lib/warnings.py]

---

Warning messages are typically issued in situations where it is useful to alert the user of some condition in a program, where that condition (normally) doesn't warrant raising an exception and terminating the program. For example, one might want to issue a warning when a program uses an obsolete module.

Python programmers issue warnings by calling the `warn()` function defined in this module. (C programmers use `PyErr_WarnEx()`; see [Exception Handling](#) for details).

Warning messages are normally written to `sys.stderr`, but their disposition can be changed flexibly, from ignoring all warnings to turning them into exceptions. The disposition of warnings can vary based on the [warning category](#), the text of the warning message, and the source location where it is issued. Repetitions of a particular warning for the same source location are typically suppressed.

There are two stages in warning control: first, each time a warning is issued, a determination is made whether a message should be issued or not; next, if a message is to be issued, it is formatted and printed using a user-settable hook.

The determination whether to issue a warning message is controlled by the [warning filter](#), which is a sequence of matching rules and actions. Rules can be added to the filter by calling `filterwarnings()` and reset to its default state by calling `resetwarnings()`.

The printing of warning messages is done by calling `showwarning()`, which may be overridden; the default

implementation of this function formats the message by calling `formatwarning()`, which is also available for use by custom implementations.

See also

`logging.captureWarnings()` allows you to handle all warnings with the standard logging infrastructure.

## Warning Categories

There are a number of built-in exceptions that represent warning categories. This categorization is useful to be able to filter out groups of warnings.

While these are technically [built-in exceptions](#), they are documented here, because conceptually they belong to the warnings mechanism.

User code can define additional warning categories by subclassing one of the standard warning categories. A warning category must always be a subclass of the `Warning` class.

The following warnings category classes are currently defined:

Description
This is the base class of all warning category classes. It is a subclass of <code>Exception</code> .
The default category for <code>warn()</code> .
Base category for warnings about deprecated features when those warnings are intended for other Python developers (ignored by default, unless triggered by code in <code>__main__</code> ).
Base category for warnings about dubious syntactic features.
Base category for warnings about dubious runtime features.
Base category for warnings about deprecated features when those warnings are intended for end users of applications that are written in Python.
Base category for warnings about features that will be deprecated in the future (ignored by default).

**Base category for** warnings triggered during the process of importing a module (ignored by default).

---

**Base category for** warnings related to Unicode.

---

**Base category for** warnings related to **bytes** and **bytearray**.

---

**Base category for** warnings related to resource usage (ignored by default).

---

*Changed in version 3.7:* Previously **DeprecationWarning** and **FutureWarning** were distinguished based on whether a feature was being removed entirely or changing its behaviour. They are now distinguished based on their intended audience and the way they're handled by the default warnings filters.

## The Warnings Filter

The warnings filter controls whether warnings are ignored, displayed, or turned into errors (raising an exception).

Conceptually, the warnings filter maintains an ordered list of filter specifications; any specific warning is matched against each filter specification in the list in turn until a match is found; the filter determines the disposition of the match. Each entry is a tuple of the form (*action*, *message*, *category*, *module*, *lineno*), where:

- *action* is one of the following strings:

### **Disposition**

---

**print** the first occurrence of matching warnings for each location (module + line number) where the warning is issued

---

**turn** matching warnings into exceptions

---

**never print** matching warnings

---

**always print** matching warnings

---

**print** the first occurrence of matching warnings for each module where the warning is issued (regardless of line number)

---

**print only** the first occurrence of matching warnings, regardless of location

---

- *message* is a string containing a regular expression that the

start of the warning message must match, case-insensitively. In `-W` and `PYTHONWARNINGS`, *message* is a literal string that the start of the warning message must contain (case-insensitively), ignoring any whitespace at the start or end of *message*.

- *category* is a class (a subclass of `Warning`) of which the warning category must be a subclass in order to match.
- *module* is a string containing a regular expression that the start of the fully qualified module name must match, case-sensitively. In `-W` and `PYTHONWARNINGS`, *module* is a literal string that the fully qualified module name must be equal to (case-sensitively), ignoring any whitespace at the start or end of *module*.
- *lineno* is an integer that the line number where the warning occurred must match, or `0` to match all line numbers.

Since the `Warning` class is derived from the built-in `Exception` class, to turn a warning into an error we simply raise `category(message)`.

If a warning is reported and doesn't match any registered filter then the "default" action is applied (hence its name).

## Describing Warning Filters

The warnings filter is initialized by `-W` options passed to the Python interpreter command line and the `PYTHONWARNINGS` environment variable. The interpreter saves the arguments for all supplied entries without interpretation in `sys.warnoptions`; the `warnings` module parses these when it is first imported (invalid options are ignored, after printing a message to `sys.stderr`).

Individual warnings filters are specified as a sequence of fields separated by colons:

```
action:message:category:module:line
```

The meaning of each of these fields is as described in [The Warnings](#)

**Filter.** When listing multiple filters on a single line (as for **PYTHONWARNINGS**), the individual filters are separated by commas and the filters listed later take precedence over those listed before them (as they're applied left-to-right, and the most recently applied filters take precedence over earlier ones).

Commonly used warning filters apply to either all warnings, warnings in a particular category, or warnings raised by particular modules or packages. Some examples:

```
default                # Show all warnings (even t
ignore                 # Ignore all warnings
error                  # Convert all warnings to e
error::ResourceWarning # Treat ResourceWarning mes
default::DeprecationWarning # Show DeprecationWarning m
ignore,default::mymodule # Only report warnings trig
error::mymodule        # Convert warnings to error
```

## Default Warning Filter

By default, Python installs several warning filters, which can be overridden by the **-W** command-line option, the **PYTHONWARNINGS** environment variable and calls to **filterwarnings()**.

In regular release builds, the default warning filter has the following entries (in order of precedence):

```
default::DeprecationWarning:__main__
ignore::DeprecationWarning
ignore::PendingDeprecationWarning
ignore::ImportWarning
ignore::ResourceWarning
```

In a **debug build**, the list of default warning filters is empty.

*Changed in version 3.2:* **DeprecationWarning** is now ignored by default in addition to **PendingDeprecationWarning**.

*Changed in version 3.7:* **DeprecationWarning** is once again shown by default when triggered directly by code in **\_\_main\_\_**.

Changed in version 3.7: **BytesWarning** no longer appears in the default filter list and is instead configured via **sys.warnoptions** when **-b** is specified twice.

## Overriding the default filter

Developers of applications written in Python may wish to hide *all* Python level warnings from their users by default, and only display them when running tests or otherwise working on the application. The **sys.warnoptions** attribute used to pass filter configurations to the interpreter can be used as a marker to indicate whether or not warnings should be disabled:

```
import sys

if not sys.warnoptions:
    import warnings
    warnings.simplefilter("ignore")
```

Developers of test runners for Python code are advised to instead ensure that *all* warnings are displayed by default for the code under test, using code like:

```
import sys

if not sys.warnoptions:
    import os, warnings
    warnings.simplefilter("default") # Change the filter
    os.environ["PYTHONWARNINGS"] = "default" # Also affect
```

Finally, developers of interactive shells that run user code in a namespace other than `__main__` are advised to ensure that **DeprecationWarning** messages are made visible by default, using code like the following (where `user_ns` is the module used to execute code entered interactively):

```
import warnings
warnings.filterwarnings("default", category=DeprecationWarning,
                        module=user_ns.get("__
```

# Temporarily Suppressing Warnings

If you are using code that you know will raise a warning, such as a deprecated function, but do not want to see the warning (even when warnings have been explicitly configured via the command line), then it is possible to suppress the warning using the `catch_warnings` context manager:

```
import warnings

def fxn():
    warnings.warn("deprecated", DeprecationWarning)

with warnings.catch_warnings():
    warnings.simplefilter("ignore")
    fxn()
```

While within the context manager all warnings will simply be ignored. This allows you to use known-deprecated code without having to see the warning while not suppressing the warning for other code that might not be aware of its use of deprecated code. Note: this can only be guaranteed in a single-threaded application. If two or more threads use the `catch_warnings` context manager at the same time, the behavior is undefined.

## Testing Warnings

To test warnings raised by code, use the `catch_warnings` context manager. With it you can temporarily mutate the warnings filter to facilitate your testing. For instance, do the following to capture all raised warnings to check:

```
import warnings

def fxn():
    warnings.warn("deprecated", DeprecationWarning)

with warnings.catch_warnings(record=True) as w:
    # Cause all warnings to always be triggered.
```

```
warnings.simplefilter("always")
# Trigger a warning.
fxn()
# Verify some things
assert len(w) == 1
assert isinstance(w[-1].category, DeprecationWarning)
assert "deprecated" in str(w[-1].message)
```

One can also cause all warnings to be exceptions by using `error` instead of `always`. One thing to be aware of is that if a warning has already been raised because of a `once/default` rule, then no matter what filters are set the warning will not be seen again unless the warnings registry related to the warning has been cleared.

Once the context manager exits, the warnings filter is restored to its state when the context was entered. This prevents tests from changing the warnings filter in unexpected ways between tests and leading to indeterminate test results. The `showwarning()` function in the module is also restored to its original value. Note: this can only be guaranteed in a single-threaded application. If two or more threads use the `catch_warnings` context manager at the same time, the behavior is undefined.

When testing multiple operations that raise the same kind of warning, it is important to test them in a manner that confirms each operation is raising a new warning (e.g. set warnings to be raised as exceptions and check the operations raise exceptions, check that the length of the warning list continues to increase after each operation, or else delete the previous entries from the warnings list before each new operation).

## Updating Code For New Versions of Dependencies

Warning categories that are primarily of interest to Python developers (rather than end users of applications written in Python) are ignored by default.

Notably, this “ignored by default” list includes

**DeprecationWarning** (for every module except `__main__`), which means developers should make sure to test their code with typically ignored warnings made visible in order to receive timely notifications of future breaking API changes (whether in the standard library or third party packages).

In the ideal case, the code will have a suitable test suite, and the test runner will take care of implicitly enabling all warnings when running tests (the test runner provided by the **unittest** module does this).

In less ideal cases, applications can be checked for use of deprecated interfaces by passing **-Wd** to the Python interpreter (this is shorthand for **-W default**) or setting `PYTHONWARNINGS=default` in the environment. This enables default handling for all warnings, including those that are ignored by default. To change what action is taken for encountered warnings you can change what argument is passed to **-W** (e.g. **-W error**). See the **-W** flag for more details on what is possible.

## Available Functions

`warnings.warn(message, category=None, stacklevel=1, source=None)`

Issue a warning, or maybe ignore it or raise an exception. The *category* argument, if given, must be a **warning category class**; it defaults to **UserWarning**. Alternatively, *message* can be a **Warning** instance, in which case *category* will be ignored and `message.__class__` will be used. In this case, the message text will be `str(message)`. This function raises an exception if the particular warning issued is changed into an error by the **warnings filter**. The *stacklevel* argument can be used by wrapper functions written in Python, like this:

```
def deprecation(message):  
    warnings.warn(message, DeprecationWarning, stacklevel=2)
```

This makes the warning refer to **deprecation()**'s caller, rather than to the source of **deprecation()** itself (since the

latter would defeat the purpose of the warning message).

*source*, if supplied, is the destroyed object which emitted a [ResourceWarning](#).

*Changed in version 3.6:* Added *source* parameter.

`warnings.warn_explicit(message, category, filename, lineno, module=None, registry=None, module_globals=None, source=None)`

This is a low-level interface to the functionality of [warn\(\)](#), passing in explicitly the message, category, filename and line number, and optionally the module name and the registry (which should be the `__warningregistry__` dictionary of the module). The module name defaults to the filename with `.py` stripped; if no registry is passed, the warning is never suppressed. *message* must be a string and *category* a subclass of [Warning](#) or *message* may be a [Warning](#) instance, in which case *category* will be ignored.

*module\_globals*, if supplied, should be the global namespace in use by the code for which the warning is issued. (This argument is used to support displaying source for modules found in zipfiles or other non-filesystem import sources).

*source*, if supplied, is the destroyed object which emitted a [ResourceWarning](#).

*Changed in version 3.6:* Add the *source* parameter.

`warnings.showwarning(message, category, filename, lineno, file=None, line=None)`

Write a warning to a file. The default implementation calls `formatwarning(message, category, filename, lineno, line)` and writes the resulting string to *file*, which defaults to [sys.stderr](#). You may replace this function with any callable by assigning to `warnings.showwarning`. *line* is a line of source code to be included in the warning message; if *line* is not supplied, [showwarning\(\)](#) will try to read the line specified by *filename* and *lineno*.

`warnings.formatwarning(message, category, filename, lineno, line=None)`

Format a warning the standard way. This returns a string which may contain embedded newlines and ends in a newline. *line* is a line of source code to be included in the warning message; if *line* is not supplied, `formatwarning()` will try to read the line specified by *filename* and *lineno*.

`warnings.filterwarnings(action, message="", category=Warning, module="", lineno=0, append=False)`

Insert an entry into the list of [warnings filter specifications](#). The entry is inserted at the front by default; if *append* is true, it is inserted at the end. This checks the types of the arguments, compiles the *message* and *module* regular expressions, and inserts them as a tuple in the list of warnings filters. Entries closer to the front of the list override entries later in the list, if both match a particular warning. Omitted arguments default to a value that matches everything.

`warnings.simplefilter(action, category=Warning, lineno=0, append=False)`

Insert a simple entry into the list of [warnings filter specifications](#). The meaning of the function parameters is as for `filterwarnings()`, but regular expressions are not needed as the filter inserted always matches any message in any module as long as the category and line number match.

`warnings.resetwarnings()`

Reset the warnings filter. This discards the effect of all previous calls to `filterwarnings()`, including that of the `-W` command line options and calls to `simplefilter()`.

## Available Context Managers

`class warnings.catch_warnings(*, record=False, module=None, action=None, category=Warning, lineno=0, append=False)`

A context manager that copies and, upon exit, restores the warnings filter and the `showwarning()` function. If the *record* argument is `False` (the default) the context manager returns `None` on entry. If *record* is `True`, a list is returned that is progressively populated with objects as seen by a custom `showwarning()` function (which also suppresses output to `sys.stdout`). Each object in the list has attributes with the same names as the arguments to `showwarning()`.

The *module* argument takes a module that will be used instead of the module returned when you import `warnings` whose filter will be protected. This argument exists primarily for testing the `warnings` module itself.

If the *action* argument is not `None`, the remaining arguments are passed to `simplefilter()` as if it were called immediately on entering the context.

### Note

The `catch_warnings` manager works by replacing and then later restoring the module's `showwarning()` function and internal list of filter specifications. This means the context manager is modifying global state and therefore is not thread-safe.

*Changed in version 3.11:* Added the *action*, *category*, *lineno*, and *append* parameters.

# dataclasses — Data Classes

**Source code:** [Lib/dataclasses.py](https://github.com/python/cpython/tree/3.11/Lib/dataclasses.py) [https://github.com/python/cpython/tree/3.11/Lib/dataclasses.py]

---

This module provides a decorator and functions for automatically adding generated [special methods](#) such as `__init__()` and `__repr__()` to user-defined classes. It was originally described in [PEP 557](#) [https://peps.python.org/pep-0557/].

The member variables to use in these generated methods are defined using [PEP 526](#) [https://peps.python.org/pep-0526/] type annotations. For example, this code:

```
from dataclasses import dataclass

@dataclass
class InventoryItem:
    """Class for keeping track of an item in inventory."""
    name: str
    unit_price: float
    quantity_on_hand: int = 0

    def total_cost(self) -> float:
        return self.unit_price * self.quantity_on_hand
```

will add, among other things, a `__init__()` that looks like:

```
def __init__(self, name: str, unit_price: float, quantity_on_hand: int):
    self.name = name
    self.unit_price = unit_price
    self.quantity_on_hand = quantity_on_hand
```

Note that this method is automatically added to the class: it is not directly specified in the `InventoryItem` definition shown above.

*New in version 3.7.*

## Module contents

`@dataclasses.dataclass(*, init=True, repr=True, eq=True, order=False, unsafe_hash=False, frozen=False, match_args=True, kw_only=False, slots=False, weakref_slot=False)`

This function is a [decorator](#) that is used to add generated [special methods](#) to classes, as described below.

The `dataclass()` decorator examines the class to find `fields`. A `field` is defined as a class variable that has a [type annotation](#). With two exceptions described below, nothing in `dataclass()` examines the type specified in the variable annotation.

The order of the fields in all of the generated methods is the order in which they appear in the class definition.

The `dataclass()` decorator will add various “dunder” methods to the class, described below. If any of the added methods already exist in the class, the behavior depends on the parameter, as documented below. The decorator returns the same class that it is called on; no new class is created.

If `dataclass()` is used just as a simple decorator with no parameters, it acts as if it has the default values documented in this signature. That is, these three uses of `dataclass()` are equivalent:

```
@dataclass
class C:
    ...
```

```
@dataclass()
class C:
    ...
```

```
@dataclass(init=True, repr=True, eq=True, order=False,
```

```
match_args=True, kw_only=False, slots=False)
class C:
    ...
```

The parameters to `dataclass()` are:

- `init`: If true (the default), a `__init__()` method will be generated.

If the class already defines `__init__()`, this parameter is ignored.

- `repr`: If true (the default), a `__repr__()` method will be generated. The generated repr string will have the class name and the name and repr of each field, in the order they are defined in the class. Fields that are marked as being excluded from the repr are not included. For example:

```
InventoryItem(name='widget',
unit_price=3.0, quantity_on_hand=10).
```

If the class already defines `__repr__()`, this parameter is ignored.

- `eq`: If true (the default), an `__eq__()` method will be generated. This method compares the class as if it were a tuple of its fields, in order. Both instances in the comparison must be of the identical type.

If the class already defines `__eq__()`, this parameter is ignored.

- `order`: If true (the default is `False`), `__lt__()`, `__le__()`, `__gt__()`, and `__ge__()` methods will be generated. These compare the class as if it were a tuple of its fields, in order. Both instances in the comparison must be of the identical type. If `order` is true and `eq` is false, a `ValueError` is raised.

If the class already defines any of `__lt__()`, `__le__()`, `__gt__()`, or `__ge__()`, then

`TypeError` is raised.

- `unsafe_hash`: If `False` (the default), a `__hash__()` method is generated according to how `eq` and `frozen` are set.

`__hash__()` is used by built-in `hash()`, and when objects are added to hashed collections such as dictionaries and sets. Having a `__hash__()` implies that instances of the class are immutable. Mutability is a complicated property that depends on the programmer's intent, the existence and behavior of `__eq__()`, and the values of the `eq` and `frozen` flags in the `dataclass()` decorator.

By default, `dataclass()` will not implicitly add a `__hash__()` method unless it is safe to do so. Neither will it add or change an existing explicitly defined `__hash__()` method. Setting the class attribute `__hash__ = None` has a specific meaning to Python, as described in the `__hash__()` documentation.

If `__hash__()` is not explicitly defined, or if it is set to `None`, then `dataclass()` may add an implicit `__hash__()` method. Although not recommended, you can force `dataclass()` to create a `__hash__()` method with `unsafe_hash=True`. This might be the case if your class is logically immutable but can nonetheless be mutated. This is a specialized use case and should be considered carefully.

Here are the rules governing implicit creation of a `__hash__()` method. Note that you cannot both have an explicit `__hash__()` method in your dataclass and set `unsafe_hash=True`; this will result in a `TypeError`.

If `eq` and `frozen` are both true, by default `dataclass()` will generate a `__hash__()` method for you. If `eq` is true and `frozen` is false, `__hash__()` will be set to `None`, marking it

unhashable (which it is, since it is mutable). If `eq` is false, `__hash__()` will be left untouched meaning the `__hash__()` method of the superclass will be used (if the superclass is `object`, this means it will fall back to id-based hashing).

- `frozen`: If true (the default is `False`), assigning to fields will generate an exception. This emulates read-only frozen instances. If `__setattr__()` or `__delattr__()` is defined in the class, then `TypeError` is raised. See the discussion below.
- `match_args`: If true (the default is `True`), the `__match_args__` tuple will be created from the list of parameters to the generated `__init__()` method (even if `__init__()` is not generated, see above). If false, or if `__match_args__` is already defined in the class, then `__match_args__` will not be generated.

*New in version 3.10.*

- `kw_only`: If true (the default value is `False`), then all fields will be marked as keyword-only. If a field is marked as keyword-only, then the only effect is that the `__init__()` parameter generated from a keyword-only field must be specified with a keyword when `__init__()` is called. There is no effect on any other aspect of dataclasses. See the [parameter](#) glossary entry for details. Also see the `KW_ONLY` section.

*New in version 3.10.*

- `slots`: If true (the default is `False`), `__slots__` attribute will be generated and new class will be returned instead of the original one. If `__slots__` is already defined in the class, then `TypeError` is raised.

*New in version 3.10.*

*Changed in version 3.11:* If a field name is already included in the `__slots__` of a

base class, it will not be included in the generated `__slots__` to prevent [overriding them](#). Therefore, do not use `__slots__` to retrieve the field names of a dataclass. Use [fields\(\)](#) instead. To be able to determine inherited slots, base class `__slots__` may be any iterable, but *not* an iterator.

- `weakref_slot`: If true (the default is `False`), add a slot named “`_weakref_`”, which is required to make an instance weakref-able. It is an error to specify `weakref_slot=True` without also specifying `slots=True`.

*New in version 3.11.*

`fields` may optionally specify a default value, using normal Python syntax:

```
@dataclass
class C:
    a: int          # 'a' has no default value
    b: int = 0      # assign a default value for 'b'
```

In this example, both `a` and `b` will be included in the added [\\_\\_init\\_\\_\(\)](#) method, which will be defined as:

```
def __init__(self, a: int, b: int = 0):
```

[TypeError](#) will be raised if a field without a default value follows a field with a default value. This is true whether this occurs in a single class, or as a result of class inheritance.

`dataclasses.field(*, default=MISSING, default_factory=MISSING, init=True, repr=True, hash=None, compare=True, metadata=None, kw_only=MISSING)`

For common and simple use cases, no other functionality is required. There are, however, some dataclass features that require additional per-field information. To satisfy this need for additional information, you can replace the default field

value with a call to the provided `field()` function. For example:

```
@dataclass
class C:
    mylist: list[int] = field(default_factory=list)

c = C()
c.mylist += [1, 2, 3]
```

As shown above, the `MISSING` value is a sentinel object used to detect if some parameters are provided by the user. This sentinel is used because `None` is a valid value for some parameters with a distinct meaning. No code should directly use the `MISSING` value.

The parameters to `field()` are:

- `default`: If provided, this will be the default value for this field. This is needed because the `field()` call itself replaces the normal position of the default value.
- `default_factory`: If provided, it must be a zero-argument callable that will be called when a default value is needed for this field. Among other purposes, this can be used to specify fields with mutable default values, as discussed below. It is an error to specify both `default` and `default_factory`.
- `init`: If true (the default), this field is included as a parameter to the generated `__init__()` method.
- `repr`: If true (the default), this field is included in the string returned by the generated `__repr__()` method.
- `hash`: This can be a bool or `None`. If true, this field is included in the generated `__hash__()` method. If `None` (the default), use the value of `compare`: this would normally be the expected behavior. A field should be considered in the hash if it's used for comparisons. Setting this value to anything other than

None is discouraged.

One possible reason to set `hash=False` but `compare=True` would be if a field is expensive to compute a hash value for, that field is needed for equality testing, and there are other fields that contribute to the type's hash value. Even if a field is excluded from the hash, it will still be used for comparisons.

- `compare`: If true (the default), this field is included in the generated equality and comparison methods (`__eq__()`, `__gt__()`, et al.).
- `metadata`: This can be a mapping or None. None is treated as an empty dict. This value is wrapped in `MappingProxyType()` to make it read-only, and exposed on the `Field` object. It is not used at all by Data Classes, and is provided as a third-party extension mechanism. Multiple third-parties can each have their own key, to use as a namespace in the metadata.
- `kw_only`: If true, this field will be marked as keyword-only. This is used when the generated `__init__()` method's parameters are computed.

*New in version 3.10.*

If the default value of a field is specified by a call to `field()`, then the class attribute for this field will be replaced by the specified `default` value. If no `default` is provided, then the class attribute will be deleted. The intent is that after the `dataclass()` decorator runs, the class attributes will all contain the default values for the fields, just as if the default value itself were specified. For example, after:

```
@dataclass
class C:
    x: int
    y: int = field(repr=False)
```

```
z: int = field(repr=False, default=10)
t: int = 20
```

The class attribute `C.z` will be `10`, the class attribute `C.t` will be `20`, and the class attributes `C.x` and `C.y` will not be set.

### `class dataclasses.Field`

**Field** objects describe each defined field. These objects are created internally, and are returned by the `fields()` module-level method (see below). Users should never instantiate a **Field** object directly. Its documented attributes are:

- `name`: The name of the field.
- `type`: The type of the field.
- `default`, `default_factory`, `init`, `repr`, `hash`, `compare`, `metadata`, and `kw_only` have the identical meaning and values as they do in the `field()` function.

Other attributes may exist, but they are private and must not be inspected or relied on.

### `dataclasses.fields(class_or_instance)`

Returns a tuple of **Field** objects that define the fields for this dataclass. Accepts either a dataclass, or an instance of a dataclass. Raises **TypeError** if not passed a dataclass or instance of one. Does not return pseudo-fields which are `ClassVar` or `InitVar`.

### `dataclasses.asdict(obj, *, dict_factory=dict)`

Converts the dataclass `obj` to a dict (by using the factory function `dict_factory`). Each dataclass is converted to a dict of its fields, as `name: value` pairs. dataclasses, dicts, lists, and tuples are recursed into. Other objects are copied with `copy.deepcopy()`.

Example of using `asdict()` on nested dataclasses:

```
@dataclass
class Point:
    x: int
    y: int

@dataclass
class C:
    mylist: list[Point]

p = Point(10, 20)
assert asdict(p) == {'x': 10, 'y': 20}

c = C([Point(0, 0), Point(10, 4)])
assert asdict(c) == {'mylist': [{'x': 0, 'y': 0}, {
```

To create a shallow copy, the following workaround may be used:

```
dict((field.name, getattr(obj, field.name)) for field in
```

`asdict()` raises `TypeError` if `obj` is not a dataclass instance.

`dataclasses.astuple(obj, *, tuple_factory=tuple)`

Converts the dataclass `obj` to a tuple (by using the factory function `tuple_factory`). Each dataclass is converted to a tuple of its field values. dataclasses, dicts, lists, and tuples are recursed into. Other objects are copied with `copy.deepcopy()`.

Continuing from the previous example:

```
assert astuple(p) == (10, 20)
assert astuple(c) == ((0, 0), (10, 4)),)
```

To create a shallow copy, the following workaround may be used:

```
tuple(getattr(obj, field.name) for field in datacla
```

**astuple()** raises **TypeError** if `obj` is not a dataclass instance.

```
dataclasses.make_dataclass(cls_name, fields, *, bases=(),
namespace=None, init=True, repr=True, eq=True, order=False,
unsafe_hash=False, frozen=False, match_args=True, kw_only=False,
slots=False, weakref_slot=False)
```

Creates a new dataclass with name `cls_name`, fields as defined in `fields`, base classes as given in `bases`, and initialized with a namespace as given in `namespace`. `fields` is an iterable whose elements are each either `name`, `(name, type)`, or `(name, type, Field)`. If just `name` is supplied, `typing.Any` is used for `type`. The values of `init`, `repr`, `eq`, `order`, `unsafe_hash`, `frozen`, `match_args`, `kw_only`, `slots`, and `weakref_slot` have the same meaning as they do in **dataclass()**.

This function is not strictly required, because any Python mechanism for creating a new class with `__annotations__` can then apply the **dataclass()** function to convert that class to a dataclass. This function is provided as a convenience. For example:

```
C = make_dataclass('C',
                  [ ('x', int),
                    'y',
                    ('z', int, field(default=5)) ],
                  namespace={'add_one': lambda sel
```

Is equivalent to:

```
@dataclass
class C:
    x: int
    y: 'typing.Any'
    z: int = 5
```

```
def add_one(self):
    return self.x + 1
```

`dataclasses.replace(obj, /, **changes)`

Creates a new object of the same type as `obj`, replacing fields with values from `changes`. If `obj` is not a Data Class, raises `TypeError`. If values in `changes` do not specify fields, raises `TypeError`.

The newly returned object is created by calling the `__init__()` method of the dataclass. This ensures that `__post_init__`, if present, is also called.

Init-only variables without default values, if any exist, must be specified on the call to `replace()` so that they can be passed to `__init__()` and `__post_init__`.

It is an error for `changes` to contain any fields that are defined as having `init=False`. A `ValueError` will be raised in this case.

Be forewarned about how `init=False` fields work during a call to `replace()`. They are not copied from the source object, but rather are initialized in `__post_init__`, if they're initialized at all. It is expected that `init=False` fields will be rarely and judiciously used. If they are used, it might be wise to have alternate class constructors, or perhaps a custom `replace()` (or similarly named) method which handles instance copying.

`dataclasses.is_dataclass(obj)`

Return `True` if its parameter is a dataclass or an instance of one, otherwise return `False`.

If you need to know if a class is an instance of a dataclass (and not a dataclass itself), then add a further check for `not isinstance(obj, type)`:

```
def is_dataclass_instance(obj):
    return is_dataclass(obj) and not isinstance(obj,
```

`dataclasses.MISSING`

A sentinel value signifying a missing default or `default_factory`.

`dataclasses.KW_ONLY`

A sentinel value used as a type annotation. Any fields after a pseudo-field with the type of `KW_ONLY` are marked as keyword-only fields. Note that a pseudo-field of type `KW_ONLY` is otherwise completely ignored. This includes the name of such a field. By convention, a name of `_` is used for a `KW_ONLY` field. Keyword-only fields signify `__init__()` parameters that must be specified as keywords when the class is instantiated.

In this example, the fields `y` and `z` will be marked as keyword-only fields:

```
@dataclass
class Point:
    x: float
    _: KW_ONLY
    y: float
    z: float
```

```
p = Point(0, y=1.5, z=2.0)
```

In a single dataclass, it is an error to specify more than one field whose type is `KW_ONLY`.

*New in version 3.10.*

*exception* `dataclasses.FrozenInstanceError`

Raised when an implicitly defined `__setattr__()` or `__delattr__()` is called on a dataclass which was defined with `frozen=True`. It is a subclass of `AttributeError`.

## Post-init processing

The generated `__init__()` code will call a method named

`__post_init__()`, if `__post_init__()` is defined on the class. It will normally be called as `self.__post_init__()`. However, if any `InitVar` fields are defined, they will also be passed to `__post_init__()` in the order they were defined in the class. If no `__init__()` method is generated, then `__post_init__()` will not automatically be called.

Among other uses, this allows for initializing field values that depend on one or more other fields. For example:

```
@dataclass
class C:
    a: float
    b: float
    c: float = field(init=False)

    def __post_init__(self):
        self.c = self.a + self.b
```

The `__init__()` method generated by `dataclass()` does not call base class `__init__()` methods. If the base class has an `__init__()` method that has to be called, it is common to call this method in a `__post_init__()` method:

```
@dataclass
class Rectangle:
    height: float
    width: float

@dataclass
class Square(Rectangle):
    side: float

    def __post_init__(self):
        super().__init__(self.side, self.side)
```

Note, however, that in general the dataclass-generated `__init__()` methods don't need to be called, since the derived dataclass will take care of initializing all fields of any base class that is a dataclass itself.

See the section below on init-only variables for ways to pass parameters to `__post_init__()`. Also see the warning about how `replace()` handles `init=False` fields.

## Class variables

One of the few places where `dataclass()` actually inspects the type of a field is to determine if a field is a class variable as defined in [PEP 526](https://peps.python.org/pep-0526/) [https://peps.python.org/pep-0526/]. It does this by checking if the type of the field is `typing.ClassVar`. If a field is a `ClassVar`, it is excluded from consideration as a field and is ignored by the dataclass mechanisms. Such `ClassVar` pseudo-fields are not returned by the module-level `fields()` function.

## Init-only variables

Another place where `dataclass()` inspects a type annotation is to determine if a field is an init-only variable. It does this by seeing if the type of a field is of type `dataclasses.InitVar`. If a field is an `InitVar`, it is considered a pseudo-field called an init-only field. As it is not a true field, it is not returned by the module-level `fields()` function. Init-only fields are added as parameters to the generated `__init__()` method, and are passed to the optional `__post_init__` method. They are not otherwise used by dataclasses.

For example, suppose a field will be initialized from a database, if a value is not provided when creating the class:

```
@dataclass
class C:
    i: int
    j: int | None = None
    database: InitVar[DatabaseType | None] = None

    def __post_init__(self, database):
        if self.j is None and database is not None:
            self.j = database.lookup('j')

c = C(10, database=my_database)
```

In this case, `fields()` will return `Field` objects for `i` and `j`, but not for `database`.

## Frozen instances

It is not possible to create truly immutable Python objects. However, by passing `frozen=True` to the `dataclass()` decorator you can emulate immutability. In that case, dataclasses will add `__setattr__()` and `__delattr__()` methods to the class. These methods will raise a `FrozenInstanceError` when invoked.

There is a tiny performance penalty when using `frozen=True`: `__init__()` cannot use simple assignment to initialize fields, and must use `__setattr__()`.

## Inheritance

When the dataclass is being created by the `dataclass()` decorator, it looks through all of the class's base classes in reverse MRO (that is, starting at `object`) and, for each dataclass that it finds, adds the fields from that base class to an ordered mapping of fields. After all of the base class fields are added, it adds its own fields to the ordered mapping. All of the generated methods will use this combined, calculated ordered mapping of fields. Because the fields are in insertion order, derived classes override base classes. An example:

```
@dataclass
class Base:
    x: Any = 15.0
    y: int = 0

@dataclass
class C(Base):
    z: int = 10
    x: int = 15
```

The final list of fields is, in order, `x`, `y`, `z`. The final type of `x` is

`int`, as specified in class `C`.

The generated `__init__()` method for `C` will look like:

```
def __init__(self, x: int = 15, y: int = 0, z: int = 10)
```

## Re-ordering of keyword-only parameters in `__init__()`

After the parameters needed for `__init__()` are computed, any keyword-only parameters are moved to come after all regular (non-keyword-only) parameters. This is a requirement of how keyword-only parameters are implemented in Python: they must come after non-keyword-only parameters.

In this example, `Base.y`, `Base.w`, and `D.t` are keyword-only fields, and `Base.x` and `D.z` are regular fields:

```
@dataclass
class Base:
    x: Any = 15.0
    _: KW_ONLY
    y: int = 0
    w: int = 1
```

```
@dataclass
class D(Base):
    z: int = 10
    t: int = field(kw_only=True, default=0)
```

The generated `__init__()` method for `D` will look like:

```
def __init__(self, x: Any = 15.0, z: int = 10, *, y: int
```

Note that the parameters have been re-ordered from how they appear in the list of fields: parameters derived from regular fields are followed by parameters derived from keyword-only fields.

The relative ordering of keyword-only parameters is maintained in the re-ordered `__init__()` parameter list.

# Default factory functions

If a `field()` specifies a `default_factory`, it is called with zero arguments when a default value for the field is needed. For example, to create a new instance of a list, use:

```
mylist: list = field(default_factory=list)
```

If a field is excluded from `__init__()` (using `init=False`) and the field also specifies `default_factory`, then the default factory function will always be called from the generated `__init__()` function. This happens because there is no other way to give the field an initial value.

## Mutable default values

Python stores default member variable values in class attributes. Consider this example, not using dataclasses:

```
class C:
    x = []
    def add(self, element):
        self.x.append(element)
```

```
o1 = C()
o2 = C()
o1.add(1)
o2.add(2)
assert o1.x == [1, 2]
assert o1.x is o2.x
```

Note that the two instances of class `C` share the same class variable `x`, as expected.

Using dataclasses, *if* this code was valid:

```
@dataclass
class D:
    x: list = []          # This code raises ValueError
```

```
def add(self, element):
    self.x += element
```

it would generate code similar to:

```
class D:
    x = []
    def __init__(self, x=x):
        self.x = x
    def add(self, element):
        self.x += element
```

```
assert D().x is D().x
```

This has the same issue as the original example using class `C`. That is, two instances of class `D` that do not specify a value for `x` when creating a class instance will share the same copy of `x`. Because dataclasses just use normal Python class creation they also share this behavior. There is no general way for Data Classes to detect this condition. Instead, the `dataclass()` decorator will raise a `ValueError` if it detects an unhashable default parameter. The assumption is that if a value is unhashable, it is mutable. This is a partial solution, but it does protect against many common errors.

Using default factory functions is a way to create new instances of mutable types as default values for fields:

```
@dataclass
class D:
    x: list = field(default_factory=list)
```

```
assert D().x is not D().x
```

*Changed in version 3.11:* Instead of looking for and disallowing objects of type `list`, `dict`, or `set`, unhashable objects are now not allowed as default values. Unhashability is used to approximate mutability.

## Descriptor-typed fields

Fields that are assigned [descriptor objects](#) as their default value have the following special behaviors:

- The value for the field passed to the dataclass's `__init__` method is passed to the descriptor's `__set__` method rather than overwriting the descriptor object.
- Similarly, when getting or setting the field, the descriptor's `__get__` or `__set__` method is called rather than returning or overwriting the descriptor object.
- To determine whether a field contains a default value, dataclasses will call the descriptor's `__get__` method using its class access form (i.e. `descriptor.__get__(obj=None, type=cls)`). If the descriptor returns a value in this case, it will be used as the field's default. On the other hand, if the descriptor raises [AttributeError](#) in this situation, no default value will be provided for the field.

```
class IntConversionDescriptor:
    def __init__(self, *, default):
        self._default = default

    def __set_name__(self, owner, name):
        self._name = "_" + name

    def __get__(self, obj, type):
        if obj is None:
            return self._default

        return getattr(obj, self._name, self._default)

    def __set__(self, obj, value):
        setattr(obj, self._name, int(value))

@dataclass
class InventoryItem:
    quantity_on_hand: IntConversionDescriptor = IntConve

i = InventoryItem()
```

```
print(i.quantity_on_hand)    # 100
i.quantity_on_hand = 2.5     # calls __set__ with 2.5
print(i.quantity_on_hand)    # 2
```

Note that if a field is annotated with a descriptor type, but is not assigned a descriptor object as its default value, the field will act like a normal field.

# contextlib — Utilities for with-statement contexts

Source code: [Lib/contextlib.py](https://github.com/python/cpython/tree/3.11/Lib/contextlib.py) [https://github.com/python/cpython/tree/3.11/Lib/contextlib.py]

---

This module provides utilities for common tasks involving the **with** statement. For more information see also [Context Manager Types](#) and [With Statement Context Managers](#).

## Utilities

Functions and classes provided:

*class* contextlib.AbstractContextManager

An [abstract base class](#) for classes that implement [object.\\_\\_enter\\_\\_\(\)](#) and [object.\\_\\_exit\\_\\_\(\)](#). A default implementation for [object.\\_\\_enter\\_\\_\(\)](#) is provided which returns `self` while [object.\\_\\_exit\\_\\_\(\)](#) is an abstract method which by default returns `None`. See also the definition of [Context Manager Types](#).

*New in version 3.6.*

*class* contextlib.AbstractAsyncContextManager

An [abstract base class](#) for classes that implement [object.\\_\\_aenter\\_\\_\(\)](#) and [object.\\_\\_aexit\\_\\_\(\)](#). A default implementation for [object.\\_\\_aenter\\_\\_\(\)](#) is provided which returns `self` while [object.\\_\\_aexit\\_\\_\(\)](#) is an abstract method which by default returns `None`. See also the definition of [Asynchronous Context Managers](#).

*New in version 3.7.*

## @contextlib.contextmanager

This function is a **decorator** that can be used to define a factory function for **with** statement context managers, without needing to create a class or separate `__enter__()` and `__exit__()` methods.

While many objects natively support use in with statements, sometimes a resource needs to be managed that isn't a context manager in its own right, and doesn't implement a `close()` method for use with `contextlib.closing`

An abstract example would be the following to ensure correct resource management:

```
from contextlib import contextmanager

@contextmanager
def managed_resource(*args, **kwargs):
    # Code to acquire resource, e.g.:
    resource = acquire_resource(*args, **kwargs)
    try:
        yield resource
    finally:
        # Code to release resource, e.g.:
        release_resource(resource)
```

The function can then be used like this:

```
>>> with managed_resource(timeout=3600) as resource:
...     # Resource is released at the end of this block
...     # even if code in the block raises an exception
```

The function being decorated must return a **generator**-iterator when called. This iterator must yield exactly one value, which will be bound to the targets in the **with** statement's **as** clause, if any.

At the point where the generator yields, the block nested in the **with** statement is executed. The generator is then resumed after the block is exited. If an unhandled exception

occurs in the block, it is reraised inside the generator at the point where the yield occurred. Thus, you can use a `try...except...finally` statement to trap the error (if any), or ensure that some cleanup takes place. If an exception is trapped merely in order to log it or to perform some action (rather than to suppress it entirely), the generator must reraise that exception. Otherwise the generator context manager will indicate to the `with` statement that the exception has been handled, and execution will resume with the statement immediately following the `with` statement.

`contextmanager()` uses `ContextDecorator` so the context managers it creates can be used as decorators as well as in `with` statements. When used as a decorator, a new generator instance is implicitly created on each function call (this allows the otherwise “one-shot” context managers created by `contextmanager()` to meet the requirement that context managers support multiple invocations in order to be used as decorators).

*Changed in version 3.2:* Use of `ContextDecorator`.

`@contextlib.asynccontextmanager`

Similar to `contextmanager()`, but creates an `asynchronous context manager`.

This function is a `decorator` that can be used to define a factory function for `async with` statement asynchronous context managers, without needing to create a class or separate `__aenter__()` and `__aexit__()` methods. It must be applied to an `asynchronous generator` function.

A simple example:

```
from contextlib import asynccontextmanager

@asynccontextmanager
async def get_connection():
```

```

    conn = await acquire_db_connection()
    try:
        yield conn
    finally:
        await release_db_connection(conn)

async def get_all_users():
    async with get_connection() as conn:
        return conn.query('SELECT ...')

```

*New in version 3.7.*

Context managers defined with `asynccontextmanager()` can be used either as decorators or with `async with` statements:

```

import time
from contextlib import asynccontextmanager

@asynccontextmanager
async def timeit():
    now = time.monotonic()
    try:
        yield
    finally:
        print(f'it took {time.monotonic() - now} seconds')

@timeit()
async def main():
    # ... async code ...

```

When used as a decorator, a new generator instance is implicitly created on each function call. This allows the otherwise “one-shot” context managers created by `asynccontextmanager()` to meet the requirement that context managers support multiple invocations in order to be used as decorators.

*Changed in version 3.10:* Async context managers created with `asynccontextmanager()` can be used as decorators.

### `contextlib.closing(thing)`

Return a context manager that closes *thing* upon completion of the block. This is basically equivalent to:

```
from contextlib import contextmanager

@contextmanager
def closing(thing):
    try:
        yield thing
    finally:
        thing.close()
```

And lets you write code like this:

```
from contextlib import closing
from urllib.request import urlopen

with closing(urlopen('https://www.python.org')) as page:
    for line in page:
        print(line)
```

without needing to explicitly close `page`. Even if an error occurs, `page.close()` will be called when the `with` block is exited.

### `contextlib.aclosing(thing)`

Return an async context manager that calls the `aclose()` method of *thing* upon completion of the block. This is basically equivalent to:

```
from contextlib import asynccontextmanager

@asynccontextmanager
async def aclosing(thing):
    try:
```

```

        yield thing
    finally:
        await thing.aclose()

```

Significantly, `aclosing()` supports deterministic cleanup of async generators when they happen to exit early by **break** or an exception. For example:

```

from contextlib import aclosing

async with aclosing(my_generator()) as values:
    async for value in values:
        if value == 42:
            break

```

This pattern ensures that the generator’s async exit code is executed in the same context as its iterations (so that exceptions and context variables work as expected, and the exit code isn’t run after the lifetime of some task it depends on).

*New in version 3.10.*

`contextlib.nullcontext(enter_result=None)`

Return a context manager that returns *enter\_result* from `__enter__`, but otherwise does nothing. It is intended to be used as a stand-in for an optional context manager, for example:

```

def myfunction(arg, ignore_exceptions=False):
    if ignore_exceptions:
        # Use suppress to ignore all exceptions.
        cm = contextlib.suppress(Exception)
    else:
        # Do not ignore any exceptions, cm has no e
        cm = contextlib.nullcontext()
    with cm:
        # Do something

```

An example using *enter\_result*:

```
def process_file(file_or_path):
    if isinstance(file_or_path, str):
        # If string, open file
        cm = open(file_or_path)
    else:
        # Caller is responsible for closing file
        cm = nullcontext(file_or_path)

    with cm as file:
        # Perform processing on the file
```

It can also be used as a stand-in for [asynchronous context managers](#):

```
async def send_http(session=None):
    if not session:
        # If no http session, create it with aiohttp
        cm = aiohttp.ClientSession()
    else:
        # Caller is responsible for closing the session
        cm = nullcontext(session)

    async with cm as session:
        # Send http requests with session
```

*New in version 3.7.*

*Changed in version 3.10:* [asynchronous context manager](#) support was added.

`contextlib.suppress(*exceptions)`

Return a context manager that suppresses any of the specified exceptions if they occur in the body of a **with** statement and then resumes execution with the first statement following the end of the **with** statement.

As with any other mechanism that completely suppresses exceptions, this context manager should be used only to cover very specific errors where silently continuing with program

execution is known to be the right thing to do.

For example:

```
from contextlib import suppress

with suppress(FileNotFoundError):
    os.remove('somefile.tmp')

with suppress(FileNotFoundError):
    os.remove('someotherfile.tmp')
```

This code is equivalent to:

```
try:
    os.remove('somefile.tmp')
except FileNotFoundError:
    pass

try:
    os.remove('someotherfile.tmp')
except FileNotFoundError:
    pass
```

This context manager is [reentrant](#).

*New in version 3.4.*

`contextlib.redirect_stdout(new_target)`

Context manager for temporarily redirecting [sys.stdout](#) to another file or file-like object.

This tool adds flexibility to existing functions or classes whose output is hardwired to stdout.

For example, the output of [help\(\)](#) normally is sent to *sys.stdout*. You can capture that output in a string by redirecting the output to an [io.StringIO](#) object. The replacement stream is returned from the `__enter__` method and so is available as the target of the [with](#) statement:

```
with redirect_stdout(io.StringIO()) as f:
    help(pow)
s = f.getvalue()
```

To send the output of `help()` to a file on disk, redirect the output to a regular file:

```
with open('help.txt', 'w') as f:
    with redirect_stdout(f):
        help(pow)
```

To send the output of `help()` to `sys.stderr`:

```
with redirect_stdout(sys.stderr):
    help(pow)
```

Note that the global side effect on `sys.stdout` means that this context manager is not suitable for use in library code and most threaded applications. It also has no effect on the output of subprocesses. However, it is still a useful approach for many utility scripts.

This context manager is [reentrant](#).

*New in version 3.4.*

`contextlib.redirect_stderr(new_target)`

Similar to `redirect_stdout()` but redirecting `sys.stderr` to another file or file-like object.

This context manager is [reentrant](#).

*New in version 3.5.*

`contextlib.chdir(path)`

Non parallel-safe context manager to change the current working directory. As this changes a global state, the working directory, it is not suitable for use in most threaded or async contexts. It is also not suitable for most non-linear code execution, like generators, where the program execution is

temporarily relinquished – unless explicitly desired, you should not yield when this context manager is active.

This is a simple wrapper around `chdir()`, it changes the current working directory upon entering and restores the old one on exit.

This context manager is [reentrant](#).

*New in version 3.11.*

*class* `contextlib.ContextDecorator`

A base class that enables a context manager to also be used as a decorator.

Context managers inheriting from `ContextDecorator` have to implement `__enter__` and `__exit__` as normal. `__exit__` retains its optional exception handling even when used as a decorator.

`ContextDecorator` is used by [contextmanager\(\)](#), so you get this functionality automatically.

Example of `ContextDecorator`:

```
from contextlib import ContextDecorator

class mycontext(ContextDecorator):
    def __enter__(self):
        print('Starting')
        return self

    def __exit__(self, *exc):
        print('Finishing')
        return False
```

The class can then be used like this:

```
>>> @mycontext()
... def function():
...     print('The bit in the middle')
```

```

...
>>> function()
Starting
The bit in the middle
Finishing

>>> with mycontext():
...     print('The bit in the middle')
...
Starting
The bit in the middle
Finishing

```

This change is just syntactic sugar for any construct of the following form:

```

def f():
    with cm():
        # Do stuff

```

ContextDecorator lets you instead write:

```

@cm()
def f():
    # Do stuff

```

It makes it clear that the `cm` applies to the whole function, rather than just a piece of it (and saving an indentation level is nice, too).

Existing context managers that already have a base class can be extended by using `ContextDecorator` as a mixin class:

```

from contextlib import ContextDecorator

class mycontext(ContextBaseClass, ContextDecorator):
    def __enter__(self):
        return self

    def __exit__(self, *exc):

```

```
return False
```

### Note

As the decorated function must be able to be called multiple times, the underlying context manager must support use in multiple **with** statements. If this is not the case, then the original construct with the explicit **with** statement inside the function should be used.

*New in version 3.2.*

*class* contextlib.AsyncContextDecorator

Similar to **ContextDecorator** but only for asynchronous functions.

Example of AsyncContextDecorator:

```
from asyncio import run
from contextlib import AsyncContextDecorator

class mycontext(AsyncContextDecorator):
    async def __aenter__(self):
        print('Starting')
        return self

    async def __aexit__(self, *exc):
        print('Finishing')
        return False
```

The class can then be used like this:

```
>>> @mycontext()
... async def function():
...     print('The bit in the middle')
...
>>> run(function())
Starting
The bit in the middle
```

Finishing

```
>>> async def function():
...     async with mycontext():
...         print('The bit in the middle')
...
>>> run(function())
Starting
The bit in the middle
Finishing
```

*New in version 3.10.*

*class* contextlib.ExitStack

A context manager that is designed to make it easy to programmatically combine other context managers and cleanup functions, especially those that are optional or otherwise driven by input data.

For example, a set of files may easily be handled in a single with statement as follows:

```
with ExitStack() as stack:
    files = [stack.enter_context(open(fname)) for f
# All opened files will automatically be closed
# the with statement, even if attempts to open
# in the list raise an exception
```

The `__enter__()` method returns the `ExitStack` instance, and performs no additional operations.

Each instance maintains a stack of registered callbacks that are called in reverse order when the instance is closed (either explicitly or implicitly at the end of a `with` statement). Note that callbacks are *not* invoked implicitly when the context stack instance is garbage collected.

This stack model is used so that context managers that acquire their resources in their `__init__` method (such as file objects) can be handled correctly.

Since registered callbacks are invoked in the reverse order of registration, this ends up behaving as if multiple nested `with` statements had been used with the registered set of callbacks. This even extends to exception handling - if an inner callback suppresses or replaces an exception, then outer callbacks will be passed arguments based on that updated state.

This is a relatively low level API that takes care of the details of correctly unwinding the stack of exit callbacks. It provides a suitable foundation for higher level context managers that manipulate the exit stack in application specific ways.

*New in version 3.3.*

`enter_context(cm)`

Enters a new context manager and adds its `__exit__()` method to the callback stack. The return value is the result of the context manager's own `__enter__()` method.

These context managers may suppress exceptions just as they normally would if used directly as part of a `with` statement.

*Changed in version 3.11:* Raises `TypeError` instead of `AttributeError` if `cm` is not a context manager.

`push(exit)`

Adds a context manager's `__exit__()` method to the callback stack.

As `__enter__` is *not* invoked, this method can be used to cover part of an `__enter__()` implementation with a context manager's own `__exit__()` method.

If passed an object that is not a context manager, this method assumes it is a callback with the same signature as a context manager's `__exit__()` method and adds it directly to the callback stack.

By returning true values, these callbacks can suppress exceptions the same way context manager `__exit__()` methods can.

The passed in object is returned from the function, allowing this method to be used as a function decorator.

`callback(callback, /, *args, **kwargs)`

Accepts an arbitrary callback function and arguments and adds it to the callback stack.

Unlike the other methods, callbacks added this way cannot suppress exceptions (as they are never passed the exception details).

The passed in callback is returned from the function, allowing this method to be used as a function decorator.

`pop_all()`

Transfers the callback stack to a fresh `ExitStack` instance and returns it. No callbacks are invoked by this operation - instead, they will now be invoked when the new stack is closed (either explicitly or implicitly at the end of a `with` statement).

For example, a group of files can be opened as an “all or nothing” operation as follows:

```
with ExitStack() as stack:
    files = [stack.enter_context(open(fname)) for fname in filenames]
    # Hold onto the close method, but don't call it yet
    close_files = stack.pop_all().close
    # If opening any file fails, all previously opened files will
    # be closed automatically. If all files are opened successfully,
    # they will remain open even after the with block ends.
    # close_files() can then be invoked explicitly if needed.
```

`close()`

Immediately unwinds the callback stack, invoking callbacks in the reverse order of registration. For any context managers and exit callbacks registered, the arguments passed in will indicate that no exception occurred.

*class* `contextlib.AsyncExitStack`

An [asynchronous context manager](#), similar to [ExitStack](#), that supports combining both synchronous and asynchronous context managers, as well as having coroutines for cleanup logic.

The `close()` method is not implemented, `aclose()` must be used instead.

*coroutine* `enter_async_context(cm)`

Similar to `enter_context()` but expects an asynchronous context manager.

*Changed in version 3.11:* Raises [TypeError](#) instead of [AttributeError](#) if `cm` is not an asynchronous context manager.

`push_async_exit(exit)`

Similar to `push()` but expects either an asynchronous context manager or a coroutine function.

`push_async_callback(callback, /, *args, **kwargs)`

Similar to `callback()` but expects a coroutine function.

*coroutine* `aclose()`

Similar to `close()` but properly handles awaitables.

Continuing the example for `asynccontextmanager()`:

```
async with AsyncExitStack() as stack:
```

```
connections = [await stack.enter_async_context(  
    for i in range(5)]  
# All opened connections will automatically be  
# the async with statement, even if attempts to  
# later in the list raise an exception.
```

*New in version 3.7.*

## Examples and Recipes

This section describes some examples and recipes for making effective use of the tools provided by `contextlib`.

### Supporting a variable number of context managers

The primary use case for `ExitStack` is the one given in the class documentation: supporting a variable number of context managers and other cleanup operations in a single `with` statement. The variability may come from the number of context managers needed being driven by user input (such as opening a user specified collection of files), or from some of the context managers being optional:

```
with ExitStack() as stack:  
    for resource in resources:  
        stack.enter_context(resource)  
    if need_special_resource():  
        special = acquire_special_resource()  
        stack.callback(release_special_resource, special)  
    # Perform operations that use the acquired resources
```

As shown, `ExitStack` also makes it quite easy to use `with` statements to manage arbitrary resources that don't natively support the context management protocol.

### Catching exceptions from `__enter__` methods

It is occasionally desirable to catch exceptions from an `__enter__` method implementation, *without* inadvertently catching exceptions

from the `with` statement body or the context manager's `__exit__` method. By using `ExitStack` the steps in the context management protocol can be separated slightly in order to allow this:

```
stack = ExitStack()
try:
    x = stack.enter_context(cm)
except Exception:
    # handle __enter__ exception
else:
    with stack:
        # Handle normal case
```

Actually needing to do this is likely to indicate that the underlying API should be providing a direct resource management interface for use with `try/except/finally` statements, but not all APIs are well designed in that regard. When a context manager is the only resource management API provided, then `ExitStack` can make it easier to handle various situations that can't be handled directly in a `with` statement.

## Cleaning up in an `__enter__` implementation

As noted in the documentation of `ExitStack.push()`, this method can be useful in cleaning up an already allocated resource if later steps in the `__enter__()` implementation fail.

Here's an example of doing this for a context manager that accepts resource acquisition and release functions, along with an optional validation function, and maps them to the context management protocol:

```
from contextlib import contextmanager, AbstractContextManager

class ResourceManager(AbstractContextManager):

    def __init__(self, acquire_resource, release_resource,
                 validate_resource=None):
        self.acquire_resource = acquire_resource
        self.release_resource = release_resource
```

```

        if check_resource_ok is None:
            def check_resource_ok(resource):
                return True
        self.check_resource_ok = check_resource_ok

    @contextmanager
    def _cleanup_on_error(self):
        with ExitStack() as stack:
            stack.push(self)
            yield
            # The validation check passed and didn't raise
            # Accordingly, we want to keep the resource,
            # back to our caller
            stack.pop_all()

    def __enter__(self):
        resource = self.acquire_resource()
        with self._cleanup_on_error():
            if not self.check_resource_ok(resource):
                msg = "Failed validation for {!r}"
                raise RuntimeError(msg.format(resource))
        return resource

    def __exit__(self, *exc_details):
        # We don't need to duplicate any of our resource
        self.release_resource()

```

## Replacing any use of **try-finally** and flag variables

A pattern you will sometimes see is a `try-finally` statement with a flag variable to indicate whether or not the body of the `finally` clause should be executed. In its simplest form (that can't already be handled just by using an `except` clause instead), it looks something like this:

```

cleanup_needed = True
try:
    result = perform_operation()
    if result:

```

```

        cleanup_needed = False
finally:
    if cleanup_needed:
        cleanup_resources()

```

As with any `try` statement based code, this can cause problems for development and review, because the setup code and the cleanup code can end up being separated by arbitrarily long sections of code.

**ExitStack** makes it possible to instead register a callback for execution at the end of a `with` statement, and then later decide to skip executing that callback:

```

from contextlib import ExitStack

with ExitStack() as stack:
    stack.callback(cleanup_resources)
    result = perform_operation()
    if result:
        stack.pop_all()

```

This allows the intended cleanup up behaviour to be made explicit up front, rather than requiring a separate flag variable.

If a particular application uses this pattern a lot, it can be simplified even further by means of a small helper class:

```

from contextlib import ExitStack

class Callback(ExitStack):
    def __init__(self, callback, /, *args, **kwds):
        super().__init__()
        self.callback(callback, *args, **kwds)

    def cancel(self):
        self.pop_all()

with Callback(cleanup_resources) as cb:
    result = perform_operation()

```

```
if result:
    cb.cancel()
```

If the resource cleanup isn't already neatly bundled into a standalone function, then it is still possible to use the decorator form of `ExitStack.callback()` to declare the resource cleanup in advance:

```
from contextlib import ExitStack

with ExitStack() as stack:
    @stack.callback
    def cleanup_resources():
        ...
    result = perform_operation()
    if result:
        stack.pop_all()
```

Due to the way the decorator protocol works, a callback function declared this way cannot take any parameters. Instead, any resources to be released must be accessed as closure variables.

## Using a context manager as a function decorator

`ContextDecorator` makes it possible to use a context manager in both an ordinary `with` statement and also as a function decorator.

For example, it is sometimes useful to wrap functions or groups of statements with a logger that can track the time of entry and time of exit. Rather than writing both a function decorator and a context manager for the task, inheriting from `ContextDecorator` provides both capabilities in a single definition:

```
from contextlib import ContextDecorator
import logging

logging.basicConfig(level=logging.INFO)

class track_entry_and_exit(ContextDecorator):
    def __init__(self, name):
```

```

        self.name = name

    def __enter__(self):
        logging.info('Entering: %s', self.name)

    def __exit__(self, exc_type, exc, exc_tb):
        logging.info('Exiting: %s', self.name)

```

Instances of this class can be used as both a context manager:

```

with track_entry_and_exit('widget loader'):
    print('Some time consuming activity goes here')
    load_widget()

```

And also as a function decorator:

```

@track_entry_and_exit('widget loader')
def activity():
    print('Some time consuming activity goes here')
    load_widget()

```

Note that there is one additional limitation when using context managers as function decorators: there's no way to access the return value of `__enter__()`. If that value is needed, then it is still necessary to use an explicit `with` statement.

**See also**

**PEP 343** [<https://peps.python.org/pep-0343/>] - The “with” statement

The specification, background, and examples for the Python **with** statement.

## Single use, reusable and reentrant context managers

Most context managers are written in a way that means they can only be used effectively in a **with** statement once. These single use

context managers must be created afresh each time they're used - attempting to use them a second time will trigger an exception or otherwise not work correctly.

This common limitation means that it is generally advisable to create context managers directly in the header of the `with` statement where they are used (as shown in all of the usage examples above).

Files are an example of effectively single use context managers, since the first `with` statement will close the file, preventing any further IO operations using that file object.

Context managers created using `contextmanager()` are also single use context managers, and will complain about the underlying generator failing to yield if an attempt is made to use them a second time:

```
>>> from contextlib import contextmanager
>>> @contextmanager
... def singleuse():
...     print("Before")
...     yield
...     print("After")
...
>>> cm = singleuse()
>>> with cm:
...     pass
...
Before
After
>>> with cm:
...     pass
...
Traceback (most recent call last):
...
RuntimeError: generator didn't yield
```

## Reentrant context managers

More sophisticated context managers may be “reentrant”. These context managers can not only be used in multiple `with` statements, but may also be used *inside* a `with` statement that is already using the same context manager.

`threading.RLock` is an example of a reentrant context manager, as are `suppress()`, `redirect_stdout()`, and `chdir()`. Here’s a very simple example of reentrant use:

```
>>> from contextlib import redirect_stdout
>>> from io import StringIO
>>> stream = StringIO()
>>> write_to_stream = redirect_stdout(stream)
>>> with write_to_stream:
...     print("This is written to the stream rather than
...         with write_to_stream:
...         print("This is also written to the stream")
...
>>> print("This is written directly to stdout")
This is written directly to stdout
>>> print(stream.getvalue())
This is written to the stream rather than stdout
This is also written to the stream
```

Real world examples of reentrancy are more likely to involve multiple functions calling each other and hence be far more complicated than this example.

Note also that being reentrant is *not* the same thing as being thread safe. `redirect_stdout()`, for example, is definitely not thread safe, as it makes a global modification to the system state by binding `sys.stdout` to a different stream.

## Reusable context managers

Distinct from both single use and reentrant context managers are “reusable” context managers (or, to be completely explicit, “reusable, but not reentrant” context managers, since reentrant context managers are also reusable). These context managers support being used multiple times, but will fail (or otherwise not

work correctly) if the specific context manager instance has already been used in a containing with statement.

`threading.Lock` is an example of a reusable, but not reentrant, context manager (for a reentrant lock, it is necessary to use `threading.RLock` instead).

Another example of a reusable, but not reentrant, context manager is `ExitStack`, as it invokes *all* currently registered callbacks when leaving any with statement, regardless of where those callbacks were added:

```
>>> from contextlib import ExitStack
>>> stack = ExitStack()
>>> with stack:
...     stack.callback(print, "Callback: from first context")
...     print("Leaving first context")
...
Leaving first context
Callback: from first context
>>> with stack:
...     stack.callback(print, "Callback: from second context")
...     print("Leaving second context")
...
Leaving second context
Callback: from second context
>>> with stack:
...     stack.callback(print, "Callback: from outer context")
...     with stack:
...         stack.callback(print, "Callback: from inner context")
...         print("Leaving inner context")
...     print("Leaving outer context")
...
Leaving inner context
Callback: from inner context
Callback: from outer context
Leaving outer context
```

As the output from the example shows, reusing a single stack object across multiple with statements works correctly, but attempting to

nest them will cause the stack to be cleared at the end of the innermost with statement, which is unlikely to be desirable behaviour.

Using separate **ExitStack** instances instead of reusing a single instance avoids that problem:

```
>>> from contextlib import ExitStack
>>> with ExitStack() as outer_stack:
...     outer_stack.callback(print, "Callback: from outer")
...     with ExitStack() as inner_stack:
...         inner_stack.callback(print, "Callback: from inner")
...         print("Leaving inner context")
...     print("Leaving outer context")
...
Leaving inner context
Callback: from inner context
Leaving outer context
Callback: from outer context
```

# abc — Abstract Base Classes

**Source code:** [Lib/abc.py](https://github.com/python/cpython/tree/3.11/Lib/abc.py) [https://github.com/python/cpython/tree/3.11/Lib/abc.py]

---

This module provides the infrastructure for defining [abstract base classes](#) (ABCs) in Python, as outlined in [PEP 3119](https://peps.python.org/pep-3119/) [https://peps.python.org/pep-3119/]; see the PEP for why this was added to Python. (See also [PEP 3141](https://peps.python.org/pep-3141/) [https://peps.python.org/pep-3141/] and the [numbers](#) module regarding a type hierarchy for numbers based on ABCs.)

The [collections](#) module has some concrete classes that derive from ABCs; these can, of course, be further derived. In addition, the [collections.abc](#) submodule has some ABCs that can be used to test whether a class or instance provides a particular interface, for example, if it is [hashable](#) or if it is a mapping.

This module provides the metaclass [ABCMeta](#) for defining ABCs and a helper class [ABC](#) to alternatively define ABCs through inheritance:

*class* abc.ABC

A helper class that has [ABCMeta](#) as its metaclass. With this class, an abstract base class can be created by simply deriving from [ABC](#) avoiding sometimes confusing metaclass usage, for example:

```
from abc import ABC

class MyABC(ABC):
    pass
```

Note that the type of [ABC](#) is still [ABCMeta](#), therefore inheriting from [ABC](#) requires the usual precautions regarding metaclass usage, as multiple inheritance may lead to

metaclass conflicts. One may also define an abstract base class by passing the metaclass keyword and using `ABCMeta` directly, for example:

```
from abc import ABCMeta

class MyABC(metaclass=ABCMeta):
    pass
```

*New in version 3.4.*

`class abc.ABCMeta`

Metaclass for defining Abstract Base Classes (ABCs).

Use this metaclass to create an ABC. An ABC can be subclassed directly, and then acts as a mix-in class. You can also register unrelated concrete classes (even built-in classes) and unrelated ABCs as “virtual subclasses” – these and their descendants will be considered subclasses of the registering ABC by the built-in `issubclass()` function, but the registering ABC won’t show up in their MRO (Method Resolution Order) nor will method implementations defined by the registering ABC be callable (not even via `super()`). <sup>1</sup>

Classes created with a metaclass of `ABCMeta` have the following method:

`register(subclass)`

Register *subclass* as a “virtual subclass” of this ABC. For example:

```
from abc import ABC

class MyABC(ABC):
    pass

MyABC.register(tuple)

assert issubclass(tuple, MyABC)
assert isinstance(), MyABC)
```

*Changed in version 3.3:* Returns the registered subclass, to allow usage as a class decorator.

*Changed in version 3.4:* To detect calls to `register()`, you can use the `get_cache_token()` function.

You can also override this method in an abstract base class:

`__subclasshook__(subclass)`

(Must be defined as a class method.)

Check whether *subclass* is considered a subclass of this ABC. This means that you can customize the behavior of `issubclass` further without the need to call `register()` on every class you want to consider a subclass of the ABC. (This class method is called from the `__subclasscheck__()` method of the ABC.)

This method should return `True`, `False` or `NotImplemented`. If it returns `True`, the *subclass* is considered a subclass of this ABC. If it returns `False`, the *subclass* is not considered a subclass of this ABC, even if it would normally be one. If it returns `NotImplemented`, the subclass check is continued with the usual mechanism.

For a demonstration of these concepts, look at this example ABC definition:

```
class Foo:
    def __getitem__(self, index):
        ...
    def __len__(self):
        ...
    def get_iterator(self):
        return iter(self)

class MyIterable(ABC):

    @abstractmethod
```

```

def __iter__(self):
    while False:
        yield None

def get_iterator(self):
    return self.__iter__()

@classmethod
def __subclasshook__(cls, C):
    if cls is MyIterable:
        if any("__iter__" in B.__dict__ for B in C.__bases__):
            return True
    return NotImplemented

MyIterable.register(Foo)

```

The `ABC MyIterable` defines the standard iterable method, `__iter__()`, as an abstract method. The implementation given here can still be called from subclasses. The `get_iterator()` method is also part of the `MyIterable` abstract base class, but it does not have to be overridden in non-abstract derived classes.

The `__subclasshook__()` class method defined here says that any class that has an `__iter__()` method in its `__dict__` (or in that of one of its base classes, accessed via the `__mro__` list) is considered a `MyIterable` too.

Finally, the last line makes `Foo` a virtual subclass of `MyIterable`, even though it does not define an `__iter__()` method (it uses the old-style iterable protocol, defined in terms of `__len__()` and `__getitem__()`). Note that this will not make `get_iterator` available as a method of `Foo`, so it is provided separately.

The `abc` module also provides the following decorator:

```
@abc.abstractmethod
```

A decorator indicating abstract methods.

Using this decorator requires that the class's metaclass is `ABCMeta` or is derived from it. A class that has a metaclass derived from `ABCMeta` cannot be instantiated unless all of its abstract methods and properties are overridden. The abstract methods can be called using any of the normal 'super' call mechanisms. `abstractmethod()` may be used to declare abstract methods for properties and descriptors.

Dynamically adding abstract methods to a class, or attempting to modify the abstraction status of a method or class once it is created, are only supported using the `update_abstractmethods()` function. The `abstractmethod()` only affects subclasses derived using regular inheritance; "virtual subclasses" registered with the ABC's `register()` method are not affected.

When `abstractmethod()` is applied in combination with other method descriptors, it should be applied as the innermost decorator, as shown in the following usage examples:

```
class C(ABC):
    @abstractmethod
    def my_abstract_method(self, arg1):
        ...

    @classmethod
    @abstractmethod
    def my_abstract_classmethod(cls, arg2):
        ...

    @staticmethod
    @abstractmethod
    def my_abstract_staticmethod(arg3):
        ...

    @property
    @abstractmethod
    def my_abstract_property(self):
        ...

    @my_abstract_property.setter
    @abstractmethod
```

```

def my_abstract_property(self, val):
    ...

    @abstractmethod
    def _get_x(self):
        ...

    @abstractmethod
    def _set_x(self, val):
        ...

    x = property(_get_x, _set_x)

```

In order to correctly interoperate with the abstract base class machinery, the descriptor must identify itself as abstract using `__isabstractmethod__`. In general, this attribute should be `True` if any of the methods used to compose the descriptor are abstract. For example, Python's built-in `property` does the equivalent of:

```

class Descriptor:
    ...
    @property
    def __isabstractmethod__(self):
        return any(getattr(f, '__isabstractmethod__'
                           f in (self._fget, self._fset, se

```

## Note

Unlike Java abstract methods, these abstract methods may have an implementation. This implementation can be called via the `super()` mechanism from the class that overrides it. This could be useful as an end-point for a super-call in a framework that uses cooperative multiple-inheritance.

The `abc` module also supports the following legacy decorators:

`@abc.abstractclassmethod`

*New in version 3.2.*

*Deprecated since version 3.3:* It is now possible to use `classmethod` with `abstractmethod()`, making this decorator redundant.

A subclass of the built-in `classmethod()`, indicating an abstract classmethod. Otherwise it is similar to `abstractmethod()`.

This special case is deprecated, as the `classmethod()` decorator is now correctly identified as abstract when applied to an abstract method:

```
class C(ABC):
    @classmethod
    @abstractmethod
    def my_abstract_classmethod(cls, arg):
        ...
```

`@abc.abstractstaticmethod`

*New in version 3.2.*

*Deprecated since version 3.3:* It is now possible to use `staticmethod` with `abstractmethod()`, making this decorator redundant.

A subclass of the built-in `staticmethod()`, indicating an abstract staticmethod. Otherwise it is similar to `abstractmethod()`.

This special case is deprecated, as the `staticmethod()` decorator is now correctly identified as abstract when applied to an abstract method:

```
class C(ABC):
    @staticmethod
    @abstractmethod
    def my_abstract_staticmethod(arg):
        ...
```

`@abc.abstractproperty`

*Deprecated since version 3.3:* It is now possible to use `property`, `property.getter()`, `property.setter()` and `property.deleter()` with `abstractmethod()`, making this decorator redundant.

A subclass of the built-in `property()`, indicating an abstract property.

This special case is deprecated, as the `property()` decorator is now correctly identified as abstract when applied to an abstract method:

```
class C(ABC):
    @property
    @abstractmethod
    def my_abstract_property(self):
        ...
```

The above example defines a read-only property; you can also define a read-write abstract property by appropriately marking one or more of the underlying methods as abstract:

```
class C(ABC):
    @property
    def x(self):
        ...

    @x.setter
    @abstractmethod
    def x(self, val):
        ...
```

If only some components are abstract, only those components need to be updated to create a concrete property in a subclass:

```
class D(C):
    @C.x.setter
    def x(self, val):
        ...
```

The `abc` module also provides the following functions:

`abc.get_cache_token()`

Returns the current abstract base class cache token.

The token is an opaque object (that supports equality testing) identifying the current version of the abstract base class cache for virtual subclasses. The token changes with every call to `ABCMeta.register()` on any ABC.

*New in version 3.4.*

`abc.update_abstractmethods(cls)`

A function to recalculate an abstract class's abstraction status. This function should be called if a class's abstract methods have been implemented or changed after it was created. Usually, this function should be called from within a class decorator.

Returns `cls`, to allow usage as a class decorator.

If `cls` is not an instance of `ABCMeta`, does nothing.

### Note

This function assumes that `cls`'s superclasses are already updated. It does not update any subclasses.

*New in version 3.10.*

## Footnotes

1

C++ programmers should note that Python's virtual base class concept is not the same as C++'s.

# atexit — Exit handlers

---

The `atexit` module defines functions to register and unregister cleanup functions. Functions thus registered are automatically executed upon normal interpreter termination. `atexit` runs these functions in the *reverse* order in which they were registered; if you register `A`, `B`, and `C`, at interpreter termination time they will be run in the order `C`, `B`, `A`.

**Note:** The functions registered via this module are not called when the program is killed by a signal not handled by Python, when a Python fatal internal error is detected, or when `os._exit()` is called.

**Note:** The effect of registering or unregistering functions from within a cleanup function is undefined.

*Changed in version 3.7:* When used with C-API subinterpreters, registered functions are local to the interpreter they were registered in.

`atexit.register(func, *args, **kwargs)`

Register *func* as a function to be executed at termination. Any optional arguments that are to be passed to *func* must be passed as arguments to `register()`. It is possible to register the same function and arguments more than once.

At normal program termination (for instance, if `sys.exit()` is called or the main module's execution completes), all functions registered are called in last in, first out order. The assumption is that lower level modules will normally be imported before higher level modules and thus must be cleaned up later.

If an exception is raised during execution of the exit handlers,

a traceback is printed (unless `SystemExit` is raised) and the exception information is saved. After all exit handlers have had a chance to run, the last exception to be raised is re-raised.

This function returns *func*, which makes it possible to use it as a decorator.

`atexit.unregister(func)`

Remove *func* from the list of functions to be run at interpreter shutdown. `unregister()` silently does nothing if *func* was not previously registered. If *func* has been registered more than once, every occurrence of that function in the `atexit` call stack will be removed. Equality comparisons (`==`) are used internally during unregistration, so function references do not need to have matching identities.

See also

Module `readline`

Useful example of `atexit` to read and write `readline` history files.

## `atexit` Example

The following simple example demonstrates how a module can initialize a counter from a file when it is imported and save the counter's updated value automatically when the program terminates without relying on the application making an explicit call into this module at termination.

```
try:
    with open('counterfile') as infile:
        _count = int(infile.read())
except FileNotFoundError:
    _count = 0

def incrcounter(n):
```

```

global _count
_count = _count + n

def savecounter():
    with open('counterfile', 'w') as outfile:
        outfile.write('%d' % _count)

import atexit

atexit.register(savecounter)

```

Positional and keyword arguments may also be passed to `register()` to be passed along to the registered function when it is called:

```

def goodbye(name, adjective):
    print('Goodbye %s, it was %s to meet you.' % (name,

import atexit

atexit.register(goodbye, 'Donny', 'nice')
# or:
atexit.register(goodbye, adjective='nice', name='Donny')

```

Usage as a [decorator](#):

```

import atexit

@atexit.register
def goodbye():
    print('You are now leaving the Python sector.')

```

This only works with functions that can be called without arguments.

# traceback — Print or retrieve a stack traceback

**Source code:** [Lib/traceback.py](https://github.com/python/cpython/tree/3.11/Lib/traceback.py) [https://github.com/python/cpython/tree/3.11/Lib/traceback.py]

---

This module provides a standard interface to extract, format and print stack traces of Python programs. It exactly mimics the behavior of the Python interpreter when it prints a stack trace. This is useful when you want to print stack traces under program control, such as in a “wrapper” around the interpreter.

The module uses traceback objects — these are objects of type `types.TracebackType`, which are assigned to the `__traceback__` field of `BaseException` instances.

**See also**

**Module `faulthandler`**

Used to dump Python tracebacks explicitly, on a fault, after a timeout, or on a user signal.

**Module `pdb`**

Interactive source code debugger for Python programs.

The module defines the following functions:

`traceback.print_tb(tb, limit=None, file=None)`

Print up to *limit* stack trace entries from traceback object *tb* (starting from the caller’s frame) if *limit* is positive.

Otherwise, print the last `abs(limit)` entries. If *limit* is omitted or `None`, all entries are printed. If *file* is omitted or `None`, the output goes to `sys.stderr`; otherwise it should be an open file or file-like object to receive the output.

*Changed in version 3.5:* Added negative *limit* support.

```
traceback.print_exception(exc, /, [value, tb, ]limit=None,  
file=None, chain=True)
```

Print exception information and stack trace entries from traceback object *tb* to *file*. This differs from `print_tb()` in the following ways:

- if *tb* is not `None`, it prints a header `Traceback (most recent call last):`
- it prints the exception type and *value* after the stack trace
- if `type(value)` is `SyntaxError` and *value* has the appropriate format, it prints the line where the syntax error occurred with a caret indicating the approximate position of the error.

Since Python 3.10, instead of passing *value* and *tb*, an exception object can be passed as the first argument. If *value* and *tb* are provided, the first argument is ignored in order to provide backwards compatibility.

The optional *limit* argument has the same meaning as for `print_tb()`. If *chain* is true (the default), then chained exceptions (the `__cause__` or `__context__` attributes of the exception) will be printed as well, like the interpreter itself does when printing an unhandled exception.

*Changed in version 3.5:* The *etype* argument is ignored and inferred from the type of *value*.

*Changed in version 3.10:* The *etype* parameter has been renamed to *exc* and is now positional-only.

```
traceback.print_exc(limit=None, file=None, chain=True)
```

This is a shorthand for

```
print_exception(sys.exception(), limit, file,  
chain).
```

`traceback.print_last(limit=None, file=None, chain=True)`

This is a shorthand for

`print_exception(sys.last_type, sys.last_value, sys.last_traceback, limit, file, chain)`. In general it will work only after an exception has reached an interactive prompt (see `sys.last_type`).

`traceback.print_stack(f=None, limit=None, file=None)`

Print up to *limit* stack trace entries (starting from the invocation point) if *limit* is positive. Otherwise, print the last `abs(limit)` entries. If *limit* is omitted or `None`, all entries are printed. The optional *f* argument can be used to specify an alternate stack frame to start. The optional *file* argument has the same meaning as for `print_tb()`.

*Changed in version 3.5:* Added negative *limit* support.

`traceback.extract_tb(tb, limit=None)`

Return a `StackSummary` object representing a list of “pre-processed” stack trace entries extracted from the traceback object *tb*. It is useful for alternate formatting of stack traces. The optional *limit* argument has the same meaning as for `print_tb()`. A “pre-processed” stack trace entry is a `FrameSummary` object containing attributes `filename`, `lineno`, `name`, and `line` representing the information that is usually printed for a stack trace. The `line` is a string with leading and trailing whitespace stripped; if the source is not available it is `None`.

`traceback.extract_stack(f=None, limit=None)`

Extract the raw traceback from the current stack frame. The return value has the same format as for `extract_tb()`. The optional *f* and *limit* arguments have the same meaning as for `print_stack()`.

`traceback.format_list(extracted_list)`

Given a list of tuples or `FrameSummary` objects as returned

by `extract_tb()` or `extract_stack()`, return a list of strings ready for printing. Each string in the resulting list corresponds to the item with the same index in the argument list. Each string ends in a newline; the strings may contain internal newlines as well, for those items whose source text line is not `None`.

`traceback.format_exception_only(exc, [, value])`

Format the exception part of a traceback using an exception value such as given by `sys.last_value`. The return value is a list of strings, each ending in a newline. Normally, the list contains a single string; however, for `SyntaxError` exceptions, it contains several lines that (when printed) display detailed information about where the syntax error occurred. The message indicating which exception occurred is the always last string in the list.

Since Python 3.10, instead of passing *value*, an exception object can be passed as the first argument. If *value* is provided, the first argument is ignored in order to provide backwards compatibility.

*Changed in version 3.10:* The *etype* parameter has been renamed to *exc* and is now positional-only.

`traceback.format_exception(exc, /, [value, tb, ]limit=None, chain=True)`

Format a stack trace and the exception information. The arguments have the same meaning as the corresponding arguments to `print_exception()`. The return value is a list of strings, each ending in a newline and some containing internal newlines. When these lines are concatenated and printed, exactly the same text is printed as does `print_exception()`.

*Changed in version 3.5:* The *etype* argument is ignored and inferred from the type of *value*.

*Changed in version 3.10:* This function's behavior and

signature were modified to match `print_exception()`.

`traceback.format_exc(limit=None, chain=True)`

This is like `print_exc(limit)` but returns a string instead of printing to a file.

`traceback.format_tb(tb, limit=None)`

A shorthand for `format_list(extract_tb(tb, limit))`.

`traceback.format_stack(f=None, limit=None)`

A shorthand for `format_list(extract_stack(f, limit))`.

`traceback.clear_frames(tb)`

Clears the local variables of all the stack frames in a traceback `tb` by calling the `clear()` method of each frame object.

*New in version 3.4.*

`traceback.walk_stack(f)`

Walk a stack following `f.f_back` from the given frame, yielding the frame and line number for each frame. If `f` is `None`, the current stack is used. This helper is used with `StackSummary.extract()`.

*New in version 3.5.*

`traceback.walk_tb(tb)`

Walk a traceback following `tb_next` yielding the frame and line number for each frame. This helper is used with `StackSummary.extract()`.

*New in version 3.5.*

The module also defines the following classes:

# TracebackException Objects

*New in version 3.5.*

**TracebackException** objects are created from actual exceptions to capture data for later printing in a lightweight fashion.

```
class traceback.TracebackException(exc_type, exc_value,  
exc_traceback, *, limit=None, lookup_lines=True,  
capture_locals=False, compact=False, max_group_width=15,  
max_group_depth=10)
```

Capture an exception for later rendering. *limit*, *lookup\_lines* and *capture\_locals* are as for the **StackSummary** class.

If *compact* is true, only data that is required by **TracebackException**'s `format` method is saved in the class attributes. In particular, the `__context__` field is calculated only if `__cause__` is `None` and `__suppress_context__` is false.

Note that when locals are captured, they are also shown in the traceback.

*max\_group\_width* and *max\_group\_depth* control the formatting of exception groups (see **BaseExceptionGroup**). The depth refers to the nesting level of the group, and the width refers to the size of a single exception group's exceptions array. The formatted output is truncated when either limit is exceeded.

`__cause__`

A **TracebackException** of the original `__cause__`.

`__context__`

A **TracebackException** of the original `__context__`.

exceptions

If `self` represents an **ExceptionGroup**, this field

holds a list of `TracebackException` instances representing the nested exceptions. Otherwise it is `None`.

*New in version 3.11.*

`__suppress_context__`

The `__suppress_context__` value from the original exception.

`__notes__`

The `__notes__` value from the original exception, or `None` if the exception does not have any notes. If it is not `None` is it formatted in the traceback after the exception string.

*New in version 3.11.*

`stack`

A `StackSummary` representing the traceback.

`exc_type`

The class of the original traceback.

`filename`

For syntax errors - the file name where the error occurred.

`lineno`

For syntax errors - the line number where the error occurred.

`end_lineno`

For syntax errors - the end line number where the error occurred. Can be `None` if not present.

*New in version 3.10.*

text

For syntax errors - the text where the error occurred.

offset

For syntax errors - the offset into the text where the error occurred.

end\_offset

For syntax errors - the end offset into the text where the error occurred. Can be `None` if not present.

*New in version 3.10.*

msg

For syntax errors - the compiler error message.

*classmethod* `from_exception(exc, *, limit=None, lookup_lines=True, capture_locals=False)`

Capture an exception for later rendering. *limit*, *lookup\_lines* and *capture\_locals* are as for the `StackSummary` class.

Note that when locals are captured, they are also shown in the traceback.

`print(*, file=None, chain=True)`

Print to *file* (default `sys.stderr`) the exception information returned by `format()`.

*New in version 3.11.*

`format(*, chain=True)`

Format the exception.

If *chain* is not `True`, `__cause__` and `__context__` will not be formatted.

The return value is a generator of strings, each ending

in a newline and some containing internal newlines. `print_exception()` is a wrapper around this method which just prints the lines to a file.

The message indicating which exception occurred is always the last string in the output.

`format_exception_only()`

Format the exception part of the traceback.

The return value is a generator of strings, each ending in a newline.

Normally, the generator emits a single string; however, for `SyntaxError` exceptions, it emits several lines that (when printed) display detailed information about where the syntax error occurred.

The message indicating which exception occurred is always the last string in the output.

*Changed in version 3.10:* Added the *compact* parameter.

*Changed in version 3.11:* Added the *max\_group\_width* and *max\_group\_depth* parameters.

## StackSummary Objects

*New in version 3.5.*

`StackSummary` objects represent a call stack ready for formatting.

`class traceback.StackSummary`

`classmethod extract(frame_gen, *, limit=None,  
lookup_lines=True, capture_locals=False)`

Construct a `StackSummary` object from a frame generator (such as is returned by `walk_stack()` or `walk_tb()`).

If *limit* is supplied, only this many frames are taken from *frame\_gen*. If *lookup\_lines* is `False`, the returned **FrameSummary** objects will not have read their lines in yet, making the cost of creating the **StackSummary** cheaper (which may be valuable if it may not actually get formatted). If *capture\_locals* is `True` the local variables in each **FrameSummary** are captured as object representations.

*classmethod* `from_list(a_list)`

Construct a **StackSummary** object from a supplied list of **FrameSummary** objects or old-style list of tuples. Each tuple should be a 4-tuple with filename, lineno, name, line as the elements.

`format()`

Returns a list of strings ready for printing. Each string in the resulting list corresponds to a single frame from the stack. Each string ends in a newline; the strings may contain internal newlines as well, for those items with source text lines.

For long sequences of the same frame and line, the first few repetitions are shown, followed by a summary line stating the exact number of further repetitions.

*Changed in version 3.6:* Long sequences of repeated frames are now abbreviated.

`format_frame_summary(frame_summary)`

Returns a string for printing one of the frames involved in the stack. This method is called for each **FrameSummary** object to be printed by **StackSummary.format()**. If it returns `None`, the frame is omitted from the output.

*New in version 3.11.*

# FrameSummary Objects

*New in version 3.5.*

A **FrameSummary** object represents a single frame in a traceback.

```
class traceback.FrameSummary(filename, lineno, name,  
lookup_line=True, locals=None, line=None)
```

Represent a single frame in the traceback or stack that is being formatted or printed. It may optionally have a stringified version of the frames locals included in it. If *lookup\_line* is `False`, the source code is not looked up until the **FrameSummary** has the **line** attribute accessed (which also happens when casting it to a tuple). **line** may be directly provided, and will prevent line lookups happening at all. *locals* is an optional local variable dictionary, and if supplied the variable representations are stored in the summary for later display.

## Traceback Examples

This simple example implements a basic read-eval-print loop, similar to (but less useful than) the standard Python interactive interpreter loop. For a more complete implementation of the interpreter loop, refer to the [code](#) module.

```
import sys, traceback  
  
def run_user_code(envdir):  
    source = input(">>> ")  
    try:  
        exec(source, envdir)  
    except Exception:  
        print("Exception in user code:")  
        print("-"*60)  
        traceback.print_exc(file=sys.stdout)  
        print("-"*60)
```

```

envdir = {}
while True:
    run_user_code(envdir)

```

The following example demonstrates the different ways to print and format the exception and traceback:

```

import sys, traceback

def lumberjack():
    bright_side_of_life()

def bright_side_of_life():
    return tuple()[0]

try:
    lumberjack()
except IndexError:
    exc = sys.exception()
    print("*** print_tb:")
    traceback.print_tb(exc.__traceback__, limit=1, file=sys.stdout)
    print("*** print_exception:")
    traceback.print_exception(exc, limit=2, file=sys.stdout)
    print("*** print_exc:")
    traceback.print_exc(limit=2, file=sys.stdout)
    print("*** format_exc, first and last line:")
    formatted_lines = traceback.format_exc().splitlines()
    print(formatted_lines[0])
    print(formatted_lines[-1])
    print("*** format_exception:")
    print(repr(traceback.format_exception(exc)))
    print("*** extract_tb:")
    print(repr(traceback.extract_tb(exc.__traceback__)))
    print("*** format_tb:")
    print(repr(traceback.format_tb(exc.__traceback__)))
    print("*** tb_lineno:", exc.__traceback__.tb_lineno)

```

The output for the example would look similar to this:

```

*** print_tb:
    File "<doctest...>", line 10, in <module>
        lumberjack()
*** print_exception:
Traceback (most recent call last):
    File "<doctest...>", line 10, in <module>
        lumberjack()
    File "<doctest...>", line 4, in lumberjack
        bright_side_of_life()
IndexError: tuple index out of range
*** print_exc:
Traceback (most recent call last):
    File "<doctest...>", line 10, in <module>
        lumberjack()
    File "<doctest...>", line 4, in lumberjack
        bright_side_of_life()
IndexError: tuple index out of range
*** format_exc, first and last line:
Traceback (most recent call last):
IndexError: tuple index out of range
*** format_exception:
['Traceback (most recent call last):\n',
 '  File "<doctest default[0]>", line 10, in <module>\n',
 '  File "<doctest default[0]>", line 4, in lumberjack\n',
 '  File "<doctest default[0]>", line 7, in bright_side_of_life\n',
 'IndexError: tuple index out of range\n']
*** extract_tb:
[<FrameSummary file <doctest...>, line 10 in <module>>,
 <FrameSummary file <doctest...>, line 4 in lumberjack>,
 <FrameSummary file <doctest...>, line 7 in bright_side_of_life>]
*** format_tb:
['  File "<doctest default[0]>", line 10, in <module>\n',
 '  File "<doctest default[0]>", line 4, in lumberjack\n',
 '  File "<doctest default[0]>", line 7, in bright_side_of_life\n',
 'IndexError: tuple index out of range\n']
*** tb_lineno: 10

```

The following example shows the different ways to print and format the stack:

```

>>> import traceback
>>> def another_function():
...     lumberstack()
...
>>> def lumberstack():
...     traceback.print_stack()
...     print(repr(traceback.extract_stack()))
...     print(repr(traceback.format_stack()))
...
>>> another_function()
File "<doctest>", line 10, in <module>
    another_function()
File "<doctest>", line 3, in another_function
    lumberstack()
File "<doctest>", line 6, in lumberstack
    traceback.print_stack()
[('<doctest>', 10, '<module>', 'another_function()'),
 ('<doctest>', 3, 'another_function', 'lumberstack()'),
 ('<doctest>', 7, 'lumberstack', 'print(repr(traceback.e
['  File "<doctest>", line 10, in <module>\n    another_
'  File "<doctest>", line 3, in another_function\n    l
'  File "<doctest>", line 8, in lumberstack\n    print(

```

This last example demonstrates the final few formatting functions:

```

>>> import traceback
>>> traceback.format_list([('spam.py', 3, '<module>', 's
...                         ('eggs.py', 42, 'eggs', 'retu
['  File "spam.py", line 3, in <module>\n    spam.eggs()
'  File "eggs.py", line 42, in eggs\n    return "bacon"
>>> an_error = IndexError('tuple index out of range')
>>> traceback.format_exception_only(type(an_error), an_e
['IndexError: tuple index out of range\n']

```

# \_\_future\_\_ — Future statement definitions

**Source code:** [Lib/\\_future\\_.py](https://github.com/python/cpython/tree/3.11/Lib/_future_.py) [https://github.com/python/cpython/tree/3.11/Lib/\_future\_.py]

---

`__future__` is a real module, and serves three purposes:

- To avoid confusing existing tools that analyze import statements and expect to find the modules they're importing.
- To ensure that [future statements](#) run under releases prior to 2.1 at least yield runtime exceptions (the import of `__future__` will fail, because there was no module of that name prior to 2.1).
- To document when incompatible changes were introduced, and when they will be — or were — made mandatory. This is a form of executable documentation, and can be inspected programmatically via importing `__future__` and examining its contents.

Each statement in `__future__.py` is of the form:

```
FeatureName = _Feature(OptionalRelease, MandatoryRelease,
                        CompilerFlag)
```

where, normally, *OptionalRelease* is less than *MandatoryRelease*, and both are 5-tuples of the same form as [sys.version\\_info](#):

```
(PY_MAJOR_VERSION, # the 2 in 2.1.0a3; an int
 PY_MINOR_VERSION, # the 1; an int
 PY_MICRO_VERSION, # the 0; an int
 PY_RELEASE_LEVEL, # "alpha", "beta", "candidate" or "final"
 PY_RELEASE_SERIAL # the 3; an int
)
```

*OptionalRelease* records the first release in which the feature was accepted.

In the case of a *MandatoryRelease* that has not yet occurred, *MandatoryRelease* predicts the release in which the feature will become part of the language.

Else *MandatoryRelease* records when the feature became part of the language; in releases at or after that, modules no longer need a future statement to use the feature in question, but may continue to use such imports.

*MandatoryRelease* may also be `None`, meaning that a planned feature got dropped.

Instances of class **`_Feature`** have two corresponding methods, **`getOptionalRelease()`** and **`getMandatoryRelease()`**.

*CompilerFlag* is the (bitfield) flag that should be passed in the fourth argument to the built-in function **`compile()`** to enable the feature in dynamically compiled code. This flag is stored in the **`compiler_flag`** attribute on **`_Feature`** instances.

No feature description will ever be deleted from **`__future__`**. Since its introduction in Python 2.1 the following features have found their way into the language using this mechanism:

### **mandatory in**

**`Python 2.5`** **`from __future__ import nested_scopes`** Dynamically Nested Scopes

**`Python 2.5`** **`from __future__ import generators`** Simple Generators

**`Python 2.8`** **`from __future__ import division`** Changing the Division Operator

**`Python 2.8`** **`from __future__ import absolute_import`** Imports: Multi-Line and Absolute/Relative

**`Python 2.8`** **`from __future__ import with_statement`** “with” Statement

**`Python 2.6`** **`from __future__ import print_function`** Make `print` a function

**`Python 3.0`** **`from __future__ import unicode_literals`** Unicode literals in Python 3000

**`Python 3.0`** **`from __future__ import stop_iteration`** Stop iteration handling inside generators

**`Python 3.0`** **`from __future__ import annotations`** Postponed evaluation of annotations

`from __future__ import annotations` was previously scheduled to become mandatory in Python 3.10, but the

Python Steering Council twice decided to delay the change ([announcement for Python 3.10](https://mail.python.org/archives/list/python-dev@python.org/message/CLVXXPQ2T2LQ5MP2Y53VVQFCXYWQJHKZ/) [https://mail.python.org/archives/list/python-dev@python.org/message/CLVXXPQ2T2LQ5MP2Y53VVQFCXYWQJHKZ/]; [announcement for Python 3.11](https://mail.python.org/archives/list/python-dev@python.org/message/VIZEBX5EYMSYIJNDBF6DMUMZOCWHARSO/) [https://mail.python.org/archives/list/python-dev@python.org/message/VIZEBX5EYMSYIJNDBF6DMUMZOCWHARSO/]). No final decision has been made yet. See also [PEP 563](https://peps.python.org/pep-0563/) [https://peps.python.org/pep-0563/] and [PEP 649](https://peps.python.org/pep-0649/) [https://peps.python.org/pep-0649/].

### Future statements

How the compiler treats future imports.

# gc — Garbage Collector interface

---

This module provides an interface to the optional garbage collector. It provides the ability to disable the collector, tune the collection frequency, and set debugging options. It also provides access to unreachable objects that the collector found but cannot free. Since the collector supplements the reference counting already used in Python, you can disable the collector if you are sure your program does not create reference cycles. Automatic collection can be disabled by calling `gc.disable()`. To debug a leaking program call `gc.set_debug(gc.DEBUG_LEAK)`. Notice that this includes `gc.DEBUG_SAVEALL`, causing garbage-collected objects to be saved in `gc.garbage` for inspection.

The `gc` module provides the following functions:

`gc.enable()`

Enable automatic garbage collection.

`gc.disable()`

Disable automatic garbage collection.

`gc.isenabled()`

Return `True` if automatic collection is enabled.

`gc.collect(generation=2)`

With no arguments, run a full collection. The optional argument *generation* may be an integer specifying which generation to collect (from 0 to 2). A `ValueError` is raised if the generation number is invalid. The number of unreachable objects found is returned.

The free lists maintained for a number of built-in types are cleared whenever a full collection or collection of the highest generation (2) is run. Not all items in some free lists may be freed due to the particular implementation, in particular `float`.

The effect of calling `gc.collect()` while the interpreter is already performing a collection is undefined.

### `gc.set_debug(flags)`

Set the garbage collection debugging flags. Debugging information will be written to `sys.stderr`. See below for a list of debugging flags which can be combined using bit operations to control debugging.

### `gc.get_debug()`

Return the debugging flags currently set.

### `gc.get_objects(generation=None)`

Returns a list of all objects tracked by the collector, excluding the list returned. If *generation* is not `None`, return only the objects tracked by the collector that are in that generation.

*Changed in version 3.8:* New *generation* parameter.

Raises an [auditing event](#) `gc.get_objects` with argument *generation*.

### `gc.get_stats()`

Return a list of three per-generation dictionaries containing collection statistics since interpreter start. The number of keys may change in the future, but currently each dictionary will contain the following items:

- `collections` is the number of times this generation was collected;
- `collected` is the total number of objects collected inside this generation;

- `uncollectable` is the total number of objects which were found to be uncollectable (and were therefore moved to the `garbage` list) inside this generation.

*New in version 3.4.*

`gc.set_threshold(threshold0 [, threshold1 [, threshold2]])`

Set the garbage collection thresholds (the collection frequency). Setting *threshold0* to zero disables collection.

The GC classifies objects into three generations depending on how many collection sweeps they have survived. New objects are placed in the youngest generation (generation 0). If an object survives a collection it is moved into the next older generation. Since generation 2 is the oldest generation, objects in that generation remain there after a collection. In order to decide when to run, the collector keeps track of the number object allocations and deallocations since the last collection. When the number of allocations minus the number of deallocations exceeds *threshold0*, collection starts. Initially only generation 0 is examined. If generation 0 has been examined more than *threshold1* times since generation 1 has been examined, then generation 1 is examined as well. With the third generation, things are a bit more complicated, see [Collecting the oldest generation](https://devguide.python.org/garbage_collector/#collecting-the-oldest-generation) [https://devguide.python.org/garbage\_collector/#collecting-the-oldest-generation] for more information.

`gc.get_count()`

Return the current collection counts as a tuple of (*count0*, *count1*, *count2*).

`gc.get_threshold()`

Return the current collection thresholds as a tuple of (*threshold0*, *threshold1*, *threshold2*).

`gc.get_referrers(*objs)`

Return the list of objects that directly refer to any of *objs*.

This function will only locate those containers which support garbage collection; extension types which do refer to other objects but do not support garbage collection will not be found.

Note that objects which have already been dereferenced, but which live in cycles and have not yet been collected by the garbage collector can be listed among the resulting referencers. To get only currently live objects, call `collect()` before calling `get_referencers()`.

### Warning

Care must be taken when using objects returned by `get_referencers()` because some of them could still be under construction and hence in a temporarily invalid state. Avoid using `get_referencers()` for any purpose other than debugging.

Raises an [auditing event](#) `gc.get_referencers` with argument `objs`.

### `gc.get_referents(*objs)`

Return a list of objects directly referred to by any of the arguments. The referents returned are those objects visited by the arguments' C-level `tp_traverse` methods (if any), and may not be all objects actually directly reachable.

`tp_traverse` methods are supported only by objects that support garbage collection, and are only required to visit objects that may be involved in a cycle. So, for example, if an integer is directly reachable from an argument, that integer object may or may not appear in the result list.

Raises an [auditing event](#) `gc.get_referents` with argument `objs`.

### `gc.is_tracked(obj)`

Returns `True` if the object is currently tracked by the garbage collector, `False` otherwise. As a general rule,

instances of atomic types aren't tracked and instances of non-atomic types (containers, user-defined objects...) are. However, some type-specific optimizations can be present in order to suppress the garbage collector footprint of simple instances (e.g. dicts containing only atomic keys and values):

```
>>> gc.is_tracked(0)
False
>>> gc.is_tracked("a")
False
>>> gc.is_tracked([])
True
>>> gc.is_tracked({})
False
>>> gc.is_tracked({"a": 1})
False
>>> gc.is_tracked({"a": []})
True
```

*New in version 3.1.*

`gc.is_finalized(obj)`

Returns `True` if the given object has been finalized by the garbage collector, `False` otherwise.

```
>>> x = None
>>> class Lazarus:
...     def __del__(self):
...         global x
...         x = self
...
>>> lazarus = Lazarus()
>>> gc.is_finalized(lazarus)
False
>>> del lazarus
>>> gc.is_finalized(x)
True
```

*New in version 3.9.*

## `gc.freeze()`

Freeze all the objects tracked by the garbage collector; move them to a permanent generation and ignore them in all the future collections.

If a process will `fork()` without `exec()`, avoiding unnecessary copy-on-write in child processes will maximize memory sharing and reduce overall memory usage. This requires both avoiding creation of freed “holes” in memory pages in the parent process and ensuring that GC collections in child processes won’t touch the `gc_refs` counter of long-lived objects originating in the parent process. To accomplish both, call `gc.disable()` early in the parent process, `gc.freeze()` right before `fork()`, and `gc.enable()` early in child processes.

*New in version 3.7.*

## `gc.unfreeze()`

Unfreeze the objects in the permanent generation, put them back into the oldest generation.

*New in version 3.7.*

## `gc.get_freeze_count()`

Return the number of objects in the permanent generation.

*New in version 3.7.*

The following variables are provided for read-only access (you can mutate the values but should not rebind them):

## `gc.garbage`

A list of objects which the collector found to be unreachable but could not be freed (uncollectable objects). Starting with Python 3.4, this list should be empty most of the time, except when using instances of C extension types with a non-NULL `tp_del` slot.

If `DEBUG_SAVEALL` is set, then all unreachable objects will be added to this list rather than freed.

*Changed in version 3.2:* If this list is non-empty at [interpreter shutdown](#), a `ResourceWarning` is emitted, which is silent by default. If `DEBUG_UNCOLLECTABLE` is set, in addition all uncollectable objects are printed.

*Changed in version 3.4:* Following [PEP 442](https://peps.python.org/pep-0442/) [https://peps.python.org/pep-0442/], objects with a `__del__()` method don't end up in `gc.garbage` anymore.

## `gc.callbacks`

A list of callbacks that will be invoked by the garbage collector before and after collection. The callbacks will be called with two arguments, *phase* and *info*.

*phase* can be one of two values:

“start”: The garbage collection is about to start.

“stop”: The garbage collection has finished.

*info* is a dict providing more information for the callback. The following keys are currently defined:

“generation”: The oldest generation being collected.

“collected”: When *phase* is “stop”, the number of objects successfully collected.

“uncollectable”: When *phase* is “stop”, the number of objects that could not be collected and were put in `garbage`.

Applications can add their own callbacks to this list. The primary use cases are:

Gathering statistics about garbage collection,

such as how often various generations are collected, and how long the collection takes.

Allowing applications to identify and clear their own uncollectable types when they appear in [garbage](#).

*New in version 3.3.*

The following constants are provided for use with [set\\_debug\(\)](#):

`gc.DEBUG_STATS`

Print statistics during collection. This information can be useful when tuning the collection frequency.

`gc.DEBUG_COLLECTABLE`

Print information on collectable objects found.

`gc.DEBUG_UNCOLLECTABLE`

Print information of uncollectable objects found (objects which are not reachable but cannot be freed by the collector). These objects will be added to the [garbage](#) list.

*Changed in version 3.2:* Also print the contents of the [garbage](#) list at [interpreter shutdown](#), if it isn't empty.

`gc.DEBUG_SAVEALL`

When set, all unreachable objects found will be appended to *garbage* rather than being freed. This can be useful for debugging a leaking program.

`gc.DEBUG_LEAK`

The debugging flags necessary for the collector to print information about a leaking program (equal to

`DEBUG_COLLECTABLE | DEBUG_UNCOLLECTABLE |  
DEBUG_SAVEALL`).

# inspect — Inspect live objects

**Source code:** [Lib/inspect.py](#) [<https://github.com/python/cpython/tree/3.11/Lib/inspect.py>]

---

The `inspect` module provides several useful functions to help get information about live objects such as modules, classes, methods, functions, tracebacks, frame objects, and code objects. For example, it can help you examine the contents of a class, retrieve the source code of a method, extract and format the argument list for a function, or get all the information you need to display a detailed traceback.

There are four main kinds of services provided by this module: type checking, getting source code, inspecting classes and functions, and examining the interpreter stack.

## Types and members

The `getmembers()` function retrieves the members of an object such as a class or module. The functions whose names begin with “is” are mainly provided as convenient choices for the second argument to `getmembers()`. They also help you determine when you can expect to find the following special attributes (see [Import-related module attributes](#) for module attributes):

### Type description

Type	Description
<code>class</code>	documentation string
<code>name</code>	with which this class was defined
<code>qualifiedname</code>	
<code>module</code>	of module in which this class was defined
<code>doc</code>	documentation string
<code>name</code>	with which this method was defined
<code>qualifiedname</code>	
<code>function</code>	object containing implementation of method

`self` instance to which this method is bound, or `None`  
`__module__` module in which this method was defined  
`__doc__` documentation string  
`__name__` with which this function was defined  
`__qualname__`  
`code` object containing compiled function [bytecode](#)  
`tuple` of any default values for positional or keyword parameters  
`map` of default values for keyword-only parameters  
`global` namespace in which this function was defined  
`builtins` namespace  
`__annotations__` mapping of parameter names to annotations; "return" key is reserved for return annotations.  
`__module__` module in which this function was defined  
`__frame__` object at this level  
`__index__` of last attempted instruction in bytecode  
`__current__` line number in Python source code  
`__text__` traceback object (called by this level)  
`__frame__` outer frame object (this frame's caller)  
`__builtins__` namespace seen by this frame  
`code` object being executed in this frame  
`global` namespace seen by this frame  
`__index__` of last attempted instruction in bytecode  
`__current__` line number in Python source code  
`local` namespace seen by this frame  
`__trace__` function for this frame, or `None`  
`__code__` of arguments (not including keyword only arguments, \* or \*\* args)  
`__code__` of raw compiled bytecode  
`__code__` of frames of cell variables (referenced by containing scopes)  
`__code__` of constants used in the bytecode  
`__file__` file in which this code object was created  
`__firstlineno__` first line in Python source code  
`__flags__` of `CO_*` flags, read more [here](#)  
`__enclosed__` mapping of line numbers to bytecode indices  
`__free__` of names of free variables (referenced via a function's closure)  
`__posonlyargs__` of positional only arguments  
`__kwonlyargs__` of keyword only arguments (not including \*\* arg)  
`__name__` with which this code object was defined  
`__qualname__` fully qualified name with which this code object was defined

`top_level_names` names other than arguments and function locals

`num_locals` number of local variables

`virtual_size` virtual machine stack space required

`top_level_names` names of arguments and local variables

`generator`

`qualified_name`

`gframe`

`is_thengenerator` generator running?

`code`

`obj` being iterated by `yield from`, or `None`

`name`

`qualified_name`

`obj` being awaited on, or `None`

`frame`

`is_thincoroutine` coroutine running?

`code`

`cr_origin` routine was created, or `None`. See

[`sys.set\_coroutine\_origin\_tracking\_depth\(\)`](#)

`doc` documentation string

`original_name` of this function or method

`qualified_name`

`instance` to which a method is bound, or `None`

*Changed in version 3.5:* Add `__qualname__` and `gi_yieldfrom` attributes to generators.

The `__name__` attribute of generators is now set from the function name, instead of the code name, and it can now be modified.

*Changed in version 3.7:* Add `cr_origin` attribute to coroutines.

*Changed in version 3.10:* Add `__builtins__` attribute to functions.

`inspect.getmembers(object[, predicate])`

Return all the members of an object in a list of `(name, value)` pairs sorted by name. If the optional *predicate* argument—which will be called with the `value` object of each member—is supplied, only members for which the predicate returns a true value are included.

## Note

`getmembers()` will only return class attributes defined in the metaclass when the argument is a class and those attributes have been listed in the metaclass' custom `__dir__()`.

`inspect.getmembers_static(object[, predicate])`

Return all the members of an object in a list of (name, value) pairs sorted by name without triggering dynamic lookup via the descriptor protocol, `__getattr__` or `__getattribute__`. Optionally, only return members that satisfy a given predicate.

## Note

`getmembers_static()` may not be able to retrieve all members that `getmembers` can fetch (like dynamically created attributes) and may find members that `getmembers` can't (like descriptors that raise `AttributeError`). It can also return descriptor objects instead of instance members in some cases.

*New in version 3.11.*

`inspect.getmodulename(path)`

Return the name of the module named by the file *path*, without including the names of enclosing packages. The file extension is checked against all of the entries in `importlib.machinery.all_suffixes()`. If it matches, the final path component is returned with the extension removed. Otherwise, `None` is returned.

Note that this function *only* returns a meaningful name for actual Python modules - paths that potentially refer to Python packages will still return `None`.

*Changed in version 3.3:* The function is based directly on

`importlib.`

`inspect.ismodule(object)`

Return `True` if the object is a module.

`inspect.isclass(object)`

Return `True` if the object is a class, whether built-in or created in Python code.

`inspect.ismethod(object)`

Return `True` if the object is a bound method written in Python.

`inspect.isfunction(object)`

Return `True` if the object is a Python function, which includes functions created by a `lambda` expression.

`inspect.isgeneratorfunction(object)`

Return `True` if the object is a Python generator function.

*Changed in version 3.8:* Functions wrapped in `functools.partial()` now return `True` if the wrapped function is a Python generator function.

`inspect.isgenerator(object)`

Return `True` if the object is a generator.

`inspect.iscoroutinefunction(object)`

Return `True` if the object is a `coroutine function` (a function defined with an `async def` syntax).

*New in version 3.5.*

*Changed in version 3.8:* Functions wrapped in `functools.partial()` now return `True` if the wrapped function is a `coroutine function`.

`inspect.iscoroutine(object)`

Return `True` if the object is a [coroutine](#) created by an [async def](#) function.

*New in version 3.5.*

`inspect.isawaitable(object)`

Return `True` if the object can be used in [await](#) expression.

Can also be used to distinguish generator-based coroutines from regular generators:

```
def gen():
    yield
@types.coroutine
def gen_coro():
    yield

assert not isawaitable(gen())
assert isawaitable(gen_coro())
```

*New in version 3.5.*

`inspect.isasyncgenfunction(object)`

Return `True` if the object is an [asynchronous generator](#) function, for example:

```
>>> async def agen():
...     yield 1
...
>>> inspect.isasyncgenfunction(agen)
True
```

*New in version 3.6.*

*Changed in version 3.8:* Functions wrapped in [functools.partial\(\)](#) now return `True` if the wrapped function is a [asynchronous generator](#) function.

`inspect.isasyncgen(object)`

Return `True` if the object is an [asynchronous generator iterator](#) created by an [asynchronous generator function](#).

*New in version 3.6.*

`inspect.istraceback(object)`

Return `True` if the object is a traceback.

`inspect.isframe(object)`

Return `True` if the object is a frame.

`inspect.iscode(object)`

Return `True` if the object is a code.

`inspect.isbuiltin(object)`

Return `True` if the object is a built-in function or a bound built-in method.

`inspect.ismethodwrapper(object)`

Return `True` if the type of object is a [MethodWrapperType](#).

These are instances of [MethodWrapperType](#), such as [\\_\\_str\\_\\_\(\)](#), [\\_\\_eq\\_\\_\(\)](#) and [\\_\\_repr\\_\\_\(\)](#).

*New in version 3.11.*

`inspect.isroutine(object)`

Return `True` if the object is a user-defined or built-in function or method.

`inspect.isabstract(object)`

Return `True` if the object is an abstract base class.

`inspect.ismethoddescriptor(object)`

Return `True` if the object is a method descriptor, but not if `ismethod()`, `isclass()`, `isfunction()` or `isbuiltin()` are true.

This, for example, is true of `int.__add__`. An object passing this test has a `__get__()` method but not a `__set__()` method, but beyond that the set of attributes varies. A `__name__` attribute is usually sensible, and `__doc__` often is.

Methods implemented via descriptors that also pass one of the other tests return `False` from the `ismethoddescriptor()` test, simply because the other tests promise more – you can, e.g., count on having the `__func__` attribute (etc) when an object passes `ismethod()`.

`inspect.isdatadescriptor(object)`

Return `True` if the object is a data descriptor.

Data descriptors have a `__set__` or a `__delete__` method. Examples are properties (defined in Python), getsets, and members. The latter two are defined in C and there are more specific tests available for those types, which is robust across Python implementations. Typically, data descriptors will also have `__name__` and `__doc__` attributes (properties, getsets, and members have both of these attributes), but this is not guaranteed.

`inspect.isgetsetdescriptor(object)`

Return `True` if the object is a getset descriptor.

**CPython implementation detail:** getsets are attributes defined in extension modules via `PyGetSetDef` structures. For Python implementations without such types, this method will always return `False`.

`inspect.ismemberdescriptor(object)`

Return `True` if the object is a member descriptor.

**CPython implementation detail:** Member descriptors are attributes defined in extension modules via `PyMemberDef` structures. For Python implementations without such types, this method will always return `False`.

## Retrieving source code

`inspect.getdoc(object)`

Get the documentation string for an object, cleaned up with `cleandoc()`. If the documentation string for an object is not provided and the object is a class, a method, a property or a descriptor, retrieve the documentation string from the inheritance hierarchy. Return `None` if the documentation string is invalid or missing.

*Changed in version 3.5:* Documentation strings are now inherited if not overridden.

`inspect.getcomments(object)`

Return in a single string any lines of comments immediately preceding the object's source code (for a class, function, or method), or at the top of the Python source file (if the object is a module). If the object's source code is unavailable, return `None`. This could happen if the object has been defined in C or the interactive shell.

`inspect.getfile(object)`

Return the name of the (text or binary) file in which an object was defined. This will fail with a `TypeError` if the object is a built-in module, class, or function.

`inspect.getmodule(object)`

Try to guess which module an object was defined in. Return `None` if the module cannot be determined.

`inspect.getsourcefile(object)`

Return the name of the Python source file in which an object

was defined or `None` if no way can be identified to get the source. This will fail with a `TypeError` if the object is a built-in module, class, or function.

### `inspect.getsourcelines(object)`

Return a list of source lines and starting line number for an object. The argument may be a module, class, method, function, traceback, frame, or code object. The source code is returned as a list of the lines corresponding to the object and the line number indicates where in the original source file the first line of code was found. An `OSError` is raised if the source code cannot be retrieved. A `TypeError` is raised if the object is a built-in module, class, or function.

*Changed in version 3.3:* `OSError` is raised instead of `IOError`, now an alias of the former.

### `inspect.getsource(object)`

Return the text of the source code for an object. The argument may be a module, class, method, function, traceback, frame, or code object. The source code is returned as a single string. An `OSError` is raised if the source code cannot be retrieved. A `TypeError` is raised if the object is a built-in module, class, or function.

*Changed in version 3.3:* `OSError` is raised instead of `IOError`, now an alias of the former.

### `inspect.cleandoc(doc)`

Clean up indentation from docstrings that are indented to line up with blocks of code.

All leading whitespace is removed from the first line. Any leading whitespace that can be uniformly removed from the second line onwards is removed. Empty lines at the beginning and end are subsequently removed. Also, all tabs are expanded to spaces.

# Introspecting callables with the Signature object

*New in version 3.3.*

The Signature object represents the call signature of a callable object and its return annotation. To retrieve a Signature object, use the `signature()` function.

```
inspect.signature(callable, *, follow_wrapped=True, globals=None,
locals=None, eval_str=False)
```

Return a **Signature** object for the given callable:

```
>>> from inspect import signature
>>> def foo(a, *, b:int, **kwargs):
...     pass

>>> sig = signature(foo)

>>> str(sig)
'(a, *, b:int, **kwargs)'

>>> str(sig.parameters['b'])
'b:int'

>>> sig.parameters['b'].annotation
<class 'int'>
```

Accepts a wide range of Python callables, from plain functions and classes to `functools.partial()` objects.

For objects defined in modules using stringized annotations (from `__future__` import annotations), `signature()` will attempt to automatically un-stringize the annotations using `inspect.get_annotations()`. The global, locals, and eval\_str parameters are passed into `inspect.get_annotations()` when resolving the annotations; see the documentation for `inspect.get_annotations()` for instructions on how to

use these parameters.

Raises **ValueError** if no signature can be provided, and **TypeError** if that type of object is not supported. Also, if the annotations are stringized, and `eval_str` is not false, the `eval()` call(s) to un-stringize the annotations could potentially raise any kind of exception.

A slash(/) in the signature of a function denotes that the parameters prior to it are positional-only. For more info, see [the FAQ entry on positional-only parameters](#).

*New in version 3.5:* `follow_wrapped` parameter. Pass False to get a signature of `callable` specifically (`callable.__wrapped__` will not be used to unwrap decorated callables.)

*New in version 3.10:* `globals`, `locals`, and `eval_str` parameters.

## Note

Some callables may not be introspectable in certain implementations of Python. For example, in CPython, some built-in functions defined in C provide no metadata about their arguments.

```
class inspect.Signature(parameters=None, *,
return_annotation=Signature.empty)
```

A Signature object represents the call signature of a function and its return annotation. For each parameter accepted by the function it stores a **Parameter** object in its **parameters** collection.

The optional *parameters* argument is a sequence of **Parameter** objects, which is validated to check that there are no parameters with duplicate names, and that the parameters are in the right order, i.e. positional-only first, then positional-or-keyword, and that parameters with defaults

follow parameters without defaults.

The optional *return\_annotation* argument, can be an arbitrary Python object, is the “return” annotation of the callable.

Signature objects are *immutable*. Use `Signature.replace()` to make a modified copy.

*Changed in version 3.5:* Signature objects are picklable and hashable.

empty

A special class-level marker to specify absence of a return annotation.

parameters

An ordered mapping of parameters’ names to the corresponding `Parameter` objects. Parameters appear in strict definition order, including keyword-only parameters.

*Changed in version 3.7:* Python only explicitly guaranteed that it preserved the declaration order of keyword-only parameters as of version 3.7, although in practice this order had always been preserved in Python 3.

return\_annotation

The “return” annotation for the callable. If the callable has no “return” annotation, this attribute is set to `Signature.empty`.

bind(\*args, \*\*kwargs)

Create a mapping from positional and keyword arguments to parameters. Returns `BoundArguments` if `*args` and `**kwargs` match the signature, or raises a `TypeError`.

bind\_partial(\*args, \*\*kwargs)

Works the same way as `Signature.bind()`, but allows the omission of some required arguments (mimics `functools.partial()` behavior.) Returns `BoundArguments`, or raises a `TypeError` if the passed arguments do not match the signature.

`replace(*[, parameters][, return_annotation])`

Create a new `Signature` instance based on the instance `replace` was invoked on. It is possible to pass different `parameters` and/or `return_annotation` to override the corresponding properties of the base signature. To remove `return_annotation` from the copied `Signature`, pass in `Signature.empty`.

```
>>> def test(a, b):
...     pass
>>> sig = signature(test)
>>> new_sig = sig.replace(return_annotation="new return anno")
>>> str(new_sig)
"(a, b) -> 'new return anno'"
```

*`classmethod from_callable(obj, *, follow_wrapped=True, globalns=None, localns=None)`*

Return a `Signature` (or its subclass) object for a given callable `obj`. Pass `follow_wrapped=False` to get a signature of `obj` without unwrapping its `__wrapped__` chain. `globalns` and `localns` will be used as the namespaces when resolving annotations.

This method simplifies subclassing of `Signature`:

```
class MySignature(Signature):
    pass
sig = MySignature.from_callable(min)
assert isinstance(sig, MySignature)
```

*New in version 3.5.*

*New in version 3.10:* `globalns` and `localns`

parameters.

```
class inspect.Parameter(name, kind, *, default=Parameter.empty,  
annotation=Parameter.empty)
```

Parameter objects are *immutable*. Instead of modifying a Parameter object, you can use `Parameter.replace()` to create a modified copy.

*Changed in version 3.5:* Parameter objects are picklable and hashable.

empty

A special class-level marker to specify absence of default values and annotations.

name

The name of the parameter as a string. The name must be a valid Python identifier.

**CPython implementation detail:** CPython generates implicit parameter names of the form `.0` on the code objects used to implement comprehensions and generator expressions.

*Changed in version 3.6:* These parameter names are exposed by this module as names like `implicit0`.

default

The default value for the parameter. If the parameter has no default value, this attribute is set to `Parameter.empty`.

annotation

The annotation for the parameter. If the parameter has no annotation, this attribute is set to `Parameter.empty`.

kind

Describes how argument values are bound to the parameter. The possible values are accessible via **Parameter** (like `Parameter.KEYWORD_ONLY`), and support comparison and ordering, in the following order:

### Meaning

---

**POSITIONAL\_ONLY** Applied as a positional argument.

Positional only parameters are those which appear before a `/` entry (if present) in a Python function definition.

---

**POSITIONAL\_OR\_KEYWORD** Either a keyword or

positional argument (this is the standard binding behaviour for functions implemented in Python.)

---

**VAR\_POSITIONAL** Final arguments that aren't bound to any other parameter. This corresponds to a `*args` parameter in a Python function definition.

---

**KEYWORD\_ONLY** Applied as a keyword argument.

Keyword only parameters are those which appear after a `*` or `*args` entry in a Python function definition.

---

**VAR\_KEYWORD** Arguments that aren't bound to any other parameter. This corresponds to a `**kwargs` parameter in a Python function definition.

---

Example: print all keyword-only arguments without default values:

```
>>> def foo(a, b, *, c, d=10):
...     pass

>>> sig = signature(foo)
>>> for param in sig.parameters.values():
...     if (param.kind == param.KEYWORD_ONLY and
...         param.default is param.empty):
...         print('Parameter:', param)
Parameter: c
```

kind.description

Describes a enum value of `Parameter.kind`.

*New in version 3.8.*

Example: print all descriptions of arguments:

```
>>> def foo(a, b, *, c, d=10):
...     pass

>>> sig = signature(foo)
>>> for param in sig.parameters.values():
...     print(param.kind.description)
positional or keyword
positional or keyword
keyword-only
keyword-only
```

`replace(*[, name][, kind][, default][, annotation])`

Create a new `Parameter` instance based on the instance replaced was invoked on. To override a `Parameter` attribute, pass the corresponding argument. To remove a default value or/and an annotation from a `Parameter`, pass `Parameter.empty`.

```
>>> from inspect import Parameter
>>> param = Parameter('foo', Parameter.KEYWORD_ONLY)
>>> str(param)
'foo=42'

>>> str(param.replace()) # Will create a shallow copy
'foo=42'

>>> str(param.replace(default=Parameter.empty,
"foo:'spam'")
```

*Changed in version 3.4:* In Python 3.3 `Parameter` objects were allowed to have `name` set to `None` if their `kind` was set to `POSITIONAL_ONLY`. This is no longer permitted.

*class* inspect.BoundArguments

Result of a `Signature.bind()` or `Signature.bind_partial()` call. Holds the mapping of arguments to the function's parameters.

arguments

A mutable mapping of parameters' names to arguments' values. Contains only explicitly bound arguments. Changes in `arguments` will reflect in `args` and `kwargs`.

Should be used in conjunction with `Signature.parameters` for any argument processing purposes.

### Note

Arguments for which `Signature.bind()` or `Signature.bind_partial()` relied on a default value are skipped. However, if needed, use `BoundArguments.apply_defaults()` to add them.

*Changed in version 3.9:* `arguments` is now of type `dict`. Formerly, it was of type `collections.OrderedDict`.

args

A tuple of positional arguments values. Dynamically computed from the `arguments` attribute.

kwargs

A dict of keyword arguments values. Dynamically computed from the `arguments` attribute.

signature

A reference to the parent `Signature` object.

## `apply_defaults()`

Set default values for missing arguments.

For variable-positional arguments (`*args`) the default is an empty tuple.

For variable-keyword arguments (`**kwargs`) the default is an empty dict.

```
>>> def foo(a, b='ham', *args): pass
>>> ba = inspect.signature(foo).bind('spam')
>>> ba.apply_defaults()
>>> ba.arguments
{'a': 'spam', 'b': 'ham', 'args': ()}
```

*New in version 3.5.*

The `args` and `kwargs` properties can be used to invoke functions:

```
def test(a, *, b):
    ...

sig = signature(test)
ba = sig.bind(10, b=20)
test(*ba.args, **ba.kwargs)
```

## See also

**PEP 362** [<https://peps.python.org/pep-0362/>] - **Function Signature Object**.

The detailed specification, implementation details and examples.

# Classes and functions

`inspect.getclasstree(classes, unique=False)`

Arrange the given list of classes into a hierarchy of nested

lists. Where a nested list appears, it contains classes derived from the class whose entry immediately precedes the list. Each entry is a 2-tuple containing a class and a tuple of its base classes. If the *unique* argument is true, exactly one entry appears in the returned structure for each class in the given list. Otherwise, classes using multiple inheritance and their descendants will appear multiple times.

`inspect.getfullargspec(func)`

Get the names and default values of a Python function's parameters. A [named tuple](#) is returned:

```
FullArgSpec(args, varargs, varkw, defaults,
             kwonlyargs, kwonlydefaults, annotations)
```

*args* is a list of the positional parameter names. *varargs* is the name of the `*` parameter or `None` if arbitrary positional arguments are not accepted. *varkw* is the name of the `**` parameter or `None` if arbitrary keyword arguments are not accepted. *defaults* is an *n*-tuple of default argument values corresponding to the last *n* positional parameters, or `None` if there are no such defaults defined. *kwonlyargs* is a list of keyword-only parameter names in declaration order. *kwonlydefaults* is a dictionary mapping parameter names from *kwonlyargs* to the default values used if no argument is supplied. *annotations* is a dictionary mapping parameter names to annotations. The special key `"return"` is used to report the function return value annotation (if any).

Note that [signature\(\)](#) and [Signature Object](#) provide the recommended API for callable introspection, and support additional behaviours (like positional-only arguments) that are sometimes encountered in extension module APIs. This function is retained primarily for use in code that needs to maintain compatibility with the Python 2 `inspect` module API.

*Changed in version 3.4:* This function is now based on [signature\(\)](#), but still ignores `__wrapped__` attributes and includes the already bound first parameter in the

signature output for bound methods.

*Changed in version 3.6:* This method was previously documented as deprecated in favour of `signature()` in Python 3.5, but that decision has been reversed in order to restore a clearly supported standard interface for single-source Python 2/3 code migrating away from the legacy `getargspec()` API.

*Changed in version 3.7:* Python only explicitly guaranteed that it preserved the declaration order of keyword-only parameters as of version 3.7, although in practice this order had always been preserved in Python 3.

`inspect.getargvalues(frame)`

Get information about arguments passed into a particular frame. A `named tuple` `ArgInfo(args, varargs, keywords, locals)` is returned. `args` is a list of the argument names. `varargs` and `keywords` are the names of the `*` and `**` arguments or `None`. `locals` is the locals dictionary of the given frame.

### Note

This function was inadvertently marked as deprecated in Python 3.5.

`inspect.formatargvalues(args[, varargs, varkw, locals, formatarg, formatvarargs, formatvarkw, formatvalue])`

Format a pretty argument spec from the four values returned by `getargvalues()`. The `format*` arguments are the corresponding optional formatting functions that are called to turn names and values into strings.

### Note

This function was inadvertently marked as deprecated in Python 3.5.

`inspect.getmro(cls)`

Return a tuple of class `cls`'s base classes, including `cls`, in method resolution order. No class appears more than once in this tuple. Note that the method resolution order depends on `cls`'s type. Unless a very peculiar user-defined metatype is in use, `cls` will be the first element of the tuple.

`inspect.getcallargs(func, /, *args, **kwargs)`

Bind the `args` and `kwargs` to the argument names of the Python function or method `func`, as if it was called with them. For bound methods, bind also the first argument (typically named `self`) to the associated instance. A dict is returned, mapping the argument names (including the names of the `*` and `**` arguments, if any) to their values from `args` and `kwargs`. In case of invoking `func` incorrectly, i.e. whenever `func(*args, **kwargs)` would raise an exception because of incompatible signature, an exception of the same type and the same or similar message is raised. For example:

```
>>> from inspect import getcallargs
>>> def f(a, b=1, *pos, **named):
...     pass
>>> getcallargs(f, 1, 2, 3) == {'a': 1, 'named': {}}
True
>>> getcallargs(f, a=2, x=4) == {'a': 2, 'named': {}}
True
>>> getcallargs(f)
Traceback (most recent call last):
...
TypeError: f() missing 1 required positional argument
```

*New in version 3.2.*

*Deprecated since version 3.5:* Use [Signature.bind\(\)](#) and [Signature.bind\\_partial\(\)](#) instead.

`inspect.getclosurevars(func)`

Get the mapping of external name references in a Python function or method *func* to their current values. A [named tuple](#) `ClosureVars(nonlocals, globals, builtins, unbound)` is returned. *nonlocals* maps referenced names to lexical closure variables, *globals* to the function's module globals and *builtins* to the builtins visible from the function body. *unbound* is the set of names referenced in the function that could not be resolved at all given the current module globals and builtins.

[TypeError](#) is raised if *func* is not a Python function or method.

*New in version 3.3.*

`inspect.unwrap(func, *, stop=None)`

Get the object wrapped by *func*. It follows the chain of `__wrapped__` attributes returning the last object in the chain.

*stop* is an optional callback accepting an object in the wrapper chain as its sole argument that allows the unwrapping to be terminated early if the callback returns a true value. If the callback never returns a true value, the last object in the chain is returned as usual. For example, [signature\(\)](#) uses this to stop unwrapping if any object in the chain has a `__signature__` attribute defined.

[ValueError](#) is raised if a cycle is encountered.

*New in version 3.4.*

`inspect.get_annotations(obj, *, globals=None, locals=None, eval_str=False)`

Compute the annotations dict for an object.

*obj* may be a callable, class, or module. Passing in an object of any other type raises [TypeError](#).

Returns a dict. `get_annotations()` returns a new dict

every time it's called; calling it twice on the same object will return two different but equivalent dicts.

This function handles several details for you:

- If `eval_str` is true, values of type `str` will be unstringized using `eval()`. This is intended for use with stringized annotations (`from __future__ import annotations`).
- If `obj` doesn't have an annotations dict, returns an empty dict. (Functions and methods always have an annotations dict; classes, modules, and other types of callables may not.)
- Ignores inherited annotations on classes. If a class doesn't have its own annotations dict, returns an empty dict.
- All accesses to object members and dict values are done using `getattr()` and `dict.get()` for safety.
- Always, always, always returns a freshly created dict.

`eval_str` controls whether or not values of type `str` are replaced with the result of calling `eval()` on those values:

- If `eval_str` is true, `eval()` is called on values of type `str`. (Note that `get_annotations` doesn't catch exceptions; if `eval()` raises an exception, it will unwind the stack past the `get_annotations` call.)
- If `eval_str` is false (the default), values of type `str` are unchanged.

`globals` and `locals` are passed in to `eval()`; see the documentation for `eval()` for more information. If `globals` or `locals` is `None`, this function may replace that value with a context-specific default, contingent on `type(obj)`:

- If `obj` is a module, `globals` defaults to `obj.__dict__`.
- If `obj` is a class, `globals` defaults to `sys.modules[obj.__module__].__dict__` and `locals` defaults to the `obj` class namespace.

- If `obj` is a callable, `globals` defaults to `obj.__globals__`, although if `obj` is a wrapped function (using `functools.update_wrapper()`) it is first unwrapped.

Calling `get_annotations` is best practice for accessing the annotations dict of any object. See [Annotations Best Practices](#) for more information on annotations best practices.

*New in version 3.10.*

## The interpreter stack

Some of the following functions return **FrameInfo** objects. For backwards compatibility these objects allow tuple-like operations on all attributes except `positions`. This behavior is considered deprecated and may be removed in the future.

*class inspect.FrameInfo*

`frame`

The **frame object** that the record corresponds to.

`filename`

The file name associated with the code being executed by the frame this record corresponds to.

`lineno`

The line number of the current line associated with the code being executed by the frame this record corresponds to.

`function`

The function name that is being executed by the frame this record corresponds to.

`code_context`

A list of lines of context from the source code that's

being executed by the frame this record corresponds to.

index

The index of the current line being executed in the `code_context` list.

positions

A `dis.Positions` object containing the start line number, end line number, start column offset, and end column offset associated with the instruction being executed by the frame this record corresponds to.

*Changed in version 3.5:* Return a `named tuple` instead of a `tuple`.

*Changed in version 3.11:* `FrameInfo` is now a class instance (that is backwards compatible with the previous `named tuple`).

*class* inspect.Traceback

filename

The file name associated with the code being executed by the frame this traceback corresponds to.

lineno

The line number of the current line associated with the code being executed by the frame this traceback corresponds to.

function

The function name that is being executed by the frame this traceback corresponds to.

code\_context

A list of lines of context from the source code that's being executed by the frame this traceback corresponds to.

index

The index of the current line being executed in the `code_context` list.

positions

A `dis.Positions` object containing the start line number, end line number, start column offset, and end column offset associated with the instruction being executed by the frame this traceback corresponds to.

*Changed in version 3.11:* **Traceback** is now a class instance (that is backwards compatible with the previous `named tuple`).

## Note

Keeping references to frame objects, as found in the first element of the frame records these functions return, can cause your program to create reference cycles. Once a reference cycle has been created, the lifespan of all objects which can be accessed from the objects which form the cycle can become much longer even if Python's optional cycle detector is enabled. If such cycles must be created, it is important to ensure they are explicitly broken to avoid the delayed destruction of objects and increased memory consumption which occurs.

Though the cycle detector will catch these, destruction of the frames (and local variables) can be made deterministic by removing the cycle in a `finally` clause. This is also important if the cycle detector was disabled when Python was compiled or using `gc.disable()`. For example:

```
def handle_stackframe_without_leak():
    frame = inspect.currentframe()
    try:
        # do something with the frame
    finally:
        del frame
```

If you want to keep the frame around (for example to print a traceback later), you can also break reference cycles by using the `frame.clear()` method.

The optional *context* argument supported by most of these functions specifies the number of lines of context to return, which are centered around the current line.

`inspect.getframeinfo(frame, context=1)`

Get information about a frame or traceback object. A `Traceback` object is returned.

*Changed in version 3.11:* A `Traceback` object is returned instead of a named tuple.

`inspect.getouterframes(frame, context=1)`

Get a list of `FrameInfo` objects for a frame and all outer frames. These frames represent the calls that lead to the creation of *frame*. The first entry in the returned list represents *frame*; the last entry represents the outermost call on *frame*'s stack.

*Changed in version 3.5:* A list of `named tuples`

`FrameInfo(frame, filename, lineno, function, code_context, index)` is returned.

*Changed in version 3.11:* A list of `FrameInfo` objects is returned.

`inspect.getinnerframes(traceback, context=1)`

Get a list of `FrameInfo` objects for a traceback's frame and all inner frames. These frames represent calls made as a consequence of *frame*. The first entry in the list represents *traceback*; the last entry represents where the exception was raised.

*Changed in version 3.5:* A list of `named tuples`

`FrameInfo(frame, filename, lineno, function, code_context, index)` is returned.

*Changed in version 3.11:* A list of **FrameInfo** objects is returned.

`inspect.currentframe()`

Return the frame object for the caller's stack frame.

**CPython implementation detail:** This function relies on Python stack frame support in the interpreter, which isn't guaranteed to exist in all implementations of Python. If running in an implementation without Python stack frame support this function returns `None`.

`inspect.stack(context=1)`

Return a list of **FrameInfo** objects for the caller's stack. The first entry in the returned list represents the caller; the last entry represents the outermost call on the stack.

*Changed in version 3.5:* A list of **named tuples**

`FrameInfo(frame, filename, lineno, function, code_context, index)` is returned.

*Changed in version 3.11:* A list of **FrameInfo** objects is returned.

`inspect.trace(context=1)`

Return a list of **FrameInfo** objects for the stack between the current frame and the frame in which an exception currently being handled was raised in. The first entry in the list represents the caller; the last entry represents where the exception was raised.

*Changed in version 3.5:* A list of **named tuples**

`FrameInfo(frame, filename, lineno, function, code_context, index)` is returned.

*Changed in version 3.11:* A list of **FrameInfo** objects is returned.

# Fetching attributes statically

Both `getattr()` and `hasattr()` can trigger code execution when fetching or checking for the existence of attributes.

Descriptors, like properties, will be invoked and `__getattr__()` and `__getattribute__()` may be called.

For cases where you want passive introspection, like documentation tools, this can be inconvenient. `getattr_static()` has the same signature as `getattr()` but avoids executing code when it fetches attributes.

`inspect.getattr_static(obj, attr, default=None)`

Retrieve attributes without triggering dynamic lookup via the descriptor protocol, `__getattr__()` or `__getattribute__()`.

Note: this function may not be able to retrieve all attributes that `getattr` can fetch (like dynamically created attributes) and may find attributes that `getattr` can't (like descriptors that raise `AttributeError`). It can also return descriptors objects instead of instance members.

If the instance `__dict__` is shadowed by another member (for example a property) then this function will be unable to find instance members.

*New in version 3.2.*

`getattr_static()` does not resolve descriptors, for example slot descriptors or getset descriptors on objects implemented in C. The descriptor object is returned instead of the underlying attribute.

You can handle these with code like the following. Note that for arbitrary getset descriptors invoking these may trigger code execution:

```
# example code for resolving the builtin descriptor type
class _foo:
    __slots__ = ['foo']
```

```

slot_descriptor = type(_foo.foo)
getset_descriptor = type(type(open(__file__)).name)
wrapper_descriptor = type(str.__dict__['__add__'])
descriptor_types = (slot_descriptor, getset_descriptor,

result = getattr_static(some_object, 'foo')
if type(result) in descriptor_types:
    try:
        result = result.__get__()
    except AttributeError:
        # descriptors can raise AttributeError to
        # indicate there is no underlying value
        # in which case the descriptor itself will
        # have to do
        pass

```

## Current State of Generators and Coroutines

When implementing coroutine schedulers and for other advanced uses of generators, it is useful to determine whether a generator is currently executing, is waiting to start or resume or execution, or has already terminated. `getgeneratorstate()` allows the current state of a generator to be determined easily.

```
inspect.getgeneratorstate(generator)
```

Get current state of a generator-iterator.

Possible states are:

- `GEN_CREATED`: Waiting to start execution.
- `GEN_RUNNING`: Currently being executed by the interpreter.
- `GEN_SUSPENDED`: Currently suspended at a yield expression.
- `GEN_CLOSED`: Execution has completed.

*New in version 3.2.*

`inspect.getcoroutinestate(coroutine)`

Get current state of a coroutine object. The function is intended to be used with coroutine objects created by `async def` functions, but will accept any coroutine-like object that has `cr_running` and `cr_frame` attributes.

Possible states are:

- `CORO_CREATED`: Waiting to start execution.
- `CORO_RUNNING`: Currently being executed by the interpreter.
- `CORO_SUSPENDED`: Currently suspended at an await expression.
- `CORO_CLOSED`: Execution has completed.

*New in version 3.5.*

The current internal state of the generator can also be queried. This is mostly useful for testing purposes, to ensure that internal state is being updated as expected:

`inspect.getgeneratorlocals(generator)`

Get the mapping of live local variables in *generator* to their current values. A dictionary is returned that maps from variable names to values. This is the equivalent of calling `locals()` in the body of the generator, and all the same caveats apply.

If *generator* is a `generator` with no currently associated frame, then an empty dictionary is returned. `TypeError` is raised if *generator* is not a Python generator object.

**CPython implementation detail:** This function relies on the generator exposing a Python stack frame for introspection, which isn't guaranteed to be the case in all implementations of Python. In such cases, this function will always return an empty dictionary.

*New in version 3.3.*

`inspect.getcoroutinelocals(coroutine)`

This function is analogous to `getgeneratorlocals()`, but works for coroutine objects created by `async def` functions.

*New in version 3.5.*

## Code Objects Bit Flags

Python code objects have a `co_flags` attribute, which is a bitmap of the following flags:

`inspect.CO_OPTIMIZED`

The code object is optimized, using fast locals.

`inspect.CO_NEWLOCALS`

If set, a new dict will be created for the frame's `f_locals` when the code object is executed.

`inspect.CO_VARARGS`

The code object has a variable positional parameter (`*args`-like).

`inspect.CO_VARKEYWORDS`

The code object has a variable keyword parameter (`**kwargs`-like).

`inspect.CO_NESTED`

The flag is set when the code object is a nested function.

`inspect.CO_GENERATOR`

The flag is set when the code object is a generator function, i.e. a generator object is returned when the code object is executed.

`inspect.CO_COROUTINE`

The flag is set when the code object is a coroutine function.

When the code object is executed it returns a coroutine object. See [PEP 492](https://peps.python.org/pep-0492/) [https://peps.python.org/pep-0492/] for more details.

*New in version 3.5.*

#### `inspect.CO_ITERABLE_COROUTINE`

The flag is used to transform generators into generator-based coroutines. Generator objects with this flag can be used in `await` expression, and can `yield` from coroutine objects. See [PEP 492](https://peps.python.org/pep-0492/) [https://peps.python.org/pep-0492/] for more details.

*New in version 3.5.*

#### `inspect.CO_ASYNC_GENERATOR`

The flag is set when the code object is an asynchronous generator function. When the code object is executed it returns an asynchronous generator object. See [PEP 525](https://peps.python.org/pep-0525/) [https://peps.python.org/pep-0525/] for more details.

*New in version 3.6.*

### Note

The flags are specific to CPython, and may not be defined in other Python implementations. Furthermore, the flags are an implementation detail, and can be removed or deprecated in future Python releases. It's recommended to use public APIs from the [inspect](#) module for any introspection needs.

## Command Line Interface

The [inspect](#) module also provides a basic introspection capability from the command line.

By default, accepts the name of a module and prints the source of that module. A class or function within the module can be printed instead by appended a colon and the qualified name of the target

object.

--details

Print information about the specified object rather than the source code

# site — Site-specific configuration hook

**Source code:** [Lib/site.py](https://github.com/python/cpython/tree/3.11/Lib/site.py) [https://github.com/python/cpython/tree/3.11/Lib/site.py]

---

**This module is automatically imported during initialization.** The automatic import can be suppressed using the interpreter's **-S** option.

Importing this module will append site-specific paths to the module search path and add a few builtins, unless **-S** was used. In that case, this module can be safely imported with no automatic modifications to the module search path or additions to the builtins. To explicitly trigger the usual site-specific additions, call the **site.main()** function.

*Changed in version 3.3:* Importing the module used to trigger paths manipulation even when using **-S**.

It starts by constructing up to four directories from a head and a tail part. For the head part, it uses `sys.prefix` and `sys.exec_prefix`; empty heads are skipped. For the tail part, it uses the empty string and then `lib/site-packages` (on Windows) or `lib/pythonX.Y/site-packages` (on Unix and macOS). For each of the distinct head-tail combinations, it sees if it refers to an existing directory, and if so, adds it to `sys.path` and also inspects the newly added path for configuration files.

*Changed in version 3.5:* Support for the “site-python” directory has been removed.

If a file named “pyvenv.cfg” exists one directory above `sys.executable`, `sys.prefix` and `sys.exec_prefix` are set to that directory and it is also checked for site-packages (`sys.base_prefix`

and `sys.base_exec_prefix` will always be the “real” prefixes of the Python installation). If “`pyvenv.cfg`” (a bootstrap configuration file) contains the key “`include-system-site-packages`” set to anything other than “`true`” (case-insensitive), the system-level prefixes will not be searched for site-packages; otherwise they will.

A path configuration file is a file whose name has the form `name.pth` and exists in one of the four directories mentioned above; its contents are additional items (one per line) to be added to `sys.path`. Non-existing items are never added to `sys.path`, and no check is made that the item refers to a directory rather than a file. No item is added to `sys.path` more than once. Blank lines and lines beginning with `#` are skipped. Lines starting with `import` (followed by space or tab) are executed.

### Note

An executable line in a `.pth` file is run at every Python startup, regardless of whether a particular module is actually going to be used. Its impact should thus be kept to a minimum. The primary intended purpose of executable lines is to make the corresponding module(s) importable (load 3rd-party import hooks, adjust **`PATH`** etc). Any other initialization is supposed to be done upon a module’s actual import, if and when it happens. Limiting a code chunk to a single line is a deliberate measure to discourage putting anything more complex here.

For example, suppose `sys.prefix` and `sys.exec_prefix` are set to `/usr/local`. The Python X.Y library is then installed in `/usr/local/lib/pythonX.Y`. Suppose this has a subdirectory `/usr/local/lib/pythonX.Y/site-packages` with three subsubdirectories, `foo`, `bar` and `spam`, and two path configuration files, `foo.pth` and `bar.pth`. Assume `foo.pth` contains the following:

```
# foo package configuration

foo
bar
bletch
```

and `bar.pth` contains:

```
# bar package configuration  
  
bar
```

Then the following version-specific directories are added to `sys.path`, in this order:

```
/usr/local/lib/pythonX.Y/site-packages/bar  
/usr/local/lib/pythonX.Y/site-packages/foo
```

Note that `bletch` is omitted because it doesn't exist; the `bar` directory precedes the `foo` directory because `bar.pth` comes alphabetically before `foo.pth`; and `spam` is omitted because it is not mentioned in either path configuration file.

After these path manipulations, an attempt is made to import a module named **sitecustomize**, which can perform arbitrary site-specific customizations. It is typically created by a system administrator in the site-packages directory. If this import fails with an **ImportError** or its subclass exception, and the exception's **name** attribute equals to `'sitecustomize'`, it is silently ignored. If Python is started without output streams available, as with `pythonw.exe` on Windows (which is used by default to start IDLE), attempted output from **sitecustomize** is ignored. Any other exception causes a silent and perhaps mysterious failure of the process.

After this, an attempt is made to import a module named **usercustomize**, which can perform arbitrary user-specific customizations, if **ENABLE\_USER\_SITE** is true. This file is intended to be created in the user site-packages directory (see below), which is part of `sys.path` unless disabled by `-s`. If this import fails with an **ImportError** or its subclass exception, and the exception's **name** attribute equals to `'usercustomize'`, it is silently ignored.

Note that for some non-Unix systems, `sys.prefix` and `sys.exec_prefix` are empty, and the path manipulations are skipped; however the import of **sitecustomize** and

**usercustomize** is still attempted.

## Readline configuration

On systems that support **readline**, this module will also import and configure the **rlcompleter** module, if Python is started in **interactive mode** and without the **-S** option. The default behavior is enable tab-completion and to use `~/.python_history` as the history save file. To disable it, delete (or override) the **sys.\_\_interactivehook\_\_** attribute in your **sitecustomize** or **usercustomize** module or your **PYTHONSTARTUP** file.

*Changed in version 3.4:* Activation of **rlcompleter** and history was made automatic.

## Module contents

site.PREFIXES

A list of prefixes for site-packages directories.

site.ENABLE\_USER\_SITE

Flag showing the status of the user site-packages directory. True means that it is enabled and was added to `sys.path`. False means that it was disabled by user request (with **-s** or **PYTHONNOUSERSITE**). None means it was disabled for security reasons (mismatch between user or group id and effective id) or by an administrator.

site.USER\_SITE

Path to the user site-packages for the running Python. Can be None if **getusersitepackages()** hasn't been called yet. Default value is `~/.local/lib/pythonX.Y/site-packages` for UNIX and non-framework macOS builds, `~/Library/Python/X.Y/lib/python/site-packages` for macOS framework builds, and `%APPDATA%\Python\PythonXY\site-packages` on Windows. This directory is a site directory, which means that `.pth` files in it will be processed.

`site.USER_BASE`

Path to the base directory for the user site-packages. Can be `None` if `getuserbase()` hasn't been called yet. Default value is `~/.local` for UNIX and macOS non-framework builds, `~/Library/Python/X.Y` for macOS framework builds, and `%APPDATA%\Python` for Windows. This value is used by Distutils to compute the installation directories for scripts, data files, Python modules, etc. for the [user installation scheme](#). See also [PYTHONUSERBASE](#).

`site.main()`

Adds all the standard site-specific directories to the module search path. This function is called automatically when this module is imported, unless the Python interpreter was started with the `-S` flag.

*Changed in version 3.3:* This function used to be called unconditionally.

`site.addsitedir(sitedir, known_paths=None)`

Add a directory to `sys.path` and process its `.pth` files. Typically used in `sitecustomize` or `usercustomize` (see above).

`site.getsitepackages()`

Return a list containing all global site-packages directories.

*New in version 3.2.*

`site.getuserbase()`

Return the path of the user base directory, [USER\\_BASE](#). If it is not initialized yet, this function will also set it, respecting [PYTHONUSERBASE](#).

*New in version 3.2.*

`site.getusersitepackages()`

Return the path of the user-specific site-packages directory, `USER_SITE`. If it is not initialized yet, this function will also set it, respecting `USER_BASE`. To determine if the user-specific site-packages was added to `sys.path` `ENABLE_USER_SITE` should be used.

*New in version 3.2.*

## Command Line Interface

The `site` module also provides a way to get the user directories from the command line:

```
$ python3 -m site --user-site  
/home/user/.local/lib/python3.3/site-packages
```

If it is called without arguments, it will print the contents of `sys.path` on the standard output, followed by the value of `USER_BASE` and whether the directory exists, then the same thing for `USER_SITE`, and finally the value of `ENABLE_USER_SITE`.

`--user-base`

Print the path to the user base directory.

`--user-site`

Print the path to the user site-packages directory.

If both options are given, user base and user site will be printed (always in this order), separated by `os.pathsep`.

If any option is given, the script will exit with one of these values: 0 if the user site-packages directory is enabled, 1 if it was disabled by the user, 2 if it is disabled for security reasons or by an administrator, and a value greater than 2 if there is an error.

# Custom Python Interpreters

The modules described in this chapter allow writing interfaces similar to Python’s interactive interpreter. If you want a Python interpreter that supports some special feature in addition to the Python language, you should look at the [code](#) module. (The [codeop](#) module is lower-level, used to support compiling a possibly incomplete chunk of Python code.)

The full list of modules described in this chapter is:

- [code](#) — Interpreter base classes
  - [Interactive Interpreter Objects](#)
  - [Interactive Console Objects](#)
- [codeop](#) — Compile Python code

# code — Interpreter base classes

**Source code:** [Lib/code.py](https://github.com/python/cpython/tree/3.11/Lib/code.py) [https://github.com/python/cpython/tree/3.11/Lib/code.py]

---

The `code` module provides facilities to implement read-eval-print loops in Python. Two classes and convenience functions are included which can be used to build applications which provide an interactive interpreter prompt.

*class* `code.InteractiveInterpreter(locals=None)`

This class deals with parsing and interpreter state (the user's namespace); it does not deal with input buffering or prompting or input file naming (the filename is always passed in explicitly). The optional *locals* argument specifies the dictionary in which code will be executed; it defaults to a newly created dictionary with key `'__name__'` set to `'__console__'` and key `'__doc__'` set to `None`.

*class* `code.InteractiveConsole(locals=None, filename='<console>')`

Closely emulate the behavior of the interactive Python interpreter. This class builds on [InteractiveInterpreter](#) and adds prompting using the familiar `sys.ps1` and `sys.ps2`, and input buffering.

`code.interact(banner=None, readfunc=None, local=None, exitmsg=None)`

Convenience function to run a read-eval-print loop. This creates a new instance of [InteractiveConsole](#) and sets *readfunc* to be used as the [InteractiveConsole.raw\\_input\(\)](#) method, if provided. If *local* is provided, it is passed to the [InteractiveConsole](#) constructor for use as the default namespace for the interpreter loop. The [interact\(\)](#)

method of the instance is then run with *banner* and *exitmsg* passed as the banner and exit message to use, if provided. The console object is discarded after use.

*Changed in version 3.6:* Added *exitmsg* parameter.

```
code.compile_command(source, filename='<input>',  
symbol='single')
```

This function is useful for programs that want to emulate Python's interpreter main loop (a.k.a. the read-eval-print loop). The tricky part is to determine when the user has entered an incomplete command that can be completed by entering more text (as opposed to a complete command or a syntax error). This function *almost* always makes the same decision as the real interpreter main loop.

*source* is the source string; *filename* is the optional filename from which source was read, defaulting to '*<input>*'; and *symbol* is the optional grammar start symbol, which should be 'single' (the default), 'eval' or 'exec'.

Returns a code object (the same as `compile(source, filename, symbol)`) if the command is complete and valid; `None` if the command is incomplete; raises **SyntaxError** if the command is complete and contains a syntax error, or raises **OverflowError** or **ValueError** if the command contains an invalid literal.

## Interactive Interpreter Objects

```
InteractiveInterpreter.runsource(source, filename='<input>',  
symbol='single')
```

Compile and run some source in the interpreter. Arguments are the same as for `compile_command()`; the default for *filename* is '*<input>*', and for *symbol* is 'single'. One of several things can happen:

- The input is incorrect; `compile_command()` raised an exception (**SyntaxError** or **OverflowError**). A

syntax traceback will be printed by calling the `showsyntaxerror()` method. `runsource()` returns `False`.

- The input is incomplete, and more input is required; `compile_command()` returned `None`. `runsource()` returns `True`.
- The input is complete; `compile_command()` returned a code object. The code is executed by calling the `runcode()` (which also handles run-time exceptions, except for `SystemExit`). `runsource()` returns `False`.

The return value can be used to decide whether to use `sys.ps1` or `sys.ps2` to prompt the next line.

#### `InteractiveInterpreter.runcode(code)`

Execute a code object. When an exception occurs, `showtraceback()` is called to display a traceback. All exceptions are caught except `SystemExit`, which is allowed to propagate.

A note about `KeyboardInterrupt`: this exception may occur elsewhere in this code, and may not always be caught. The caller should be prepared to deal with it.

#### `InteractiveInterpreter.showsyntaxerror(filename=None)`

Display the syntax error that just occurred. This does not display a stack trace because there isn't one for syntax errors. If *filename* is given, it is stuffed into the exception instead of the default filename provided by Python's parser, because it always uses `'<string>'` when reading from a string. The output is written by the `write()` method.

#### `InteractiveInterpreter.showtraceback()`

Display the exception that just occurred. We remove the first stack item because it is within the interpreter object implementation. The output is written by the `write()` method.

*Changed in version 3.5:* The full chained traceback is displayed instead of just the primary traceback.

`InteractiveInterpreter.write(data)`

Write a string to the standard error stream (`sys.stderr`). Derived classes should override this to provide the appropriate output handling as needed.

## Interactive Console Objects

The `InteractiveConsole` class is a subclass of `InteractiveInterpreter`, and so offers all the methods of the interpreter objects as well as the following additions.

`InteractiveConsole.interact(banner=None, exitmsg=None)`

Closely emulate the interactive Python console. The optional *banner* argument specify the banner to print before the first interaction; by default it prints a banner similar to the one printed by the standard Python interpreter, followed by the class name of the console object in parentheses (so as not to confuse this with the real interpreter – since it's so close!).

The optional *exitmsg* argument specifies an exit message printed when exiting. Pass the empty string to suppress the exit message. If *exitmsg* is not given or `None`, a default message is printed.

*Changed in version 3.4:* To suppress printing any banner, pass an empty string.

*Changed in version 3.6:* Print an exit message when exiting.

`InteractiveConsole.push(line)`

Push a line of source text to the interpreter. The line should not have a trailing newline; it may have internal newlines. The line is appended to a buffer and the interpreter's `runsource()` method is called with the concatenated contents of the buffer as source. If this indicates that the

command was executed or invalid, the buffer is reset; otherwise, the command is incomplete, and the buffer is left as it was after the line was appended. The return value is `True` if more input is required, `False` if the line was dealt with in some way (this is the same as `runsource()`).

`InteractiveConsole.resetbuffer()`

Remove any unhandled source text from the input buffer.

`InteractiveConsole.raw_input(prompt="")`

Write a prompt and read a line. The returned line does not include the trailing newline. When the user enters the EOF key sequence, `EOFError` is raised. The base implementation reads from `sys.stdin`; a subclass may replace this with a different implementation.

# codeop — Compile Python code

**Source code:** [Lib/codeop.py](https://github.com/python/cpython/tree/3.11/Lib/codeop.py) [https://github.com/python/cpython/tree/3.11/Lib/codeop.py]

---

The `codeop` module provides utilities upon which the Python read-eval-print loop can be emulated, as is done in the `code` module. As a result, you probably don't want to use the module directly; if you want to include such a loop in your program you probably want to use the `code` module instead.

There are two parts to this job:

1. Being able to tell if a line of input completes a Python statement: in short, telling whether to print '>>>' or '...' next.
2. Remembering which future statements the user has entered, so subsequent input can be compiled with these in effect.

The `codeop` module provides a way of doing each of these things, and a way of doing them both.

To do just the former:

```
codeop.compile_command(source, filename = '<input>',  
symbol = 'single')
```

Tries to compile *source*, which should be a string of Python code and return a code object if *source* is valid Python code. In that case, the filename attribute of the code object will be *filename*, which defaults to '*<input>*'. Returns `None` if *source* is *not* valid Python code, but is a prefix of valid Python code.

If there is a problem with *source*, an exception will be raised.

**SyntaxError** is raised if there is invalid Python syntax, and **OverflowError** or **ValueError** if there is an invalid literal.

The *symbol* argument determines whether *source* is compiled as a statement ('single', the default), as a sequence of **statement** ('exec') or as an **expression** ('eval'). Any other value will cause **ValueError** to be raised.

### Note

It is possible (but not likely) that the parser stops parsing with a successful outcome before reaching the end of the source; in this case, trailing symbols may be ignored instead of causing an error. For example, a backslash followed by two newlines may be followed by arbitrary garbage. This will be fixed once the API for the parser is better.

### *class* codeop.Compile

Instances of this class have **\_\_call\_\_()** methods identical in signature to the built-in function **compile()**, but with the difference that if the instance compiles program text containing a **\_\_future\_\_** statement, the instance ‘remembers’ and compiles all subsequent program texts with the statement in force.

### *class* codeop.CommandCompiler

Instances of this class have **\_\_call\_\_()** methods identical in signature to **compile\_command()**; the difference is that if the instance compiles program text containing a **\_\_future\_\_** statement, the instance ‘remembers’ and compiles all subsequent program texts with the statement in force.

# Importing Modules

The modules described in this chapter provide new ways to import other Python modules and hooks for customizing the import process.

The full list of modules described in this chapter is:

- **zipimport** — Import modules from Zip archives
  - **zipimporter** Objects
  - Examples
- **pkgutil** — Package extension utility
- **modulefinder** — Find modules used by a script
  - Example usage of **ModuleFinder**
- **runpy** — Locating and executing Python modules
- **importlib** — The implementation of **import**
  - Introduction
  - Functions
  - **importlib.abc** – Abstract base classes related to import
  - **importlib.machinery** – Importers and path hooks
  - **importlib.util** – Utility code for importers
  - Examples
    - Importing programmatically
    - Checking if a module can be imported
    - Importing a source file directly
    - Implementing lazy imports
    - Setting up an importer
    - Approximating `importlib.import_module()`

- `importlib.resources` – Resources
- Deprecated functions
- `importlib.resources.abc` – Abstract base classes for resources
- Using `importlib.metadata`
  - Overview
  - Functional API
    - Entry points
    - Distribution metadata
    - Distribution versions
    - Distribution files
    - Distribution requirements
    - Mapping import to distribution packages
  - Distributions
  - Distribution Discovery
  - Extending the search algorithm
- The initialization of the `sys.path` module search path
  - Virtual environments
  - `_pth` files
  - Embedded Python

# zipimport — Import modules from Zip archives

**Source code:** [Lib/zipimport.py](https://github.com/python/cpython/tree/3.11/Lib/zipimport.py) [https://github.com/python/cpython/tree/3.11/Lib/zipimport.py]

---

This module adds the ability to import Python modules (`*.py`, `*.pyc`) and packages from ZIP-format archives. It is usually not needed to use the `zipimport` module explicitly; it is automatically used by the built-in `import` mechanism for `sys.path` items that are paths to ZIP archives.

Typically, `sys.path` is a list of directory names as strings. This module also allows an item of `sys.path` to be a string naming a ZIP file archive. The ZIP archive can contain a subdirectory structure to support package imports, and a path within the archive can be specified to only import from a subdirectory. For example, the path `example.zip/lib/` would only import from the `lib/` subdirectory within the archive.

Any files may be present in the ZIP archive, but importers are only invoked for `.py` and `.pyc` files. ZIP import of dynamic modules (`.pyd`, `.so`) is disallowed. Note that if an archive only contains `.py` files, Python will not attempt to modify the archive by adding the corresponding `.pyc` file, meaning that if a ZIP archive doesn't contain `.pyc` files, importing may be rather slow.

*Changed in version 3.8:* Previously, ZIP archives with an archive comment were not supported.

## See also

**PKZIP Application Note** [https://pkware.cachefly.net/webdocs/casestudies/APPNOTE.TXT]

Documentation on the ZIP file format by Phil Katz, the

creator of the format and algorithms used.

### PEP 273 [https://peps.python.org/pep-0273/] - Import Modules from Zip Archives

Written by James C. Ahlstrom, who also provided an implementation. Python 2.3 follows the specification in [PEP 273](https://peps.python.org/pep-0273/) [https://peps.python.org/pep-0273/], but uses an implementation written by Just van Rossum that uses the import hooks described in [PEP 302](https://peps.python.org/pep-0302/) [https://peps.python.org/pep-0302/].

### `importlib` - The implementation of the import machinery

Package providing the relevant protocols for all importers to implement.

This module defines an exception:

*exception* `zipimport.ZipImportError`

Exception raised by `zipimporter` objects. It's a subclass of [`ImportError`](#), so it can be caught as [`ImportError`](#), too.

## zipimporter Objects

[`zipimporter`](#) is the class for importing ZIP files.

*class* `zipimport.zipimporter(archivepath)`

Create a new `zipimporter` instance. *archivepath* must be a path to a ZIP file, or to a specific path within a ZIP file. For example, an *archivepath* of `foo/bar.zip/lib` will look for modules in the `lib` directory inside the ZIP file `foo/bar.zip` (provided that it exists).

[`ZipImportError`](#) is raised if *archivepath* doesn't point to a valid ZIP archive.

`create_module(spec)`

Implementation of

[`importlib.abc.Loader.create\_module\(\)`](#) that returns [`None`](#) to explicitly request the default

semantics.

*New in version 3.10.*

`exec_module(module)`

Implementation of

`importlib.abc.Loader.exec_module()`.

*New in version 3.10.*

`find_loader(fullname, path=None)`

An implementation of

`importlib.abc.PathEntryFinder.find_loader()`.

*Deprecated since version 3.10:* Use `find_spec()` instead.

`find_module(fullname, path=None)`

Search for a module specified by *fullname*. *fullname* must be the fully qualified (dotted) module name. It returns the zipimporter instance itself if the module was found, or `None` if it wasn't. The optional *path* argument is ignored—it's there for compatibility with the importer protocol.

*Deprecated since version 3.10:* Use `find_spec()` instead.

`find_spec(fullname, target=None)`

An implementation of

`importlib.abc.PathEntryFinder.find_spec()`.

*New in version 3.10.*

`get_code(fullname)`

Return the code object for the specified module. Raise `ZipImportError` if the module couldn't be imported.

`get_data(pathname)`

Return the data associated with *pathname*. Raise **OSError** if the file wasn't found.

*Changed in version 3.3:* **IOError** used to be raised instead of **OSError**.

`get_filename(fullname)`

Return the value `__file__` would be set to if the specified module was imported. Raise **ZipImportError** if the module couldn't be imported.

*New in version 3.1.*

`get_source(fullname)`

Return the source code for the specified module. Raise **ZipImportError** if the module couldn't be found, return **None** if the archive does contain the module, but has no source for it.

`is_package(fullname)`

Return **True** if the module specified by *fullname* is a package. Raise **ZipImportError** if the module couldn't be found.

`load_module(fullname)`

Load the module specified by *fullname*. *fullname* must be the fully qualified (dotted) module name. Returns the imported module on success, raises **ZipImportError** on failure.

*Deprecated since version 3.10:* Use **exec\_module()** instead.

`invalidate_caches()`

Clear out the internal cache of information about files found within the ZIP archive.

*New in version 3.10.*

### archive

The file name of the importer's associated ZIP file, without a possible subpath.

### prefix

The subpath within the ZIP file where modules are searched. This is the empty string for `zipimporter` objects which point to the root of the ZIP file.

The `archive` and `prefix` attributes, when combined with a slash, equal the original *archivepath* argument given to the `zipimporter` constructor.

## Examples

Here is an example that imports a module from a ZIP archive - note that the `zipimport` module is not explicitly used.

```
$ unzip -l example.zip
Archive:  example.zip
  Length      Date    Time    Name
  -----
    8467   11-26-02  22:30   jwzthreading.py
  -----
    8467
                   1 file

$ ./python
Python 2.3 (#1, Aug 1 2003, 19:54:32)
>>> import sys
>>> sys.path.insert(0, 'example.zip') # Add .zip file to path
>>> import jwzthreading
>>> jwzthreading.__file__
'example.zip/jwzthreading.py'
```

# pkgutil — Package extension utility

**Source code:** [Lib/pkgutil.py](https://github.com/python/cpython/tree/3.11/Lib/pkgutil.py) [https://github.com/python/cpython/tree/3.11/Lib/pkgutil.py]

---

This module provides utilities for the import system, in particular package support.

`class pkgutil.ModuleInfo(module_finder, name, ispkg)`

A namedtuple that holds a brief summary of a module's info.

*New in version 3.6.*

`pkgutil.extend_path(path, name)`

Extend the search path for the modules which comprise a package. Intended use is to place the following code in a package's `__init__.py`:

```
from pkgutil import extend_path
__path__ = extend_path(__path__, __name__)
```

For each directory on `sys.path` that has a subdirectory that matches the package name, add the subdirectory to the package's `__path__`. This is useful if one wants to distribute different parts of a single logical package as multiple directories.

It also looks for `*.pkg` files beginning where `*` matches the `name` argument. This feature is similar to `*.pth` files (see the `site` module for more information), except that it doesn't special-case lines starting with `import`. A `*.pkg` file is trusted at face value: apart from checking for duplicates, all entries found in a `*.pkg` file are added to the path,

regardless of whether they exist on the filesystem. (This is a feature.)

If the input path is not a list (as is the case for frozen packages) it is returned unchanged. The input path is not modified; an extended copy is returned. Items are only appended to the copy at the end.

It is assumed that `sys.path` is a sequence. Items of `sys.path` that are not strings referring to existing directories are ignored. Unicode items on `sys.path` that cause errors when used as filenames may cause this function to raise an exception (in line with `os.path.isdir()` behavior).

`class pkgutil.ImpImporter(dirname=None)`

**PEP 302** [<https://peps.python.org/pep-0302/>] Finder that wraps Python’s “classic” import algorithm.

If `dirname` is a string, a **PEP 302** [<https://peps.python.org/pep-0302/>] finder is created that searches that directory. If `dirname` is `None`, a **PEP 302** [<https://peps.python.org/pep-0302/>] finder is created that searches the current `sys.path`, plus any modules that are frozen or built-in.

Note that `ImpImporter` does not currently support being used by placement on `sys.meta_path`.

*Deprecated since version 3.3:* This emulation is no longer needed, as the standard import mechanism is now fully **PEP 302** [<https://peps.python.org/pep-0302/>] compliant and available in `importlib`.

`class pkgutil.ImpLoader(fullname, file, filename, etc)`

**Loader** that wraps Python’s “classic” import algorithm.

*Deprecated since version 3.3:* This emulation is no longer needed, as the standard import mechanism is now fully **PEP 302** [<https://peps.python.org/pep-0302/>] compliant and available in `importlib`.

`pkgutil.find_loader(fullname)`

Retrieve a module **loader** for the given *fullname*.

This is a backwards compatibility wrapper around `importlib.util.find_spec()` that converts most failures to `ImportError` and only returns the loader rather than the full `importlib.machinery.ModuleSpec`.

*Changed in version 3.3:* Updated to be based directly on `importlib` rather than relying on the package internal **PEP 302** [<https://peps.python.org/pep-0302/>] import emulation.

*Changed in version 3.4:* Updated to be based on **PEP 451** [<https://peps.python.org/pep-0451/>]

`pkgutil.get_importer(path_item)`

Retrieve a **finder** for the given *path\_item*.

The returned finder is cached in `sys.path_importer_cache` if it was newly created by a path hook.

The cache (or part of it) can be cleared manually if a rescan of `sys.path_hooks` is necessary.

*Changed in version 3.3:* Updated to be based directly on `importlib` rather than relying on the package internal **PEP 302** [<https://peps.python.org/pep-0302/>] import emulation.

`pkgutil.get_loader(module_or_name)`

Get a **loader** object for *module\_or\_name*.

If the module or package is accessible via the normal import mechanism, a wrapper around the relevant part of that machinery is returned. Returns `None` if the module cannot be found or imported. If the named module is not already imported, its containing package (if any) is imported, in order to establish the package `__path__`.

*Changed in version 3.3:* Updated to be based directly on

**importlib** rather than relying on the package internal **PEP 302** [<https://peps.python.org/pep-0302/>] import emulation.

*Changed in version 3.4:* Updated to be based on **PEP 451** [<https://peps.python.org/pep-0451/>]

`pkgutil.iter_importers(fullname="")`

Yield **finder** objects for the given module name.

If fullname contains a `'.'`, the finders will be for the package containing fullname, otherwise they will be all registered top level finders (i.e. those on both **sys.meta\_path** and **sys.path\_hooks**).

If the named module is in a package, that package is imported as a side effect of invoking this function.

If no module name is specified, all top level finders are produced.

*Changed in version 3.3:* Updated to be based directly on **importlib** rather than relying on the package internal **PEP 302** [<https://peps.python.org/pep-0302/>] import emulation.

`pkgutil.iter_modules(path=None, prefix="")`

Yields **ModuleInfo** for all submodules on *path*, or, if *path* is `None`, all top-level modules on **sys.path**.

*path* should be either `None` or a list of paths to look for modules in.

*prefix* is a string to output on the front of every module name on output.

## Note

Only works for a **finder** which defines an `iter_modules()` method. This interface is non-standard, so the module also provides implementations for **importlib.machinery.FileFinder** and

`zipimport.zipimporter.`

*Changed in version 3.3:* Updated to be based directly on `importlib` rather than relying on the package internal [PEP 302](https://peps.python.org/pep-0302/) [https://peps.python.org/pep-0302/] import emulation.

`pkgutil.walk_packages(path=None, prefix="", onerror=None)`

Yields `ModuleInfo` for all modules recursively on *path*, or, if *path* is `None`, all accessible modules.

*path* should be either `None` or a list of paths to look for modules in.

*prefix* is a string to output on the front of every module name on output.

Note that this function must import all *packages* (not all modules!) on the given *path*, in order to access the `__path__` attribute to find submodules.

*onerror* is a function which gets called with one argument (the name of the package which was being imported) if any exception occurs while trying to import a package. If no *onerror* function is supplied, `ImportErrors` are caught and ignored, while all other exceptions are propagated, terminating the search.

Examples:

```
# list all modules python can access
walk_packages()
```

```
# list all submodules of ctypes
walk_packages(ctypes.__path__, ctypes.__name__ + '.')
```

## Note

Only works for a [finder](#) which defines an `iter_modules()` method. This interface is non-standard, so the module also provides implementations for

`importlib.machinery.FileFinder` and  
`zipimport.zipimporter`.

*Changed in version 3.3:* Updated to be based directly on `importlib` rather than relying on the package internal [PEP 302](https://peps.python.org/pep-0302/) [https://peps.python.org/pep-0302/] import emulation.

`pkgutil.get_data(package, resource)`

Get a resource from a package.

This is a wrapper for the `loader.get_data` API. The *package* argument should be the name of a package, in standard module format (`foo.bar`). The *resource* argument should be in the form of a relative filename, using `/` as the path separator. The parent directory name `..` is not allowed, and nor is a rooted name (starting with a `/`).

The function returns a binary string that is the contents of the specified resource.

For packages located in the filesystem, which have already been imported, this is the rough equivalent of:

```
d = os.path.dirname(sys.modules[package].__file__)
data = open(os.path.join(d, resource), 'rb').read()
```

If the package cannot be located or loaded, or it uses a `loader` which does not support `get_data`, then `None` is returned. In particular, the `loader` for [namespace packages](#) does not support `get_data`.

`pkgutil.resolve_name(name)`

Resolve a name to an object.

This functionality is used in numerous places in the standard library (see [bpo-12915](https://bugs.python.org/issue?@action=redirect&bpo=12915) [https://bugs.python.org/issue?@action=redirect&bpo=12915]) - and equivalent functionality is also in widely used third-party packages such as `setuptools`, `Django` and `Pyramid`.

It is expected that *name* will be a string in one of the following formats, where W is shorthand for a valid Python identifier and dot stands for a literal period in these pseudo-regexes:

- $W(.W)^*$
- $W(.W)^* : (W(.W)^*)^?$

The first form is intended for backward compatibility only. It assumes that some part of the dotted name is a package, and the rest is an object somewhere within that package, possibly nested inside other objects. Because the place where the package stops and the object hierarchy starts can't be inferred by inspection, repeated attempts to import must be done with this form.

In the second form, the caller makes the division point clear through the provision of a single colon: the dotted name to the left of the colon is a package to be imported, and the dotted name to the right is the object hierarchy within that package. Only one import is needed in this form. If it ends with the colon, then a module object is returned.

The function will return an object (which might be a module), or raise one of the following exceptions:

**ValueError** – if *name* isn't in a recognised format.

**ImportError** – if an import failed when it shouldn't have.

**AttributeError** – If a failure occurred when traversing the object hierarchy within the imported package to get to the desired object.

*New in version 3.9.*

# modulefinder — Find modules used by a script

**Source code:** [Lib/modulefinder.py](https://github.com/python/cpython/tree/3.11/Lib/modulefinder.py) [https://github.com/python/cpython/tree/3.11/Lib/modulefinder.py]

---

This module provides a `ModuleFinder` class that can be used to determine the set of modules imported by a script. `modulefinder.py` can also be run as a script, giving the filename of a Python script as its argument, after which a report of the imported modules will be printed.

`modulefinder.AddPackagePath(pkg_name, path)`

Record that the package named *pkg\_name* can be found in the specified *path*.

`modulefinder.ReplacePackage(oldname, newname)`

Allows specifying that the module named *oldname* is in fact the package named *newname*.

`class modulefinder.ModuleFinder(path=None, debug=0, excludes=[], replace_paths=[])`

This class provides `run_script()` and `report()` methods to determine the set of modules imported by a script. *path* can be a list of directories to search for modules; if not specified, `sys.path` is used. *debug* sets the debugging level; higher values make the class print debugging messages about what it's doing. *excludes* is a list of module names to exclude from the analysis. *replace\_paths* is a list of (*oldpath*, *newpath*) tuples that will be replaced in module paths.

`report()`

Print a report to standard output that lists the modules imported by the script and their paths, as well as modules that are missing or seem to be missing.

`run_script(pathname)`

Analyze the contents of the *pathname* file, which must contain Python code.

`modules`

A dictionary mapping module names to modules. See [Example usage of ModuleFinder](#).

## Example usage of **ModuleFinder**

The script that is going to get analyzed later on (bacon.py):

```
import re, itertools

try:
    import baconhameggs
except ImportError:
    pass

try:
    import guido.python.ham
except ImportError:
    pass
```

The script that will output the report of bacon.py:

```
from modulefinder import ModuleFinder

finder = ModuleFinder()
finder.run_script('bacon.py')

print('Loaded modules:')
for name, mod in finder.modules.items():
    print('%s: ' % name, end='')
```

```
print(','.join(list(mod.globalnames.keys())[0:3]))

print('-'*50)
print('Modules not imported:')
print('\n'.join(finder.badmodules.keys()))
```

**Sample output (may vary depending on the architecture):**

```
Loaded modules:
_types:
copyreg:  _inverted_registry, _slotnames, __all__
re._compiler:  isstring, _sre, _optimize_unicode
_sre:
re._constants:  REPEAT_ONE, makedict, AT_END_LINE
sys:
re:  __module__, finditer, _expand
itertools:
__main__:  re, itertools, baconhameggs
re._parser:  _PATTERNENDERS, SRE_FLAG_UNICODE
array:
types:  __module__, IntType, TypeType
-----
```

```
Modules not imported:
guido.python.ham
baconhameggs
```

# runpy — Locating and executing Python modules

Source code: [Lib/runpy.py](https://github.com/python/cpython/tree/3.11/Lib/runpy.py) [https://github.com/python/cpython/tree/3.11/Lib/runpy.py]

---

The **runpy** module is used to locate and run Python modules without importing them first. Its main use is to implement the **-m** command line switch that allows scripts to be located using the Python module namespace rather than the filesystem.

Note that this is *not* a sandbox module - all code is executed in the current process, and any side effects (such as cached imports of other modules) will remain in place after the functions have returned.

Furthermore, any functions and classes defined by the executed code are not guaranteed to work correctly after a **runpy** function has returned. If that limitation is not acceptable for a given use case, **importlib** is likely to be a more suitable choice than this module.

The **runpy** module provides two functions:

`runpy.run_module(mod_name, init_globals=None, run_name=None, alter_sys=False)`

Execute the code of the specified module and return the resulting module globals dictionary. The module's code is first located using the standard import mechanism (refer to [PEP 302](https://peps.python.org/pep-0302/) [https://peps.python.org/pep-0302/] for details) and then executed in a fresh module namespace.

The *mod\_name* argument should be an absolute module name. If the module name refers to a package rather than a normal

module, then that package is imported and the `__main__` submodule within that package is then executed and the resulting module globals dictionary returned.

The optional dictionary argument `init_globals` may be used to pre-populate the module's globals dictionary before the code is executed. The supplied dictionary will not be modified. If any of the special global variables below are defined in the supplied dictionary, those definitions are overridden by `run_module()`.

The special global variables `__name__`, `__spec__`, `__file__`, `__cached__`, `__loader__` and `__package__` are set in the globals dictionary before the module code is executed (Note that this is a minimal set of variables - other variables may be set implicitly as an interpreter implementation detail).

`__name__` is set to *run\_name* if this optional argument is not `None`, to `mod_name + '.__main__'` if the named module is a package and to the *mod\_name* argument otherwise.

`__spec__` will be set appropriately for the *actually* imported module (that is, `__spec__.name` will always be *mod\_name* or `mod_name + '.__main__'`, never *run\_name*).

`__file__`, `__cached__`, `__loader__` and `__package__` are **set as normal** based on the module spec.

If the argument *alter\_sys* is supplied and evaluates to `True`, then `sys.argv[0]` is updated with the value of `__file__` and `sys.modules[__name__]` is updated with a temporary module object for the module being executed. Both `sys.argv[0]` and `sys.modules[__name__]` are restored to their original values before the function returns.

Note that this manipulation of `sys` is not thread-safe. Other threads may see the partially initialised module, as well as the altered list of arguments. It is recommended that the `sys` module be left alone when invoking this function from threaded code.

## See also

The `-m` option offering equivalent functionality from the command line.

*Changed in version 3.1:* Added ability to execute packages by looking for a `__main__` submodule.

*Changed in version 3.2:* Added `__cached__` global variable (see [PEP 3147](https://peps.python.org/pep-3147/) [https://peps.python.org/pep-3147/]).

*Changed in version 3.4:* Updated to take advantage of the module spec feature added by [PEP 451](https://peps.python.org/pep-0451/) [https://peps.python.org/pep-0451/]. This allows `__cached__` to be set correctly for modules run this way, as well as ensuring the real module name is always accessible as `__spec__.name`.

`runpy.run_path(path_name, init_globals=None, run_name=None)`

Execute the code at the named filesystem location and return the resulting module globals dictionary. As with a script name supplied to the CPython command line, the supplied path may refer to a Python source file, a compiled bytecode file or a valid `sys.path` entry containing a `__main__` module (e.g. a zipfile containing a top-level `__main__.py` file).

For a simple script, the specified code is simply executed in a fresh module namespace. For a valid `sys.path` entry (typically a zipfile or directory), the entry is first added to the beginning of `sys.path`. The function then looks for and executes a `__main__` module using the updated path. Note that there is no special protection against invoking an existing `__main__` entry located elsewhere on `sys.path` if there is no such module at the specified location.

The optional dictionary argument `init_globals` may be used to pre-populate the module's globals dictionary before the code is executed. The supplied dictionary will not be modified. If any of the special global variables below are defined in the supplied dictionary, those definitions are overridden by `run_path()`.

The special global variables `__name__`, `__spec__`, `__file__`, `__cached__`, `__loader__` and `__package__` are set in the globals dictionary before the module code is executed (Note that this is a minimal set of variables - other variables may be set implicitly as an interpreter implementation detail).

`__name__` is set to *run\_name* if this optional argument is not **None** and to `'<run_path>'` otherwise.

If the supplied path directly references a script file (whether as source or as precompiled byte code), then `__file__` will be set to the supplied path, and `__spec__`, `__cached__`, `__loader__` and `__package__` will all be set to **None**.

If the supplied path is a reference to a valid `sys.path` entry, then `__spec__` will be set appropriately for the imported `__main__` module (that is, `__spec__.name` will always be `__main__`). `__file__`, `__cached__`, `__loader__` and `__package__` will be **set as normal** based on the module spec.

A number of alterations are also made to the **sys** module. Firstly, `sys.path` may be altered as described above. `sys.argv[0]` is updated with the value of `path_name` and `sys.modules[__name__]` is updated with a temporary module object for the module being executed. All modifications to items in **sys** are reverted before the function returns.

Note that, unlike **run\_module()**, the alterations made to **sys** are not optional in this function as these adjustments are essential to allowing the execution of `sys.path` entries. As the thread-safety limitations still apply, use of this function in threaded code should be either serialised with the import lock or delegated to a separate process.

## See also

**Interface options** for equivalent functionality on the command line (`python path/to/script`).

*New in version 3.2.*

*Changed in version 3.4:* Updated to take advantage of the module spec feature added by [PEP 451](https://peps.python.org/pep-0451/) [https://peps.python.org/pep-0451/]. This allows `__cached__` to be set correctly in the case where `__main__` is imported from a valid `sys.path` entry rather than being executed directly.

# `importlib` — The implementation of `import`

*New in version 3.1.*

**Source code:** [Lib/importlib/\\_init\\_.py](https://github.com/python/cpython/tree/3.11/Lib/importlib/_init_.py) [https://github.com/python/cpython/tree/3.11/Lib/importlib/\_init\_.py]

---

## Introduction

The purpose of the `importlib` package is three-fold.

One is to provide the implementation of the `import` statement (and thus, by extension, the `__import__()` function) in Python source code. This provides an implementation of `import` which is portable to any Python interpreter. This also provides an implementation which is easier to comprehend than one implemented in a programming language other than Python.

Two, the components to implement `import` are exposed in this package, making it easier for users to create their own custom objects (known generically as an `importer`) to participate in the import process.

Three, the package contains modules exposing additional functionality for managing aspects of Python packages:

- `importlib.metadata` presents access to metadata from third-party distributions.
- `importlib.resources` provides routines for accessing non-code “resources” from Python packages.

## Functions

`importlib._import_(name, globals=None, locals=None, fromlist=(), level=0)`

An implementation of the built-in `__import__()` function.

### Note

Programmatic importing of modules should use `import_module()` instead of this function.

`importlib.import_module(name, package=None)`

Import a module. The *name* argument specifies what module to import in absolute or relative terms (e.g. either `pkg.mod` or `..mod`). If the name is specified in relative terms, then the *package* argument must be set to the name of the package which is to act as the anchor for resolving the package name (e.g. `import_module('..mod', 'pkg.subpkg')` will import `pkg.mod`).

The `import_module()` function acts as a simplifying wrapper around `importlib._import__()`. This means all semantics of the function are derived from `importlib._import__()`. The most important difference between these two functions is that `import_module()` returns the specified package or module (e.g. `pkg.mod`), while `__import__()` returns the top-level package or module (e.g. `pkg`).

If you are dynamically importing a module that was created since the interpreter began execution (e.g., created a Python source file), you may need to call `invalidate_caches()` in order for the new module to be noticed by the import system.

*Changed in version 3.3:* Parent packages are automatically imported.

`importlib.find_loader(name, path=None)`

Find the loader for a module, optionally within the specified *path*. If the module is in `sys.modules`, then `sys.modules[name].__loader__` is returned (unless the loader would be `None` or is not set, in which case `ValueError` is raised). Otherwise a search using `sys.meta_path` is done. `None` is returned if no loader is found.

A dotted name does not have its parents implicitly imported as that requires loading them and that may not be desired. To properly import a submodule you will need to import all parent packages of the submodule and use the correct argument to *path*.

*New in version 3.3.*

*Changed in version 3.4:* If `__loader__` is not set, raise `ValueError`, just like when the attribute is set to `None`.

*Deprecated since version 3.4:* Use `importlib.util.find_spec()` instead.

`importlib.invalidate_caches()`

Invalidate the internal caches of finders stored at `sys.meta_path`. If a finder implements `invalidate_caches()` then it will be called to perform the invalidation. This function should be called if any modules are created/installed while your program is running to guarantee all finders will notice the new module's existence.

*New in version 3.3.*

*Changed in version 3.10:* Namespace packages created/installed in a different `sys.path` location after the same namespace was already imported are noticed.

`importlib.reload(module)`

Reload a previously imported *module*. The argument must be a module object, so it must have been successfully imported before. This is useful if you have edited the module source file using an external editor and want to try out the new version without leaving the Python interpreter. The return value is the module object (which can be different if re-importing causes a different object to be placed in `sys.modules`).

When `reload()` is executed:

- Python module's code is recompiled and the module-level code re-executed, defining a new set of objects which are bound to names in the module's dictionary by reusing the `loader` which originally loaded the module. The `init` function of extension modules is not called a second time.
- As with all other objects in Python the old objects are only reclaimed after their reference counts drop to zero.
- The names in the module namespace are updated to point to any new or changed objects.
- Other references to the old objects (such as names external to the module) are not rebound to refer to the new objects and must be updated in each namespace where they occur if that is desired.

There are a number of other caveats:

When a module is reloaded, its dictionary (containing the module's global variables) is retained. Redefinitions of names will override the old definitions, so this is generally not a problem. If the new version of a module does not define a name that was defined by the old version, the old definition

remains. This feature can be used to the module's advantage if it maintains a global table or cache of objects — with a **try** statement it can test for the table's presence and skip its initialization if desired:

```
try:
    cache
except NameError:
    cache = {}
```

It is generally not very useful to reload built-in or dynamically loaded modules. Reloading **sys**, **\_\_main\_\_**, **builtins** and other key modules is not recommended. In many cases extension modules are not designed to be initialized more than once, and may fail in arbitrary ways when reloaded.

If a module imports objects from another module using **from ... import ...**, calling **reload()** for the other module does not redefine the objects imported from it — one way around this is to re-execute the **from** statement, another is to use **import** and qualified names (*module.name*) instead.

If a module instantiates instances of a class, reloading the module that defines the class does not affect the method definitions of the instances — they continue to use the old class definition. The same is true for derived classes.

*New in version 3.4.*

*Changed in version 3.7:* **ModuleNotFoundError** is raised when the module being reloaded lacks a **ModuleSpec**.

## **importlib.abc** – Abstract base classes related to import

**Source code:** [Lib/importlib/abc.py](https://github.com/python/cpython/tree/3.11/Lib/importlib/abc.py) [https://github.com/python/cpython/tree/3.11/Lib/importlib/abc.py]

---

The `importlib.abc` module contains all of the core abstract base classes used by `import`. Some subclasses of the core abstract base classes are also provided to help in implementing the core ABCs.

ABC hierarchy:

```
object
+-- Finder (deprecated)
+-- MetaPathFinder
+-- PathEntryFinder
+-- Loader
    +-- ResourceLoader -----+
    +-- InspectLoader          |
        +-- ExecutionLoader --+
                                   +-- FileLoader
                                   +-- SourceLoader
```

`class importlib.abc.Finder`

An abstract base class representing a [finder](#).

*Deprecated since version 3.3:* Use [MetaPathFinder](#) or [PathEntryFinder](#) instead.

*abstractmethod* `find_module(fullname, path=None)`

An abstract method for finding a [loader](#) for the specified module. Originally specified in [PEP 302](#) [<https://peps.python.org/pep-0302/>], this method was meant for use in `sys.meta_path` and in the path-based import subsystem.

*Changed in version 3.4:* Returns `None` when called instead of raising [NotImplementedError](#).

*Deprecated since version 3.10:* Implement [MetaPathFinder.find\\_spec\(\)](#) or [PathEntryFinder.find\\_spec\(\)](#) instead.

`class importlib.abc.MetaPathFinder`

An abstract base class representing a [meta path finder](#).

*New in version 3.3.*

*Changed in version 3.10:* No longer a subclass of `Finder`.

`find_spec(fullname, path, target=None)`

An abstract method for finding a `spec` for the specified module. If this is a top-level import, `path` will be `None`. Otherwise, this is a search for a subpackage or module and `path` will be the value of `__path__` from the parent package. If a spec cannot be found, `None` is returned. When passed in, `target` is a module object that the finder may use to make a more educated guess about what spec to return.

`importlib.util.spec_from_loader()` may be useful for implementing concrete `MetaPathFinders`.

*New in version 3.4.*

`find_module(fullname, path)`

A legacy method for finding a `loader` for the specified module. If this is a top-level import, `path` will be `None`. Otherwise, this is a search for a subpackage or module and `path` will be the value of `__path__` from the parent package. If a loader cannot be found, `None` is returned.

If `find_spec()` is defined, backwards-compatible functionality is provided.

*Changed in version 3.4:* Returns `None` when called instead of raising `NotImplementedError`. Can use `find_spec()` to provide functionality.

*Deprecated since version 3.4:* Use `find_spec()` instead.

`invalidate_caches()`

An optional method which, when called, should invalidate any internal cache used by the finder. Used

by `importlib.invalidate_caches()` when invalidating the caches of all finders on `sys.meta_path`.

*Changed in version 3.4:* Returns `None` when called instead of `NotImplemented`.

`class importlib.abc.PathEntryFinder`

An abstract base class representing a [path entry finder](#). Though it bears some similarities to [MetaPathFinder](#), `PathEntryFinder` is meant for use only within the path-based import subsystem provided by [importlib.machinery.PathFinder](#).

*New in version 3.3.*

*Changed in version 3.10:* No longer a subclass of [Finder](#).

`find_spec(fullname, target=None)`

An abstract method for finding a [spec](#) for the specified module. The finder will search for the module only within the [path entry](#) to which it is assigned. If a spec cannot be found, `None` is returned. When passed in, `target` is a module object that the finder may use to make a more educated guess about what spec to return. [importlib.util.spec\\_from\\_loader\(\)](#) may be useful for implementing concrete `PathEntryFinders`.

*New in version 3.4.*

`find_loader(fullname)`

A legacy method for finding a [loader](#) for the specified module. Returns a 2-tuple of (`loader`, `portion`) where `portion` is a sequence of file system locations contributing to part of a namespace package. The loader may be `None` while specifying `portion` to signify the contribution of the file system locations to a namespace package. An empty list can be used for

portion to signify the loader is not part of a namespace package. If `loader` is `None` and `portion` is the empty list then no loader or location for a namespace package were found (i.e. failure to find anything for the module).

If `find_spec()` is defined then backwards-compatible functionality is provided.

*Changed in version 3.4:* Returns `(None, [])` instead of raising `NotImplementedError`. Uses `find_spec()` when available to provide functionality.

*Deprecated since version 3.4:* Use `find_spec()` instead.

`find_module(fullname)`

A concrete implementation of `Finder.find_module()` which is equivalent to `self.find_loader(fullname)[0]`.

*Deprecated since version 3.4:* Use `find_spec()` instead.

`invalidate_caches()`

An optional method which, when called, should invalidate any internal cache used by the finder. Used by

`importlib.machinery.PathFinder.invalidate_caches()` when invalidating the caches of all cached finders.

`class importlib.abc.Loader`

An abstract base class for a `loader`. See [PEP 302](https://peps.python.org/pep-0302/) [https://peps.python.org/pep-0302/] for the exact definition for a loader.

Loaders that wish to support resource reading should implement a `get_resource_reader()` method as specified by

`importlib.resources.abc.ResourceReader`.

*Changed in version 3.7:* Introduced the optional `get_resource_reader()` method.

`create_module(spec)`

A method that returns the module object to use when importing a module. This method may return `None`, indicating that default module creation semantics should take place.

*New in version 3.4.*

*Changed in version 3.6:* This method is no longer optional when `exec_module()` is defined.

`exec_module(module)`

An abstract method that executes the module in its own namespace when a module is imported or reloaded. The module should already be initialized when `exec_module()` is called. When this method exists, `create_module()` must be defined.

*New in version 3.4.*

*Changed in version 3.6:* `create_module()` must also be defined.

`load_module(fullname)`

A legacy method for loading a module. If the module cannot be loaded, `ImportError` is raised, otherwise the loaded module is returned.

If the requested module already exists in `sys.modules`, that module should be used and reloaded. Otherwise the loader should create a new module and insert it into `sys.modules` before any loading begins, to prevent recursion from the import. If the loader inserted a module and the load fails, it must be removed by the loader from `sys.modules`; modules already in `sys.modules` before the loader

began execution should be left alone (see `importlib.util.module_for_loader()`).

The loader should set several attributes on the module (note that some of these attributes can change when a module is reloaded):

- `__name__`  
The module's fully qualified name. It is `'__main__'` for an executed module.
- `__file__`  
The location the `loader` used to load the module. For example, for modules loaded from a `.py` file this is the filename. It is not set on all modules (e.g. built-in modules).
- `__cached__`  
The filename of a compiled version of the module's code. It is not set on all modules (e.g. built-in modules).
- `__path__`  
The list of locations where the package's submodules will be found. Most of the time this is a single directory. The import system passes this attribute to `__import__()` and to finders in the same way as `sys.path` but just for the package. It is not set on non-package modules so it can be used as an indicator that the module is a package.
- `__package__`  
The fully qualified name of the package the module is in (or the empty string for a top-level module). If the module is a package then this is the same as `__name__`.
- `__loader__`

The `loader` used to load the module.

When `exec_module()` is available then backwards-compatible functionality is provided.

*Changed in version 3.4:* Raise `ImportError` when called instead of `NotImplementedError`.  
Functionality provided when `exec_module()` is available.

*Deprecated since version 3.4:* The recommended API for loading a module is `exec_module()` (and `create_module()`). Loaders should implement it instead of `load_module()`. The import machinery takes care of all the other responsibilities of `load_module()` when `exec_module()` is implemented.

`module_repr(module)`

A legacy method which when implemented calculates and returns the given module's representation, as a string. The module type's default `__repr__()` will use the result of this method as appropriate.

*New in version 3.3.*

*Changed in version 3.4:* Made optional instead of an abstractmethod.

*Deprecated since version 3.4:* The import machinery now takes care of this automatically.

`class importlib.abc.ResourceLoader`

An abstract base class for a `loader` which implements the optional [PEP 302](https://peps.python.org/pep-0302/) [https://peps.python.org/pep-0302/] protocol for loading arbitrary resources from the storage back-end.

*Deprecated since version 3.7:* This ABC is deprecated in favour of supporting resource loading through `importlib.resources.abc.ResourceReader`.

*abstractmethod* get\_data(path)

An abstract method to return the bytes for the data located at *path*. Loaders that have a file-like storage back-end that allows storing arbitrary data can implement this abstract method to give direct access to the data stored. **OSError** is to be raised if the *path* cannot be found. The *path* is expected to be constructed using a module's `__file__` attribute or an item from a package's `__path__`.

*Changed in version 3.4:* Raises **OSError** instead of **NotImplementedError**.

*class* importlib.abc.InspectLoader

An abstract base class for a **loader** which implements the optional **PEP 302** [<https://peps.python.org/pep-0302/>] protocol for loaders that inspect modules.

*get\_code*(fullname)

Return the code object for a module, or `None` if the module does not have a code object (as would be the case, for example, for a built-in module). Raise an **ImportError** if loader cannot find the requested module.

### Note

While the method has a default implementation, it is suggested that it be overridden if possible for performance.

*Changed in version 3.4:* No longer abstract and a concrete implementation is provided.

*abstractmethod* get\_source(fullname)

An abstract method to return the source of a module. It is returned as a text string using **universal newlines**, translating all recognized line separators into `'\n'`

characters. Returns `None` if no source is available (e.g. a built-in module). Raises `ImportError` if the loader cannot find the module specified.

*Changed in version 3.4:* Raises `ImportError` instead of `NotImplementedError`.

`is_package(fullname)`

An optional method to return a true value if the module is a package, a false value otherwise. `ImportError` is raised if the `loader` cannot find the module.

*Changed in version 3.4:* Raises `ImportError` instead of `NotImplementedError`.

*static* `source_to_code(data, path = '<string>')`

Create a code object from Python source.

The `data` argument can be whatever the `compile()` function supports (i.e. string or bytes). The `path` argument should be the “path” to where the source code originated from, which can be an abstract concept (e.g. location in a zip file).

With the subsequent code object one can execute it in a module by running `exec(code, module.__dict__)`.

*New in version 3.4.*

*Changed in version 3.5:* Made the method static.

`exec_module(module)`

Implementation of `Loader.exec_module()`.

*New in version 3.4.*

`load_module(fullname)`

Implementation of `Loader.load_module()`.

*Deprecated since version 3.4:* use `exec_module()` instead.

*class* `importlib.abc.ExecutionLoader`

An abstract base class which inherits from `InspectLoader` that, when implemented, helps a module to be executed as a script. The ABC represents an optional [PEP 302](https://peps.python.org/pep-0302/) protocol.

*abstractmethod* `get_filename(fullname)`

An abstract method that is to return the value of `__file__` for the specified module. If no path is available, `ImportError` is raised.

If source code is available, then the method should return the path to the source file, regardless of whether a bytecode was used to load the module.

*Changed in version 3.4:* Raises `ImportError` instead of `NotImplementedError`.

*class* `importlib.abc.FileLoader(fullname, path)`

An abstract base class which inherits from `ResourceLoader` and `ExecutionLoader`, providing concrete implementations of `ResourceLoader.get_data()` and `ExecutionLoader.get_filename()`.

The *fullname* argument is a fully resolved name of the module the loader is to handle. The *path* argument is the path to the file for the module.

*New in version 3.3.*

*name*

The name of the module the loader can handle.

*path*

Path to the file of the module.

`load_module(fullname)`

Calls super's `load_module()`.

*Deprecated since version 3.4:* Use `Loader.exec_module()` instead.

*abstractmethod* `get_filename(fullname)`

Returns `path`.

*abstractmethod* `get_data(path)`

Reads `path` as a binary file and returns the bytes from it.

`class importlib.abc.SourceLoader`

An abstract base class for implementing source (and optionally bytecode) file loading. The class inherits from both `ResourceLoader` and `ExecutionLoader`, requiring the implementation of:

- `ResourceLoader.get_data()`
- `ExecutionLoader.get_filename()`  
Should only return the path to the source file; sourceless loading is not supported.

The abstract methods defined by this class are to add optional bytecode file support. Not implementing these optional methods (or causing them to raise `NotImplementedError`) causes the loader to only work with source code.

Implementing the methods allows the loader to work with source *and* bytecode files; it does not allow for *sourceless* loading where only bytecode is provided. Bytecode files are an optimization to speed up loading by removing the parsing step of Python's compiler, and so no bytecode-specific API is exposed.

`path_stats(path)`

Optional abstract method which returns a `dict` containing metadata about the specified path.

Supported dictionary keys are:

- 'mtime' (mandatory): an integer or floating-point number representing the modification time of the source code;
- 'size' (optional): the size in bytes of the source code.

Any other keys in the dictionary are ignored, to allow for future extensions. If the path cannot be handled, **OSError** is raised.

*New in version 3.3.*

*Changed in version 3.4:* Raise **OSError** instead of **NotImplementedError**.

### `path_mtime(path)`

Optional abstract method which returns the modification time for the specified path.

*Deprecated since version 3.3:* This method is deprecated in favour of `path_stats()`. You don't have to implement it, but it is still available for compatibility purposes. Raise **OSError** if the path cannot be handled.

*Changed in version 3.4:* Raise **OSError** instead of **NotImplementedError**.

### `set_data(path, data)`

Optional abstract method which writes the specified bytes to a file path. Any intermediate directories which do not exist are to be created automatically.

When writing to the path fails because the path is read-only (**errno.EACCES/PermissionError**), do not propagate the exception.

*Changed in version 3.4:* No longer raises

`NotImplementedError` when called.

`get_code(fullname)`

Concrete implementation of  
`InspectLoader.get_code()`.

`exec_module(module)`

Concrete implementation of  
`Loader.exec_module()`.

*New in version 3.4.*

`load_module(fullname)`

Concrete implementation of  
`Loader.load_module()`.

*Deprecated since version 3.4:* Use `exec_module()` instead.

`get_source(fullname)`

Concrete implementation of  
`InspectLoader.get_source()`.

`is_package(fullname)`

Concrete implementation of  
`InspectLoader.is_package()`. A module is determined to be a package if its file path (as provided by `ExecutionLoader.get_filename()`) is a file named `__init__` when the file extension is removed and the module name itself does not end in `__init__`.

## **`importlib.machinery` – Importers and path hooks**

Source code: [`Lib/importlib/machinery.py`](https://github.com/python/) [https://github.com/python/

This module contains the various objects that help `import` find and load modules.

`importlib.machinery.SOURCE_SUFFIXES`

A list of strings representing the recognized file suffixes for source modules.

*New in version 3.3.*

`importlib.machinery.DEBUG_BYTECODE_SUFFIXES`

A list of strings representing the file suffixes for non-optimized bytecode modules.

*New in version 3.3.*

*Deprecated since version 3.5:* Use `BYTECODE_SUFFIXES` instead.

`importlib.machinery.OPTIMIZED_BYTECODE_SUFFIXES`

A list of strings representing the file suffixes for optimized bytecode modules.

*New in version 3.3.*

*Deprecated since version 3.5:* Use `BYTECODE_SUFFIXES` instead.

`importlib.machinery.BYTECODE_SUFFIXES`

A list of strings representing the recognized file suffixes for bytecode modules (including the leading dot).

*New in version 3.3.*

*Changed in version 3.5:* The value is no longer dependent on `__debug__`.

`importlib.machinery.EXTENSION_SUFFIXES`

A list of strings representing the recognized file suffixes for extension modules.

*New in version 3.3.*

`importlib.machinery.all_suffixes()`

Returns a combined list of strings representing all file suffixes for modules recognized by the standard import machinery. This is a helper for code which simply needs to know if a filesystem path potentially refers to a module without needing any details on the kind of module (for example, `inspect.getmodule()`).

*New in version 3.3.*

`class importlib.machinery.BuiltinImporter`

An **importer** for built-in modules. All known built-in modules are listed in `sys.builtin_module_names`. This class implements the `importlib.abc.MetaPathFinder` and `importlib.abc.InspectLoader` ABCs.

Only class methods are defined by this class to alleviate the need for instantiation.

*Changed in version 3.5:* As part of **PEP 489** [<https://peps.python.org/pep-0489/>], the builtin importer now implements `Loader.create_module()` and `Loader.exec_module()`

`class importlib.machinery.FrozenImporter`

An **importer** for frozen modules. This class implements the `importlib.abc.MetaPathFinder` and `importlib.abc.InspectLoader` ABCs.

Only class methods are defined by this class to alleviate the need for instantiation.

*Changed in version 3.4:* Gained `create_module()` and `exec_module()` methods.

`class importlib.machinery.WindowsRegistryFinder`

`Finder` for modules declared in the Windows registry. This class implements the `importlib.abc.MetaPathFinder` ABC.

Only class methods are defined by this class to alleviate the need for instantiation.

*New in version 3.3.*

*Deprecated since version 3.6:* Use `site` configuration instead. Future versions of Python may not enable this finder by default.

`class importlib.machinery.PathFinder`

A `Finder` for `sys.path` and package `__path__` attributes. This class implements the `importlib.abc.MetaPathFinder` ABC.

Only class methods are defined by this class to alleviate the need for instantiation.

`classmethod find_spec(fullname, path=None, target=None)`

Class method that attempts to find a `spec` for the module specified by `fullname` on `sys.path` or, if defined, on `path`. For each path entry that is searched, `sys.path_importer_cache` is checked. If a non-false object is found then it is used as the `path entry finder` to look for the module being searched for. If no entry is found in `sys.path_importer_cache`, then `sys.path_hooks` is searched for a finder for the path entry and, if found, is stored in `sys.path_importer_cache` along with being queried about the module. If no finder is ever found then `None` is both stored in the cache and returned.

*New in version 3.4.*

*Changed in version 3.5:* If the current working directory – represented by an empty string – is no longer valid

then `None` is returned but no value is cached in `sys.path_importer_cache`.

*classmethod* `find_module(fullname, path=None)`

A legacy wrapper around `find_spec()`.

*Deprecated since version 3.4:* Use `find_spec()` instead.

*classmethod* `invalidate_caches()`

Calls

`importlib.abc.PathEntryFinder.invalidate_caches` on all finders stored in `sys.path_importer_cache` that define the method. Otherwise entries in `sys.path_importer_cache` set to `None` are deleted.

*Changed in version 3.7:* Entries of `None` in `sys.path_importer_cache` are deleted.

*Changed in version 3.4:* Calls objects in `sys.path_hooks` with the current working directory for `''` (i.e. the empty string).

*class* `importlib.machinery.FileFinder(path, *loader_details)`

A concrete implementation of

`importlib.abc.PathEntryFinder` which caches results from the file system.

The *path* argument is the directory for which the finder is in charge of searching.

The *loader\_details* argument is a variable number of 2-item tuples each containing a loader and a sequence of file suffixes the loader recognizes. The loaders are expected to be callables which accept two arguments of the module's name and the path to the file found.

The finder will cache the directory contents as necessary,

making stat calls for each module search to verify the cache is not outdated. Because cache staleness relies upon the granularity of the operating system's state information of the file system, there is a potential race condition of searching for a module, creating a new file, and then searching for the module the new file represents. If the operations happen fast enough to fit within the granularity of stat calls, then the module search will fail. To prevent this from happening, when you create a module dynamically, make sure to call `importlib.invalidate_caches()`.

*New in version 3.3.*

`path`

The path the finder will search in.

`find_spec(fullname, target=None)`

Attempt to find the spec to handle *fullname* within `path`.

*New in version 3.4.*

`find_loader(fullname)`

Attempt to find the loader to handle *fullname* within `path`.

*Deprecated since version 3.10:* Use `find_spec()` instead.

`invalidate_caches()`

Clear out the internal cache.

*classmethod* `path_hook(*loader_details)`

A class method which returns a closure for use on `sys.path_hooks`. An instance of `FileFinder` is returned by the closure using the path argument given to the closure directly and *loader\_details* indirectly.

If the argument to the closure is not an existing directory, `ImportError` is raised.

`class importlib.machinery.SourceFileLoader(fullname, path)`

A concrete implementation of `importlib.abc.SourceLoader` by subclassing `importlib.abc.FileLoader` and providing some concrete implementations of other methods.

*New in version 3.3.*

`name`

The name of the module that this loader will handle.

`path`

The path to the source file.

`is_package(fullname)`

Return `True` if `path` appears to be for a package.

`path_stats(path)`

Concrete implementation of `importlib.abc.SourceLoader.path_stats()`.

`set_data(path, data)`

Concrete implementation of `importlib.abc.SourceLoader.set_data()`.

`load_module(name=None)`

Concrete implementation of `importlib.abc.Loader.load_module()` where specifying the name of the module to load is optional.

*Deprecated since version 3.6:* Use `importlib.abc.Loader.exec_module()` instead.

`class importlib.machinery.SourcelessFileLoader(fullname, path)`

A concrete implementation of `importlib.abc.FileLoader` which can import bytecode files (i.e. no source code files exist).

Please note that direct use of bytecode files (and thus not source code files) inhibits your modules from being usable by all Python implementations or new versions of Python which change the bytecode format.

*New in version 3.3.*

`name`

The name of the module the loader will handle.

`path`

The path to the bytecode file.

`is_package(fullname)`

Determines if the module is a package based on `path`.

`get_code(fullname)`

Returns the code object for `name` created from `path`.

`get_source(fullname)`

Returns `None` as bytecode files have no source when this loader is used.

`load_module(name=None)`

Concrete implementation of `importlib.abc.Loader.load_module()` where specifying the name of the module to load is optional.

*Deprecated since version 3.6:* Use

`importlib.abc.Loader.exec_module()` instead.

`class importlib.machinery.ExtensionFileLoader(fullname, path)`

A concrete implementation of `importlib.abc.ExecutionLoader` for extension modules.

The *fullname* argument specifies the name of the module the loader is to support. The *path* argument is the path to the extension module's file.

*New in version 3.3.*

*name*

Name of the module the loader supports.

*path*

Path to the extension module.

*create\_module(spec)*

Creates the module object from the given specification in accordance with [PEP 489](https://peps.python.org/pep-0489/) [https://peps.python.org/pep-0489/].

*New in version 3.5.*

*exec\_module(module)*

Initializes the given module object in accordance with [PEP 489](https://peps.python.org/pep-0489/) [https://peps.python.org/pep-0489/].

*New in version 3.5.*

*is\_package(fullname)*

Returns `True` if the file path points to a package's `__init__` module based on [EXTENSION\\_SUFFIXES](#).

*get\_code(fullname)*

Returns `None` as extension modules lack a code object.

*get\_source(fullname)*

Returns `None` as extension modules do not have source code.

`get_filename(fullname)`

Returns `path`.

*New in version 3.4.*

`NamespaceLoader(name, path, path_finder):`

A concrete implementation of `importlib.abc.InspectLoader` for namespace packages. This is an alias for a private class and is only made public for introspecting the `__loader__` attribute on namespace packages:

```
>>> from importlib.machinery import NamespaceLoader
>>> import my_namespace
>>> isinstance(my_namespace.__loader__, NamespaceLoader)
True
>>> import importlib.abc
>>> isinstance(my_namespace.__loader__, importlib.abc.Loader)
True
```

*New in version 3.11.*

`class importlib.machinery.ModuleSpec(name, loader, *,  
origin=None, loader_state=None, is_package=None)`

A specification for a module's import-system-related state. This is typically exposed as the module's `__spec__` attribute. In the descriptions below, the names in parentheses give the corresponding attribute available directly on the module object, e.g. `module.__spec__.origin == module.__file__`. Note, however, that while the *values* are usually equivalent, they can differ since there is no synchronization between the two objects. For example, it is possible to update the module's `__file__` at runtime and this will not be automatically reflected in the module's `__spec__.origin`, and vice versa.

*New in version 3.4.*

name

([\\_\\_name\\_\\_](#))

The module's fully qualified name. The [finder](#) should always set this attribute to a non-empty string.

loader

([\\_\\_loader\\_\\_](#))

The [loader](#) used to load the module. The [finder](#) should always set this attribute.

origin

([\\_\\_file\\_\\_](#))

The location the [loader](#) should use to load the module. For example, for modules loaded from a .py file this is the filename. The [finder](#) should always set this attribute to a meaningful value for the [loader](#) to use. In the uncommon case that there is not one (like for namespace packages), it should be set to `None`.

submodule\_search\_locations

([\\_\\_path\\_\\_](#))

The list of locations where the package's submodules will be found. Most of the time this is a single directory. The [finder](#) should set this attribute to a list, even an empty one, to indicate to the import system that the module is a package. It should be set to `None` for non-package modules. It is set automatically later to a special object for namespace packages.

loader\_state

The `finder` may set this attribute to an object containing additional, module-specific data to use when loading the module. Otherwise it should be set to `None`.

`cached`

(`__cached__`)

The filename of a compiled version of the module's code. The `finder` should always set this attribute but it may be `None` for modules that do not need compiled code stored.

`parent`

(`__package__`)

(Read-only) The fully qualified name of the package the module is in (or the empty string for a top-level module). If the module is a package then this is the same as `name`.

`has_location`

`True` if the spec's `origin` refers to a loadable location, `False` otherwise. This value impacts how `origin` is interpreted and how the module's `__file__` is populated.

## `importlib.util` – Utility code for importers

**Source code:** [Lib/importlib/util.py](https://github.com/python/cpython/tree/3.11/Lib/importlib/util.py) [https://github.com/python/cpython/tree/3.11/Lib/importlib/util.py]

---

This module contains the various objects that help in the construction of an `importer`.

`importlib.util.MAGIC_NUMBER`

The bytes which represent the bytecode version number. If you need help with loading/writing bytecode then consider

`importlib.abc.SourceLoader.`

*New in version 3.4.*

`importlib.util.cache_from_source(path, debug_override=None, *, optimization=None)`

Return the [PEP 3147](https://peps.python.org/pep-3147/) [https://peps.python.org/pep-3147/] / [PEP 488](https://peps.python.org/pep-0488/) [https://peps.python.org/pep-0488/] `path` to the byte-compiled file associated with the source `path`. For example, if `path` is `/foo/bar/baz.py` the return value would be `/foo/bar/__pycache__/baz.cpython-32.pyc` for Python 3.2. The `cpython-32` string comes from the current magic tag (see `get_tag()`; if `sys.implementation.cache_tag` is not defined then `NotImplementedError` will be raised).

The `optimization` parameter is used to specify the optimization level of the bytecode file. An empty string represents no optimization, so `/foo/bar/baz.py` with an `optimization` of `''` will result in a bytecode path of `/foo/bar/__pycache__/baz.cpython-32.pyc`. `None` causes the interpreter's optimization level to be used. Any other value's string representation is used, so `/foo/bar/baz.py` with an `optimization` of `2` will lead to the bytecode path of `/foo/bar/__pycache__/baz.cpython-32.opt-2.pyc`. The string representation of `optimization` can only be alphanumeric, else `ValueError` is raised.

The `debug_override` parameter is deprecated and can be used to override the system's value for `__debug__`. A `True` value is the equivalent of setting `optimization` to the empty string. A `False` value is the same as setting `optimization` to `1`. If both `debug_override` and `optimization` are not `None` then `TypeError` is raised.

*New in version 3.4.*

*Changed in version 3.5:* The `optimization` parameter was added and the `debug_override` parameter was deprecated.

*Changed in version 3.6:* Accepts a [path-like object](#).

`importlib.util.source_from_cache(path)`

Given the *path* to a [PEP 3147](https://peps.python.org/pep-3147/) file name, return the associated source code file path. For example, if *path* is `/foo/bar/__pycache__/baz.cpython-32.pyc` the returned path would be `/foo/bar/baz.py`. *path* need not exist, however if it does not conform to [PEP 3147](https://peps.python.org/pep-3147/) or [PEP 488](https://peps.python.org/pep-0488/) format, a `ValueError` is raised. If `sys.implementation.cache_tag` is not defined, `NotImplementedError` is raised.

*New in version 3.4.*

*Changed in version 3.6:* Accepts a [path-like object](#).

`importlib.util.decode_source(source_bytes)`

Decode the given bytes representing source code and return it as a string with universal newlines (as required by `importlib.abc.InspectLoader.get_source()`).

*New in version 3.4.*

`importlib.util.resolve_name(name, package)`

Resolve a relative module name to an absolute one.

If **name** has no leading dots, then **name** is simply returned. This allows for usage such as

```
importlib.util.resolve_name('sys',
__spec__.parent)
```

 without doing a check to see if the **package** argument is needed.

`ImportError` is raised if **name** is a relative module name but **package** is a false value (e.g. `None` or the empty string). `ImportError` is also raised if a relative name would escape its containing package (e.g. requesting `..bacon` from within the `spam` package).

*New in version 3.3.*

*Changed in version 3.9:* To improve consistency with `import`

statements, raise `ImportError` instead of `ValueError` for invalid relative import attempts.

`importlib.util.find_spec(name, package=None)`

Find the `spec` for a module, optionally relative to the specified `package` name. If the module is in `sys.modules`, then `sys.modules[name].__spec__` is returned (unless the `spec` would be `None` or is not set, in which case `ValueError` is raised). Otherwise a search using `sys.meta_path` is done. `None` is returned if no `spec` is found.

If `name` is for a submodule (contains a dot), the parent module is automatically imported.

`name` and `package` work the same as for `import_module()`.

*New in version 3.4.*

*Changed in version 3.7:* Raises `ModuleNotFoundError` instead of `AttributeError` if `package` is in fact not a package (i.e. lacks a `__path__` attribute).

`importlib.util.module_from_spec(spec)`

Create a new module based on `spec` and `spec.loader.create_module`.

If `spec.loader.create_module` does not return `None`, then any pre-existing attributes will not be reset. Also, no `AttributeError` will be raised if triggered while accessing `spec` or setting an attribute on the module.

This function is preferred over using `types.ModuleType` to create a new module as `spec` is used to set as many import-controlled attributes on the module as possible.

*New in version 3.5.*

`@importlib.util.module_for_loader`

A **decorator** for

`importlib.abc.Loader.load_module()` to handle selecting the proper module object to load with. The decorated method is expected to have a call signature taking two positional arguments (e.g. `load_module(self, module)`) for which the second argument will be the module **object** to be used by the loader. Note that the decorator will not work on static methods because of the assumption of two arguments.

The decorated method will take in the **name** of the module to be loaded as expected for a **loader**. If the module is not found in `sys.modules` then a new one is constructed. Regardless of where the module came from, `__loader__` set to **self** and `__package__` is set based on what `importlib.abc.InspectLoader.is_package()` returns (if available). These attributes are set unconditionally to support reloading.

If an exception is raised by the decorated method and a module was added to `sys.modules`, then the module will be removed to prevent a partially initialized module from being left in `sys.modules`. If the module was already in `sys.modules` then it is left alone.

*Changed in version 3.3:* `__loader__` and `__package__` are automatically set (when possible).

*Changed in version 3.4:* Set `__name__`, `__loader__` `__package__` unconditionally to support reloading.

*Deprecated since version 3.4:* The import machinery now directly performs all the functionality provided by this function.

`@importlib.util.set_loader`

A **decorator** for

`importlib.abc.Loader.load_module()` to set the `__loader__` attribute on the returned module. If the attribute is already set the decorator does nothing. It is

assumed that the first positional argument to the wrapped method (i.e. `self`) is what `__loader__` should be set to.

*Changed in version 3.4:* Set `__loader__` if set to `None`, as if the attribute does not exist.

*Deprecated since version 3.4:* The import machinery takes care of this automatically.

`@importlib.util.set_package`

A [decorator](#) for `importlib.abc.Loader.load_module()` to set the `__package__` attribute on the returned module. If `__package__` is set and has a value other than `None` it will not be changed.

*Deprecated since version 3.4:* The import machinery takes care of this automatically.

`importlib.util.spec_from_loader(name, loader, *, origin=None, is_package=None)`

A factory function for creating a [ModuleSpec](#) instance based on a loader. The parameters have the same meaning as they do for `ModuleSpec`. The function uses available [loader](#) APIs, such as `InspectLoader.is_package()`, to fill in any missing information on the spec.

*New in version 3.4.*

`importlib.util.spec_from_file_location(name, location, *, loader=None, submodule_search_locations=None)`

A factory function for creating a [ModuleSpec](#) instance based on the path to a file. Missing information will be filled in on the spec by making use of loader APIs and by the implication that the module will be file-based.

*New in version 3.4.*

*Changed in version 3.6:* Accepts a [path-like object](#).

`importlib.util.source_hash(source_bytes)`

Return the hash of `source_bytes` as bytes. A hash-based `.pyc` file embeds the `source_hash()` of the corresponding source file's contents in its header.

*New in version 3.7.*

`class importlib.util.LazyLoader(loader)`

A class which postpones the execution of the loader of a module until the module has an attribute accessed.

This class **only** works with loaders that define `exec_module()` as control over what module type is used for the module is required. For those same reasons, the loader's `create_module()` method must return `None` or a type for which its `__class__` attribute can be mutated along with not using `slots`. Finally, modules which substitute the object placed into `sys.modules` will not work as there is no way to properly replace the module references throughout the interpreter safely; `ValueError` is raised if such a substitution is detected.

### Note

For projects where startup time is critical, this class allows for potentially minimizing the cost of loading a module if it is never used. For projects where startup time is not essential then use of this class is **heavily** discouraged due to error messages created during loading being postponed and thus occurring out of context.

*New in version 3.5.*

*Changed in version 3.6:* Began calling `create_module()`, removing the compatibility warning for `importlib.machinery.BuiltinImporter` and `importlib.machinery.ExtensionFileLoader`.

`classmethod factory(loader)`

A class method which returns a callable that creates a lazy loader. This is meant to be used in situations where the loader is passed by class instead of by instance.

```
suffixes = importlib.machinery.SOURCE_SUFFIXES
loader = importlib.machinery.SourceFileLoader
lazy_loader = importlib.util.LazyLoader.factory
finder = importlib.machinery.FileFinder(path, 0)
```

## Examples

### Importing programmatically

To programmatically import a module, use `importlib.import_module()`.

```
import importlib
```

```
itertools = importlib.import_module('itertools')
```

### Checking if a module can be imported

If you need to find out if a module can be imported without actually doing the import, then you should use `importlib.util.find_spec()`.

Note that if `name` is a submodule (contains a dot), `importlib.util.find_spec()` will import the parent module.

```
import importlib.util
import sys
```

```
# For illustrative purposes.
name = 'itertools'
```

```
if name in sys.modules:
    print(f"{name!r} already in sys.modules")
elif (spec := importlib.util.find_spec(name)) is not None:
```

```

    # If you chose to perform the actual import ...
    module = importlib.util.module_from_spec(spec)
    sys.modules[name] = module
    spec.loader.exec_module(module)
    print(f"{name!r} has been imported")
else:
    print(f"can't find the {name!r} module")

```

## Importing a source file directly

To import a Python source file directly, use the following recipe:

```

import importlib.util
import sys

# For illustrative purposes.
import tokenize
file_path = tokenize.__file__
module_name = tokenize.__name__

spec = importlib.util.spec_from_file_location(module_name, file_path)
module = importlib.util.module_from_spec(spec)
sys.modules[module_name] = module
spec.loader.exec_module(module)

```

## Implementing lazy imports

The example below shows how to implement lazy imports:

```

>>> import importlib.util
>>> import sys
>>> def lazy_import(name):
...     spec = importlib.util.find_spec(name)
...     loader = importlib.util.LazyLoader(spec.loader)
...     spec.loader = loader
...     module = importlib.util.module_from_spec(spec)
...     sys.modules[name] = module
...     loader.exec_module(module)
...     return module

```

```
...
>>> lazy_typing = lazy_import("typing")
>>> #lazy_typing is a real module object,
>>> #but it is not loaded in memory yet.
>>> lazy_typing.TYPE_CHECKING
False
```

## Setting up an importer

For deep customizations of import, you typically want to implement an [importer](#). This means managing both the [finder](#) and [loader](#) side of things. For finders there are two flavours to choose from depending on your needs: a [meta path finder](#) or a [path entry finder](#). The former is what you would put on [sys.meta\\_path](#) while the latter is what you create using a [path entry hook](#) on [sys.path\\_hooks](#) which works with [sys.path](#) entries to potentially create a finder. This example will show you how to register your own importers so that import will use them (for creating an importer for yourself, read the documentation for the appropriate classes defined within this package):

```
import importlib.machinery
import sys

# For illustrative purposes only.
SpamMetaPathFinder = importlib.machinery.PathFinder
SpamPathEntryFinder = importlib.machinery.FileFinder
loader_details = (importlib.machinery.SourceFileLoader,
                  importlib.machinery.SOURCE_SUFFIXES)

# Setting up a meta path finder.
# Make sure to put the finder in the proper location in
# priority.
sys.meta_path.append(SpamMetaPathFinder)

# Setting up a path entry finder.
# Make sure to put the path hook in the proper location
# of priority.
sys.path_hooks.append(SpamPathEntryFinder.path_hook(loader_details))
```

## Approximating `importlib.import_module()`

Import itself is implemented in Python code, making it possible to expose most of the import machinery through `importlib`. The following helps illustrate the various APIs that `importlib` exposes by providing an approximate implementation of

`importlib.import_module()`:

```
import importlib.util
import sys

def import_module(name, package=None):
    """An approximate implementation of import."""
    absolute_name = importlib.util.resolve_name(name, package)
    try:
        return sys.modules[absolute_name]
    except KeyError:
        pass

    path = None
    if '.' in absolute_name:
        parent_name, _, child_name = absolute_name.rpartition('.')
        parent_module = import_module(parent_name)
        path = parent_module.__spec__.submodule_search_locations
    for finder in sys.meta_path:
        spec = finder.find_spec(absolute_name, path)
        if spec is not None:
            break
    else:
        msg = f'No module named {absolute_name!r}'
        raise ModuleNotFoundError(msg, name=absolute_name)
    module = importlib.util.module_from_spec(spec)
    sys.modules[absolute_name] = module
    spec.loader.exec_module(module)
    if path is not None:
        setattr(parent_module, child_name, module)
    return module
```

# importlib.resources – Resources

**Source code:** [Lib/importlib/resources/\\_init\\_.py](https://github.com/python/cpython/tree/3.11/Lib/importlib/resources/_init_.py) [https://github.com/python/cpython/tree/3.11/Lib/importlib/resources/\_init\_.py]

---

*New in version 3.7.*

This module leverages Python’s import system to provide access to *resources* within *packages*. If you can import a package, you can access resources within that package. Resources can be opened or read, in either binary or text mode.

Resources are roughly akin to files inside directories, though it’s important to keep in mind that this is just a metaphor. Resources and packages **do not** have to exist as physical files and directories on the file system: for example, a package and its resources can be imported from a zip file using [zipimport](#).

## Note

This module provides functionality similar to [pkg\\_resources](https://setuptools.readthedocs.io/en/latest/pkg_resources.html) [https://setuptools.readthedocs.io/en/latest/pkg\_resources.html] [Basic Resource Access](https://setuptools.readthedocs.io/en/latest/pkg_resources.html#basic-resource-access) [https://setuptools.readthedocs.io/en/latest/pkg\_resources.html#basic-resource-access] without the performance overhead of that package. This makes reading resources included in packages easier, with more stable and consistent semantics.

The standalone backport of this module provides more information on [using importlib.resources](https://importlib-resources.readthedocs.io/en/latest/using.html) [https://importlib-resources.readthedocs.io/en/latest/using.html] and [migrating from pkg\\_resources to importlib.resources](https://importlib-resources.readthedocs.io/en/latest/migration.html) [https://importlib-resources.readthedocs.io/en/latest/migration.html].

**Loaders** that wish to support resource reading should implement a `get_resource_reader(fullname)` method as specified by `importlib.resources.abc.ResourceReader`.

`importlib.resources.Package`

Whenever a function accepts a `Package` argument, you can pass in either a **module object** or a module name as a string. You can only pass module objects whose `__spec__.submodule_search_locations` is not `None`.

The `Package` type is defined as `Union[str, ModuleType]`.

`importlib.resources.files(package)`

Returns a **Traversable** object representing the resource container for the package (think directory) and its resources (think files). A `Traversable` may contain other containers (think subdirectories).

*package* is either a name or a module object which conforms to the **Package** requirements.

*New in version 3.9.*

`importlib.resources.as_file(traversable)`

Given a **Traversable** object representing a file, typically from `importlib.resources.files()`, return a context manager for use in a **with** statement. The context manager provides a `pathlib.Path` object.

Exiting the context manager cleans up any temporary file created when the resource was extracted from e.g. a zip file.

Use `as_file` when the `Traversable` methods (`read_text`, etc) are insufficient and an actual file on the file system is required.

*New in version 3.9.*

# Deprecated functions

An older, deprecated set of functions is still available, but is scheduled for removal in a future version of Python. The main drawback of these functions is that they do not support directories: they assume all resources are located directly within a *package*.

`importlib.resources.Resource`

For *resource* arguments of the functions below, you can pass in the name of a resource as a string or a **path-like object**.

The `Resource` type is defined as `Union[str, os.PathLike]`.

`importlib.resources.open_binary(package, resource)`

Open for binary reading the *resource* within *package*.

*package* is either a name or a module object which conforms to the `Package` requirements. *resource* is the name of the resource to open within *package*; it may not contain path separators and it may not have sub-resources (i.e. it cannot be a directory). This function returns a `typing.BinaryIO` instance, a binary I/O stream open for reading.

*Deprecated since version 3.11:* Calls to this function can be replaced by:

```
files(package).joinpath(resource).open('rb')
```

`importlib.resources.open_text(package, resource, encoding='utf-8', errors='strict')`

Open for text reading the *resource* within *package*. By default, the resource is opened for reading as UTF-8.

*package* is either a name or a module object which conforms to the `Package` requirements. *resource* is the name of the resource to open within *package*; it may not contain path

separators and it may not have sub-resources (i.e. it cannot be a directory). *encoding* and *errors* have the same meaning as with built-in `open()`.

This function returns a `typing.TextIO` instance, a text I/O stream open for reading.

*Deprecated since version 3.11:* Calls to this function can be replaced by:

```
files(package).joinpath(resource).open('r', encoding=encoding)
```

`importlib.resources.read_binary(package, resource)`

Read and return the contents of the *resource* within *package* as bytes.

*package* is either a name or a module object which conforms to the `Package` requirements. *resource* is the name of the resource to open within *package*; it may not contain path separators and it may not have sub-resources (i.e. it cannot be a directory). This function returns the contents of the resource as `bytes`.

*Deprecated since version 3.11:* Calls to this function can be replaced by:

```
files(package).joinpath(resource).read_bytes()
```

`importlib.resources.read_text(package, resource, encoding='utf-8', errors='strict')`

Read and return the contents of *resource* within *package* as a `str`. By default, the contents are read as strict UTF-8.

*package* is either a name or a module object which conforms to the `Package` requirements. *resource* is the name of the resource to open within *package*; it may not contain path separators and it may not have sub-resources (i.e. it cannot be a directory). *encoding* and *errors* have the same meaning as with built-in `open()`. This function returns the contents of the resource as `str`.

*Deprecated since version 3.11:* Calls to this function can be replaced by:

```
files(package).joinpath(resource).read_text(encoding=encoding)
```

`importlib.resources.path(package, resource)`

Return the path to the *resource* as an actual file system path. This function returns a context manager for use in a `with` statement. The context manager provides a `pathlib.Path` object.

Exiting the context manager cleans up any temporary file created when the resource needs to be extracted from e.g. a zip file.

*package* is either a name or a module object which conforms to the `Package` requirements. *resource* is the name of the resource to open within *package*; it may not contain path separators and it may not have sub-resources (i.e. it cannot be a directory).

*Deprecated since version 3.11:* Calls to this function can be replaced using `as_file()`:

```
as_file(files(package).joinpath(resource))
```

`importlib.resources.is_resource(package, name)`

Return `True` if there is a resource named *name* in the package, otherwise `False`. This function does not consider directories to be resources. *package* is either a name or a module object which conforms to the `Package` requirements.

*Deprecated since version 3.11:* Calls to this function can be replaced by:

```
files(package).joinpath(resource).is_file()
```

`importlib.resources.contents(package)`

Return an iterable over the named items within the package. The iterable returns `str` resources (e.g. files) and non-resources (e.g. directories). The iterable does not recurse into subdirectories.

*package* is either a name or a module object which conforms to the `Package` requirements.

*Deprecated since version 3.11:* Calls to this function can be replaced by:

```
(resource.name for resource in files(package).iterd
```

# `importlib.resources.abc` – Abstract base classes for resources

**Source code:** [Lib/importlib/resources/abc.py](https://github.com/python/cpython/tree/3.11/Lib/importlib/resources/abc.py) [https://github.com/python/cpython/tree/3.11/Lib/importlib/resources/abc.py]

---

*New in version 3.11.*

`class importlib.resources.abc.ResourceReader`

*Superseded by `TraversableResources`*

An [abstract base class](#) to provide the ability to read *resources*.

From the perspective of this ABC, a *resource* is a binary artifact that is shipped within a package. Typically this is something like a data file that lives next to the `__init__.py` file of the package. The purpose of this class is to help abstract out the accessing of such data files so that it does not matter if the package and its data file(s) are stored in a e.g. zip file versus on the file system.

For any of methods of this class, a *resource* argument is expected to be a [path-like object](#) which represents conceptually just a file name. This means that no subdirectory paths should be included in the *resource* argument. This is because the location of the package the reader is for, acts as the “directory”. Hence the metaphor for directories and file names is packages and resources, respectively. This is also why instances of this class are expected to directly correlate to a specific package (instead of potentially representing multiple packages or a module).

Loaders that wish to support resource reading are expected to

provide a method called `get_resource_reader(fullname)` which returns an object implementing this ABC's interface. If the module specified by `fullname` is not a package, this method should return **None**. An object compatible with this ABC should only be returned when the specified module is a package.

*New in version 3.7.*

*abstractmethod* `open_resource(resource)`

Returns an opened, **file-like object** for binary reading of the *resource*.

If the resource cannot be found, **FileNotFoundError** is raised.

*abstractmethod* `resource_path(resource)`

Returns the file system path to the *resource*.

If the resource does not concretely exist on the file system, raise **FileNotFoundError**.

*abstractmethod* `is_resource(name)`

Returns **True** if the named *name* is considered a resource. **FileNotFoundError** is raised if *name* does not exist.

*abstractmethod* `contents()`

Returns an **iterable** of strings over the contents of the package. Do note that it is not required that all names returned by the iterator be actual resources, e.g. it is acceptable to return names for which **is\_resource()** would be false.

Allowing non-resource names to be returned is to allow for situations where how a package and its resources are stored are known a priori and the non-resource names would be useful. For instance, returning subdirectory names is allowed so that when it is known

that the package and resources are stored on the file system then those subdirectory names can be used directly.

The abstract method returns an iterable of no items.

*class* `importlib.resources.abc.Traversable`

An object with a subset of `pathlib.Path` methods suitable for traversing directories and opening files.

For a representation of the object on the file-system, use `importlib.resources.as_file()`.

*New in version 3.9.*

*name*

Abstract. The base name of this object without any parent references.

*abstractmethod* `iterdir()`

Yield Traversable objects in self.

*abstractmethod* `is_dir()`

Return True if self is a directory.

*abstractmethod* `is_file()`

Return True if self is a file.

*abstractmethod* `joinpath(child)`

Return Traversable child in self.

*abstractmethod* `_truediv_(child)`

Return Traversable child in self.

*abstractmethod* `open(mode='r', *args, **kwargs)`

`mode` may be 'r' or 'rb' to open as text or binary. Return a handle suitable for reading (same as

`pathlib.Path.open()`.

When opening as text, accepts encoding parameters such as those accepted by `io.TextIOWrapper`.

`read_bytes()`

Read contents of self as bytes.

`read_text(encoding=None)`

Read contents of self as text.

*class* `importlib.resources.abc.TraversableResources`

An abstract base class for resource readers capable of serving the `importlib.resources.files()` interface. Subclasses `importlib.resources.abc.ResourceReader` and provides concrete implementations of the `importlib.resources.abc.ResourceReader`'s abstract methods. Therefore, any loader supplying `importlib.abc.TraversableResources` also supplies `ResourceReader`.

Loaders that wish to support resource reading are expected to implement this interface.

*New in version 3.9.*

*abstractmethod* `files()`

Returns a

`importlib.resources.abc.Traversable` object for the loaded package.

# Using `importlib.metadata`

*New in version 3.8.*

*Changed in version 3.10:* `importlib.metadata` is no longer provisional.

**Source code:** [Lib/importlib/metadata/\\_init\\_.py](https://github.com/python/cpython/tree/3.11/Lib/importlib/metadata/_init_.py) [https://github.com/python/cpython/tree/3.11/Lib/importlib/metadata/\_init\_.py]

`importlib.metadata` is a library that provides access to the metadata of an installed [Distribution Package](https://packaging.python.org/en/latest/glossary/#term-Distribution-Package) [https://packaging.python.org/en/latest/glossary/#term-Distribution-Package], such as its entry points or its top-level names ([Import Package](https://packaging.python.org/en/latest/glossary/#term-Import-Package) [https://packaging.python.org/en/latest/glossary/#term-Import-Package]s, modules, if any). Built in part on Python's import system, this library intends to replace similar functionality in the [entry point API](https://setuptools.readthedocs.io/en/latest/pkg_resources.html#entry-points) [https://setuptools.readthedocs.io/en/latest/pkg\_resources.html#entry-points] and [metadata API](https://setuptools.readthedocs.io/en/latest/pkg_resources.html#metadata-api) [https://setuptools.readthedocs.io/en/latest/pkg\_resources.html#metadata-api] of `pkg_resources`. Along with [importlib.resources](#), this package can eliminate the need to use the older and less efficient `pkg_resources` package.

`importlib.metadata` operates on third-party *distribution packages* installed into Python's `site-packages` directory via tools such as [pip](https://pypi.org/project/pip/) [https://pypi.org/project/pip/]. Specifically, it works with distributions with discoverable `dist-info` or `egg-info` directories, and metadata defined by the [Core metadata specifications](https://packaging.python.org/en/latest/specifications/core-metadata/#core-metadata) [https://packaging.python.org/en/latest/specifications/core-metadata/#core-metadata].

## Important

These are *not* necessarily equivalent to or correspond 1:1 with the top-level *import package* names that can be imported inside Python code. One *distribution package* can contain multiple *import packages* (and single modules), and one top-level *import package*

may map to multiple *distribution packages* if it is a namespace package. You can use `package_distributions()` to get a mapping between them.

By default, distribution metadata can live on the file system or in zip archives on `sys.path`. Through an extension mechanism, the metadata can live almost anywhere.

## See also

<https://importlib-metadata.readthedocs.io/>

The documentation for `importlib_metadata`, which supplies a backport of `importlib.metadata`. This includes an [API reference](https://importlib-metadata.readthedocs.io/en/latest/api.html) [https://importlib-metadata.readthedocs.io/en/latest/api.html] for this module's classes and functions, as well as a [migration guide](https://importlib-metadata.readthedocs.io/en/latest/migration.html) [https://importlib-metadata.readthedocs.io/en/latest/migration.html] for existing users of `pkg_resources`.

## Overview

Let's say you wanted to get the version string for a [Distribution Package](https://packaging.python.org/en/latest/glossary/#term-Distribution-Package) [https://packaging.python.org/en/latest/glossary/#term-Distribution-Package] you've installed using `pip`. We start by creating a virtual environment and installing something into it:

```
$ python -m venv example
$ source example/bin/activate
(example) $ python -m pip install wheel
```

You can get the version string for `wheel` by running the following:

```
(example) $ python
>>> from importlib.metadata import version
>>> version('wheel')
'0.32.3'
```

You can also get a collection of entry points selectable by properties of the `EntryPoint` (typically 'group' or 'name'), such as

`console_scripts`, `distutils.commands` and others. Each group contains a collection of [EntryPoint](#) objects.

You can get the [metadata for a distribution](#):

```
>>> list(metadata('wheel'))  
['Metadata-Version', 'Name', 'Version', 'Summary', 'Home
```

You can also get a [distribution's version number](#), list its [constituent files](#), and get a list of the distribution's [Distribution requirements](#).

## Functional API

This package provides the following functionality via its public API.

### Entry points

The `entry_points()` function returns a collection of entry points. Entry points are represented by `EntryPoint` instances; each `EntryPoint` has a `.name`, `.group`, and `.value` attributes and a `.load()` method to resolve the value. There are also `.module`, `.attr`, and `.extras` attributes for getting the components of the `.value` attribute.

Query all entry points:

```
>>> eps = entry_points()
```

The `entry_points()` function returns an `EntryPoints` object, a collection of all `EntryPoint` objects with names and groups attributes for convenience:

```
>>> sorted(eps.groups)  
['console_scripts', 'distutils.commands', 'distutils.set
```

`EntryPoints` has a `select` method to select entry points matching specific properties. Select entry points in the `console_scripts` group:

```
>>> scripts = eps.select(group='console_scripts')
```

Equivalently, since `entry_points` passes keyword arguments through to select:

```
>>> scripts = entry_points(group='console_scripts')
```

Pick out a specific script named “wheel” (found in the wheel project):

```
>>> 'wheel' in scripts.names
True
>>> wheel = scripts['wheel']
```

Equivalently, query for that entry point during selection:

```
>>> (wheel,) = entry_points(group='console_scripts', name='wheel')
>>> (wheel,) = entry_points().select(group='console_scripts', name='wheel')
```

Inspect the resolved entry point:

```
>>> wheel
EntryPoint(name='wheel', value='wheel.cli:main', group='console_scripts')
>>> wheel.module
'wheel.cli'
>>> wheel.attr
'main'
>>> wheel.extras
[]
>>> main = wheel.load()
>>> main
<function main at 0x103528488>
```

The `group` and `name` are arbitrary values defined by the package author and usually a client will wish to resolve all entry points for a particular group. Read [the `setuptools` docs](https://setuptools.pypa.io/en/latest/userguide/entry_point.html) [https://setuptools.pypa.io/en/latest/userguide/entry\_point.html] for more information on entry points, their definition, and usage.

### *Compatibility Note*

The “selectable” entry points were introduced in `importlib_metadata` 3.6 and Python 3.10. Prior to those

changes, `entry_points` accepted no parameters and always returned a dictionary of entry points, keyed by group. For compatibility, if no parameters are passed to `entry_points`, a `SelectableGroups` object is returned, implementing that dict interface. In the future, calling `entry_points` with no parameters will return an `EntryPoint` object. Users should rely on the selection interface to retrieve entry points by group.

## Distribution metadata

Every [Distribution Package](https://packaging.python.org/en/latest/glossary/#term-Distribution-Package) [https://packaging.python.org/en/latest/glossary/#term-Distribution-Package] includes some metadata, which you can extract using the `metadata()` function:

```
>>> wheel_metadata = metadata('wheel')
```

The keys of the returned data structure, a `PackageMetadata`, name the metadata keywords, and the values are returned unparsed from the distribution metadata:

```
>>> wheel_metadata['Requires-Python']
'>=2.7, !=3.0.*, !=3.1.*, !=3.2.*, !=3.3.*'
```

`PackageMetadata` also presents a `json` attribute that returns all the metadata in a JSON-compatible form per [PEP 566](https://peps.python.org/pep-0566/) [https://peps.python.org/pep-0566/]:

```
>>> wheel_metadata.json['requires_python']
'>=2.7, !=3.0.*, !=3.1.*, !=3.2.*, !=3.3.*'
```

### Note

The actual type of the object returned by `metadata()` is an implementation detail and should be accessed only through the interface described by the [PackageMetadata protocol](https://importlib-metadata.readthedocs.io/en/latest/api.html#importlib_metadata.PackageMetadata) [https://importlib-metadata.readthedocs.io/en/latest/api.html#importlib\_metadata.PackageMetadata].

*Changed in version 3.10:* The `Description` is now included in the metadata when presented through the payload. Line continuation

characters have been removed.

*New in version 3.10:* The `json` attribute was added.

## Distribution versions

The `version()` function is the quickest way to get a [Distribution Package](https://packaging.python.org/en/latest/glossary/#term-Distribution-Package) [https://packaging.python.org/en/latest/glossary/#term-Distribution-Package]’s version number, as a string:

```
>>> version('wheel')
'0.32.3'
```

## Distribution files

You can also get the full set of files contained within a distribution. The `files()` function takes a [Distribution Package](https://packaging.python.org/en/latest/glossary/#term-Distribution-Package) [https://packaging.python.org/en/latest/glossary/#term-Distribution-Package] name and returns all of the files installed by this distribution. Each file object returned is a `PackagePath`, a [pathlib.PurePath](#) derived object with additional `dist`, `size`, and `hash` properties as indicated by the metadata. For example:

```
>>> util = [p for p in files('wheel') if 'util.py' in str(p)]
>>> util
PackagePath('wheel/util.py')
>>> util.size
859
>>> util.dist
<importlib.metadata._hooks.PathDistribution object at 0x...>
>>> util.hash
<FileHash mode: sha256 value: bYkw5oMccfazVCoYQwKkkemoVy...
```

Once you have the file, you can also read its contents:

```
>>> print(util.read_text())
import base64
import sys
...
def as_bytes(s):
```

```

if isinstance(s, text_type):
    return s.encode('utf-8')
return s

```

You can also use the `locate` method to get a the absolute path to the file:

```

>>> util.locate()
PosixPath('/home/gustav/example/lib/site-packages/wheel/

```

In the case where the metadata file listing files (RECORD or SOURCES.txt) is missing, `files()` will return `None`. The caller may wish to wrap calls to `files()` in [always\\_iterable](https://more-itertools.readthedocs.io/en/stable/api.html#more_itertools.always_iterable) [https://more-itertools.readthedocs.io/en/stable/api.html#more\_itertools.always\_iterable] or otherwise guard against this condition if the target distribution is not known to have the metadata present.

## Distribution requirements

To get the full set of requirements for a [Distribution Package](https://packaging.python.org/en/latest/glossary/#term-Distribution-Package) [https://packaging.python.org/en/latest/glossary/#term-Distribution-Package], use the `requires()` function:

```

>>> requires('wheel')
["pytest (>=3.0.0) ; extra == 'test'", "pytest-cov ; ext

```

## Mapping import to distribution packages

A convenience method to resolve the [Distribution Package](https://packaging.python.org/en/latest/glossary/#term-Distribution-Package) [https://packaging.python.org/en/latest/glossary/#term-Distribution-Package] `name` (or names, in the case of a namespace package) that provide each importable top-level Python module or [Import Package](https://packaging.python.org/en/latest/glossary/#term-Import-Package) [https://packaging.python.org/en/latest/glossary/#term-Import-Package]:

```

>>> packages_distributions()
{'importlib_metadata': ['importlib-metadata'], 'yaml': [

```

*New in version 3.10.*

## Distributions

While the above API is the most common and convenient usage, you can get all of that information from the `Distribution` class. A `Distribution` is an abstract object that represents the metadata for a Python [Distribution Package](https://packaging.python.org/en/latest/glossary/#term-Distribution-Package) [https://packaging.python.org/en/latest/glossary/#term-Distribution-Package]. You can get the `Distribution` instance:

```
>>> from importlib.metadata import distribution
>>> dist = distribution('wheel')
```

Thus, an alternative way to get the version number is through the `Distribution` instance:

```
>>> dist.version
'0.32.3'
```

There are all kinds of additional metadata available on the `Distribution` instance:

```
>>> dist.metadata['Requires-Python']
'>=2.7, !=3.0.*, !=3.1.*, !=3.2.*, !=3.3.*'
>>> dist.metadata['License']
'MIT'
```

The full set of available metadata is not described here. See the [Core metadata specifications](https://packaging.python.org/en/latest/specifications/core-metadata/#core-metadata) [https://packaging.python.org/en/latest/specifications/core-metadata/#core-metadata] for additional details.

## Distribution Discovery

By default, this package provides built-in support for discovery of metadata for file system and zip file [Distribution Package](https://packaging.python.org/en/latest/glossary/#term-Distribution-Package) [https://packaging.python.org/en/latest/glossary/#term-Distribution-Package]s. This metadata finder search defaults to `sys.path`, but varies slightly in how it interprets those values from how other import machinery does. In particular:

- `importlib.metadata` does not honor [bytes](#) objects on `sys.path`.
- `importlib.metadata` will incidentally honor

`pathlib.Path` objects on `sys.path` even though such values will be ignored for imports.

## Extending the search algorithm

Because [Distribution Package](https://packaging.python.org/en/latest/glossary/#term-Distribution-Package) [https://packaging.python.org/en/latest/glossary/#term-Distribution-Package] metadata is not available through `sys.path` searches, or package loaders directly, the metadata for a distribution is found through import system [finders](https://docs.python.org/3/reference/import.html#finders-and-loaders) [https://docs.python.org/3/reference/import.html#finders-and-loaders]. To find a distribution package's metadata, `importlib.metadata` queries the list of [meta path finders](#) on `sys.meta_path`.

By default `importlib_metadata` installs a finder for distribution packages found on the file system. This finder doesn't actually find any *distributions*, but it can find their metadata.

The abstract class `importlib.abc.MetaPathFinder` defines the interface expected of finders by Python's import system. `importlib.metadata` extends this protocol by looking for an optional `find_distributions` callable on the finders from `sys.meta_path` and presents this extended interface as the `DistributionFinder` abstract base class, which defines this abstract method:

```
@abc.abstractmethod
def find_distributions(context=DistributionFinder.Context):
    """Return an iterable of all Distribution instances
    loading the metadata for packages for the indicated
    """
```

The `DistributionFinder.Context` object provides `.path` and `.name` properties indicating the path to search and name to match and may supply other relevant context.

What this means in practice is that to support finding distribution package metadata in locations other than the file system, subclass `DistributionFinder` and implement the abstract methods. Then from a custom finder, return instances of this derived `Distribution` in the `find_distributions()` method.

# The initialization of the `sys.path` module search path

A module search path is initialized when Python starts. This module search path may be accessed at `sys.path`.

The first entry in the module search path is the directory that contains the input script, if there is one. Otherwise, the first entry is the current directory, which is the case when executing the interactive shell, a `-c` command, or `-m` module.

The `PYTHONPATH` environment variable is often used to add directories to the search path. If this environment variable is found then the contents are added to the module search path.

## Note

`PYTHONPATH` will affect all installed Python versions/environments. Be wary of setting this in your shell profile or global environment variables. The `site` module offers more nuanced techniques as mentioned below.

The next items added are the directories containing standard Python modules as well as any `extension modules` that these modules depend on. Extension modules are `.pyd` files on Windows and `.so` files on other platforms. The directory with the platform-independent Python modules is called `prefix`. The directory with the extension modules is called `exec_prefix`.

The `PYTHONHOME` environment variable may be used to set the `prefix` and `exec_prefix` locations. Otherwise these directories are found by using the Python executable as a starting point and then looking for various ‘landmark’ files and directories. Note that any symbolic links are followed so the real Python executable location is used as the search starting point. The Python executable

location is called `home`.

Once `home` is determined, the `prefix` directory is found by first looking for `pythonmajorversionminorversion.zip` (`python311.zip`). On Windows the zip archive is searched for in `home` and on Unix the archive is expected to be in `lib`. Note that the expected zip archive location is added to the module search path even if the archive does not exist. If no archive was found, Python on Windows will continue the search for `prefix` by looking for `Lib\os.py`. Python on Unix will look for `lib/pythonmajorversion.minorversion/os.py` (`lib/python3.11/os.py`). On Windows `prefix` and `exec_prefix` are the same, however on other platforms `lib/pythonmajorversion.minorversion/lib-dynload` (`lib/python3.11/lib-dynload`) is searched for and used as an anchor for `exec_prefix`. On some platforms `lib` may be `lib64` or another value, see [sys.platlibdir](#) and [PYTHONPLATLIBDIR](#).

Once found, `prefix` and `exec_prefix` are available at [sys.prefix](#) and [sys.exec\\_prefix](#) respectively.

Finally, the [site](#) module is processed and `site-packages` directories are added to the module search path. A common way to customize the search path is to create `sitecustomize` or `usercustomize` modules as described in the [site](#) module documentation.

### Note

Certain command line options may further affect path calculations. See [-E](#), [-I](#), [-s](#) and [-S](#) for further details.

## Virtual environments

If Python is run in a virtual environment (as described at [Virtual Environments and Packages](#)) then `prefix` and `exec_prefix` are specific to the virtual environment.

If a `pyvenv.cfg` file is found alongside the main executable, or in the directory one level above the executable, the following variations apply:

- If `home` is an absolute path and `PYTHONHOME` is not set, this path is used instead of the path to the main executable when deducing `prefix` and `exec_prefix`.

## `_pth` files

To completely override `sys.path` create a `._pth` file with the same name as the shared library or executable (`python._pth` or `python311._pth`). The shared library path is always known on Windows, however it may not be available on other platforms. In the `._pth` file specify one line for each path to add to `sys.path`. The file based on the shared library name overrides the one based on the executable, which allows paths to be restricted for any program loading the runtime if desired.

When the file exists, all registry and environment variables are ignored, isolated mode is enabled, and `site` is not imported unless one line in the file specifies `import site`. Blank paths and lines starting with `#` are ignored. Each path may be absolute or relative to the location of the file. Import statements other than to `site` are not permitted, and arbitrary code cannot be specified.

Note that `.pth` files (without leading underscore) will be processed normally by the `site` module when `import site` has been specified.

## Embedded Python

If Python is embedded within another application `Py_InitializeFromConfig()` and the `PyConfig` structure can be used to initialize Python. The path specific details are described at [Python Path Configuration](#). Alternatively the older `Py_SetPath()` can be used to bypass the initialization of the module search path.

# Python Language Services

Python provides a number of modules to assist in working with the Python language. These modules support tokenizing, parsing, syntax analysis, bytecode disassembly, and various other facilities.

These modules include:

- **ast** — Abstract Syntax Trees
  - Abstract Grammar
  - Node classes
    - Root nodes
    - Literals
    - Variables
    - Expressions
      - Subscripting
      - Comprehensions
    - Statements
      - Imports
    - Control flow
    - Pattern matching
    - Function and class definitions
    - Async and await
  - **ast** Helpers
  - Compiler Flags
  - Command-Line Usage
- **symtable** — Access to the compiler's symbol tables
  - Generating Symbol Tables
  - Examining Symbol Tables

- **token** — Constants used with Python parse trees
- **keyword** — Testing for Python keywords
- **tokenize** — Tokenizer for Python source
  - Tokenizing Input
  - Command-Line Usage
  - Examples
- **tabnanny** — Detection of ambiguous indentation
- **pyclbr** — Python module browser support
  - Function Objects
  - Class Objects
- **py\_compile** — Compile Python source files
  - Command-Line Interface
- **compileall** — Byte-compile Python libraries
  - Command-line use
  - Public functions
- **dis** — Disassembler for Python bytecode
  - Bytecode analysis
  - Analysis functions
  - Python Bytecode Instructions
  - Opcode collections
- **pickletools** — Tools for pickle developers
  - Command line usage
    - Command line options
  - Programmatic Interface

# ast — Abstract Syntax Trees

**Source code:** [Lib/ast.py](https://github.com/python/cpython/tree/3.11/Lib/ast.py) [https://github.com/python/cpython/tree/3.11/Lib/ast.py]

---

The `ast` module helps Python applications to process trees of the Python abstract syntax grammar. The abstract syntax itself might change with each Python release; this module helps to find out programmatically what the current grammar looks like.

An abstract syntax tree can be generated by passing `ast.PyCF_ONLY_AST` as a flag to the `compile()` built-in function, or using the `parse()` helper provided in this module. The result will be a tree of objects whose classes all inherit from `ast.AST`. An abstract syntax tree can be compiled into a Python code object using the built-in `compile()` function.

## Abstract Grammar

The abstract grammar is currently defined as follows:

```
-- ASDL's 4 builtin types are:  
-- identifier, int, string, constant
```

```
module Python
```

```
{  
    mod = Module(stmt* body, type_ignore* type_ignores)  
        | Interactive(stmt* body)  
        | Expression(expr body)  
        | FunctionType(expr* argtypes, expr returns)  
  
    stmt = FunctionDef(identifier name, arguments args,  
                        stmt* body, expr* decorator_list,  
                        string? type_comment)
```

```

| AsyncFunctionDef(identifier name, arguments
                    stmt* body, expr* decorator
                    string? type_comment)

| ClassDef(identifier name,
            expr* bases,
            keyword* keywords,
            stmt* body,
            expr* decorator_list)
| Return(expr? value)

| Delete(expr* targets)
| Assign(expr* targets, expr value, string? ty
| AugAssign(expr target, operator op, expr val
-- 'simple' indicates that we annotate simple
| AnnAssign(expr target, expr annotation, expr

-- use 'orelse' because else is a keyword in t
| For(expr target, expr iter, stmt* body, stmt
| AsyncFor(expr target, expr iter, stmt* body,
| While(expr test, stmt* body, stmt* orelse)
| If(expr test, stmt* body, stmt* orelse)
| With(withitem* items, stmt* body, string? ty
| AsyncWith(withitem* items, stmt* body, strin

| Match(expr subject, match_case* cases)

| Raise(expr? exc, expr? cause)
| Try(stmt* body, excepthandler* handlers, stm
| TryStar(stmt* body, excepthandler* handlers,
| Assert(expr test, expr? msg)

| Import(alias* names)
| ImportFrom(identifier? module, alias* names,

| Global(identifier* names)
| Nonlocal(identifier* names)
| Expr(expr value)

```

| Pass | Break | Continue

-- col\_offset is the byte offset in the utf8 s  
attributes (int lineno, int col\_offset, int? e

```
-- BoolOp() can use left & right?
expr = BoolOp(boolop op, expr* values)
| NamedExpr(expr target, expr value)
| BinOp(expr left, operator op, expr right)
| UnaryOp(unaryop op, expr operand)
| Lambda(arguments args, expr body)
| IfExp(expr test, expr body, expr orelse)
| Dict(expr* keys, expr* values)
| Set(expr* elts)
| ListComp(expr elt, comprehension* generators)
| SetComp(expr elt, comprehension* generators)
| DictComp(expr key, expr value, comprehension* generators)
| GeneratorExp(expr elt, comprehension* generators)
-- the grammar constrains where yield expressions can appear
| Await(expr value)
| Yield(expr? value)
| YieldFrom(expr value)
-- need sequences for compare to distinguish between < and <=
-- x < 4 < 3 and (x < 4) < 3
| Compare(expr left, cmpop* ops, expr* comparators)
| Call(expr func, expr* args, keyword* keywords)
| FormattedValue(expr value, int conversion, expr* format_spec)
| JoinedStr(expr* values)
| Constant(constant value, string? kind)

-- the following expression can appear in assignment
| Attribute(expr value, identifier attr, expr_context ctx)
| Subscript(expr value, expr slice, expr_context ctx)
| Starred(expr value, expr_context ctx)
| Name(identifier id, expr_context ctx)
| List(expr* elts, expr_context ctx)
| Tuple(expr* elts, expr_context ctx)
```

```

-- can appear only in Subscript
| Slice(expr? lower, expr? upper, expr? step)

-- col_offset is the byte offset in the utf8 s
attributes (int lineno, int col_offset, int? e

expr_context = Load | Store | Del

boolop = And | Or

operator = Add | Sub | Mult | MatMult | Div | Mod |
          | RShift | BitOr | BitXor | BitAnd | FL

unaryop = Invert | Not | UAdd | USub

cmpop = Eq | NotEq | Lt | LtE | Gt | GtE | Is | IsNo

comprehension = (expr target, expr iter, expr* ifs,

excepthandler = ExceptHandler(expr? type, identifier
                           attributes (int lineno, int col_offs

arguments = (arg* posonlyargs, arg* args, arg? vararg
           expr* kw_defaults, arg? kwarg, expr* de

arg = (identifier arg, expr? annotation, string? typ
     attributes (int lineno, int col_offset, int?

-- keyword arguments supplied to call (NULL identifi
keyword = (identifier? arg, expr value)
         attributes (int lineno, int col_offset, i

-- import name with optional 'as' alias.
alias = (identifier name, identifier? asname)
        attributes (int lineno, int col_offset, int

withitem = (expr context_expr, expr? optional_vars)

        | MatchMapping(expr* keys, pattern* patterns)
        | MatchClass(expr cls, pattern* patterns, identifier? name)
        | MatchStar(identifier? name)
-- The optional "rest" MatchMapping parameter

        | MatchAs(pattern? pattern, identifier? name)
        | MatchOr(pattern* patterns)

attributes (int lineno, int col_offset, int end_lineno, int end_col_offset)

type_ignore = TypeIgnore(int lineno, string tag)
}

```

## Node classes

*class ast.AST*

This is the base of all AST node classes. The actual node classes are derived from the `Parser/Python.asdl` file, which is reproduced [above](#). They are defined in the `_ast` C module and re-exported in `ast`.

There is one class defined for each left-hand side symbol in the abstract grammar (for example, `ast.stmt` or `ast.expr`). In addition, there is one class defined for each constructor on the right-hand side; these classes inherit from the classes for the left-hand side trees. For example, `ast.BinOp` inherits from `ast.expr`. For production rules with alternatives (aka “sums”), the left-hand side class is abstract: only instances of specific constructor nodes are ever created.

`_fields`

Each concrete class has an attribute `_fields` which gives the names of all child nodes.

Each instance of a concrete class has one attribute for each child node, of the type as defined in the grammar. For example, `ast.BinOp` instances have an attribute `left` of type `ast.expr`.

If these attributes are marked as optional in the grammar (using a question mark), the value might be `None`. If the attributes can have zero-or-more values (marked with an asterisk), the values are represented as Python lists. All possible attributes must be present and have valid values when compiling an AST with `compile()`.

`lineno`

`col_offset`

`end_lineno`

`end_col_offset`

Instances of `ast.expr` and `ast.stmt` subclasses have `lineno`, `col_offset`, `end_lineno`, and `end_col_offset` attributes. The `lineno` and `end_lineno` are the first and last line numbers of source text span (1-indexed so the first line is line 1) and the `col_offset` and `end_col_offset` are the corresponding UTF-8 byte offsets of the first and last tokens that generated the node. The UTF-8 offset is recorded because the parser uses UTF-8 internally.

Note that the end positions are not required by the compiler and are therefore optional. The end offset is *after* the last symbol, for example one can get the source segment of a one-line expression node using `source_line[node.col_offset : node.end_col_offset]`.

The constructor of a class `ast.T` parses its arguments as follows:

- If there are positional arguments, there must be as many as there are items in **T.\_fields**; they will be assigned as attributes of these names.
- If there are keyword arguments, they will set the attributes of the same names to the given values.

For example, to create and populate an **ast.UnaryOp** node, you could use

```
node = ast.UnaryOp()
node.op = ast.USub()
node.operand = ast.Constant()
node.operand.value = 5
node.operand.lineno = 0
node.operand.col_offset = 0
node.lineno = 0
node.col_offset = 0
```

or the more compact

```
node = ast.UnaryOp(ast.USub(), ast.Constant(5, lineno=0, col_offset=0))
```

*Changed in version 3.8:* Class **ast.Constant** is now used for all constants.

*Changed in version 3.9:* Simple indices are represented by their value, extended slices are represented as tuples.

*Deprecated since version 3.8:* Old classes **ast.Num**, **ast.Str**, **ast.Bytes**, **ast.NameConstant** and **ast.Ellipsis** are still available, but they will be removed in future Python releases. In the meantime, instantiating them will return an instance of a different class.

*Deprecated since version 3.9:* Old classes **ast.Index** and **ast.ExtSlice** are still available, but they will be removed in future Python releases. In the meantime, instantiating them will return an instance of a different class.

## Note

The descriptions of the specific node classes displayed here were initially adapted from the fantastic [Green Tree Snakes](https://greentreesnakes.readthedocs.io/en/latest/) [https://greentreesnakes.readthedocs.io/en/latest/] project and all its contributors.

## Root nodes

*class ast.Module(*body*, *type\_ignores*)*

A Python module, as with [file input](#). Node type generated by [ast.parse\(\)](#) in the default "exec" mode.

*body* is a [list](#) of the module's [Statements](#).

*type\_ignores* is a [list](#) of the module's type ignore comments; see [ast.parse\(\)](#) for more details.

```
>>> print(ast.dump(ast.parse('x = 1'), indent=4))
Module(
    body=[
        Assign(
            targets=[
                Name(id='x', ctx=Store())],
            value=Constant(value=1)),
        type_ignores=[])
```

*class ast.Expression(*body*)*

A single Python [expression input](#). Node type generated by [ast.parse\(\)](#) when *mode* is "eval".

*body* is a single node, one of the [expression types](#).

```
>>> print(ast.dump(ast.parse('123', mode='eval'), i
Expression(
    body=Constant(value=123))
```

*class ast.Interactive(*body*)*

A single [interactive input](#), like in [Interactive Mode](#). Node type generated by `ast.parse()` when *mode* is "single".

*body* is a [list](#) of [statement nodes](#).

```
>>> print(ast.dump(ast.parse('x = 1; y = 2', mode='Interactive(
    body=[
        Assign(
            targets=[
                Name(id='x', ctx=Store())],
            value=Constant(value=1)),
        Assign(
            targets=[
                Name(id='y', ctx=Store())],
            value=Constant(value=2))])
```

*class* `ast.FunctionType(argtypes, returns)`

A representation of an old-style type comments for functions, as Python versions prior to 3.5 didn't support [PEP 484](#) [<https://peps.python.org/pep-0484/>] annotations. Node type generated by `ast.parse()` when *mode* is "func\_type".

Such type comments would look like this:

```
def sum_two_number(a, b):
    # type: (int, int) -> int
    return a + b
```

*argtypes* is a [list](#) of [expression nodes](#).

*returns* is a single [expression node](#).

```
>>> print(ast.dump(ast.parse('(int, str) -> List[int]
FunctionType(
    argtypes=[
        Name(id='int', ctx=Load()),
        Name(id='str', ctx=Load())],
    returns=Subscript(
        value=Name(id='List', ctx=Load()),
```

```
slice=Name(id='int', ctx=Load()),
ctx=Load()))
```

*New in version 3.8.*

## Literals

*class* ast.Constant(*value*)

A constant value. The `value` attribute of the `Constant` literal contains the Python object it represents. The values represented can be simple types such as a number, string or `None`, but also immutable container types (tuples and frozensets) if all of their elements are constant.

```
>>> print(ast.dump(ast.parse('123', mode='eval'), i
Expression(
    body=Constant(value=123))
```

*class* ast.FormattedValue(*value*, *conversion*, *format\_spec*)

Node representing a single formatting field in an f-string. If the string contains a single formatting field and nothing else the node can be isolated otherwise it appears in [JoinedStr](#).

- `value` is any expression node (such as a literal, a variable, or a function call).
- `conversion` is an integer:
  - -1: no formatting
  - 115: !s string formatting
  - 114: !r repr formatting
  - 97: !a ascii formatting
- `format_spec` is a [JoinedStr](#) node representing the formatting of the value, or `None` if no format was specified. Both `conversion` and `format_spec` can be set at the same time.

*class* ast.JoinedStr(*values*)

An f-string, comprising a series of [FormattedValue](#) and [Constant](#) nodes.

```
>>> print(ast.dump(ast.parse('f"sin({a}) is {sin(a)}'
Expression(
  body=JoinedStr(
    values=[
      Constant(value='sin('),
      FormattedValue(
        value=Name(id='a', ctx=Load()),
        conversion=-1),
      Constant(value=') is '),
      FormattedValue(
        value=Call(
          func=Name(id='sin', ctx=Load()),
          args=[
            Name(id='a', ctx=Load())],
          keywords=[]),
        conversion=-1,
        format_spec=JoinedStr(
          values=[
            Constant(value='.3')])))))))
```

*class ast.List(elts, ctx)*

*class ast.Tuple(elts, ctx)*

A list or tuple. `elts` holds a list of nodes representing the elements. `ctx` is **Store** if the container is an assignment target (i.e. `(x,y)=something`), and **Load** otherwise.

```
>>> print(ast.dump(ast.parse('[1, 2, 3]', mode='eval')
Expression(
  body=List(
    elts=[
      Constant(value=1),
      Constant(value=2),
      Constant(value=3)],
    ctx=Load()))))

>>> print(ast.dump(ast.parse('(1, 2, 3)', mode='eval')
Expression(
  body=Tuple(
    elts=[
```

```

        Constant (value=1),
        Constant (value=2),
        Constant (value=3)] ,
    ctx=Load()) )

```

### *class ast.Set(elts)*

A set. `elts` holds a list of nodes representing the set's elements.

```

>>> print(ast.dump(ast.parse('{1, 2, 3}', mode='eval'),
Expression(
    body=Set(
        elts=[
            Constant (value=1),
            Constant (value=2),
            Constant (value=3)]))

```

### *class ast.Dict(keys, values)*

A dictionary. `keys` and `values` hold lists of nodes representing the keys and the values respectively, in matching order (what would be returned when calling `dictionary.keys()` and `dictionary.values()`).

When doing dictionary unpacking using dictionary literals the expression to be expanded goes in the `values` list, with a `None` at the corresponding position in `keys`.

```

>>> print(ast.dump(ast.parse('{"a":1, **d}', mode='eval'),
Expression(
    body=Dict(
        keys=[
            Constant (value='a'),
            None],
        values=[
            Constant (value=1),
            Name(id='d', ctx=Load())]))

```

## **Variables**

*class ast.Name(id, ctx)*

A variable name. `id` holds the name as a string, and `ctx` is one of the following types.

*class ast.Load*

*class ast.Store*

*class ast.Del*

Variable references can be used to load the value of a variable, to assign a new value to it, or to delete it. Variable references are given a context to distinguish these cases.

```
>>> print(ast.dump(ast.parse('a'), indent=4))
Module(
  body=[
    Expr(
      value=Name(id='a', ctx=Load()))],
  type_ignores=[])
```

```
>>> print(ast.dump(ast.parse('a = 1'), indent=4))
Module(
  body=[
    Assign(
      targets=[
        Name(id='a', ctx=Store())],
      value=Constant(value=1)],
  type_ignores=[])
```

```
>>> print(ast.dump(ast.parse('del a'), indent=4))
Module(
  body=[
    Delete(
      targets=[
        Name(id='a', ctx=Del())]]],
  type_ignores=[])
```

*class ast.Starred(value, ctx)*

A `*var` variable reference. `value` holds the variable, typically a **Name** node. This type must be used when building

a **Call** node with `*args`.

```
>>> print(ast.dump(ast.parse('a, *b = it'), indent=
Module(
    body=[
        Assign(
            targets=[
                Tuple(
                    elts=[
                        Name(id='a', ctx=Store()),
                        Starred(
                            value=Name(id='b', ctx=
                            ctx=Store()))],
                        ctx=Store()))],
                    value=Name(id='it', ctx=Load()))],
            type_ignores=[])
```

## Expressions

*class* `ast.Expr(value)`

When an expression, such as a function call, appears as a statement by itself with its return value not used or stored, it is wrapped in this container. `value` holds one of the other nodes in this section, a **Constant**, a **Name**, a **Lambda**, a **Yield** or **YieldFrom** node.

```
>>> print(ast.dump(ast.parse('-a'), indent=4))
Module(
    body=[
        Expr(
            value=UnaryOp(
                op=USub(),
                operand=Name(id='a', ctx=Load())))]
    type_ignores=[])
```

*class* `ast.UnaryOp(op, operand)`

A unary operation. `op` is the operator, and `operand` any expression node.

```
class ast.UAdd
class ast.USub
class ast.Not
class ast.Invert
```

Unary operator tokens. **Not** is the `not` keyword, **Invert** is the `~` operator.

```
>>> print(ast.dump(ast.parse('not x', mode='eval'),
Expression(
    body=UnaryOp(
        op=Not(),
        operand=Name(id='x', ctx=Load()))))
```

```
class ast.BinOp(left, op, right)
```

A binary operation (like addition or division). `op` is the operator, and `left` and `right` are any expression nodes.

```
>>> print(ast.dump(ast.parse('x + y', mode='eval'),
Expression(
    body=BinOp(
        left=Name(id='x', ctx=Load()),
        op=Add(),
        right=Name(id='y', ctx=Load()))))
```

```
class ast.Add
class ast.Sub
class ast.Mult
class ast.Div
class ast.FloorDiv
class ast.Mod
class ast.Pow
class ast.LShift
class ast.RShift
class ast.BitOr
class ast.BitXor
class ast.BitAnd
class ast.MatMult
```

Binary operator tokens.

*class ast.BoolOp(op, values)*

A boolean operation, 'or' or 'and'. *op* is **Or** or **And**.  
*values* are the values involved. Consecutive operations with the same operator, such as `a or b or c`, are collapsed into one node with several values.

This doesn't include `not`, which is a **UnaryOp**.

```
>>> print(ast.dump(ast.parse('x or y', mode='eval')
Expression(
  body=BoolOp(
    op=Or(),
    values=[
      Name(id='x', ctx=Load()),
      Name(id='y', ctx=Load())])))
```

*class ast.And*

*class ast.Or*

Boolean operator tokens.

*class ast.Compare(left, ops, comparators)*

A comparison of two or more values. *left* is the first value in the comparison, *ops* the list of operators, and *comparators* the list of values after the first element in the comparison.

```
>>> print(ast.dump(ast.parse('1 <= a < 10', mode='e
Expression(
  body=Compare(
    left=Constant(value=1),
    ops=[
      LtE(),
      Lt()],
    comparators=[
      Name(id='a', ctx=Load()),
      Constant(value=10)])))
```

*class ast.Eq*

```

class ast.NotEq
class ast.Lt
class ast.LtE
class ast.Gt
class ast.GtE
class ast.Is
class ast.IsNot
class ast.In
class ast.NotIn

```

Comparison operator tokens.

```

class ast.Call(func, args, keywords)

```

A function call. `func` is the function, which will often be a **Name** or **Attribute** object. Of the arguments:

- `args` holds a list of the arguments passed by position.
- `keywords` holds a list of **keyword** objects representing arguments passed by keyword.

When creating a `Call` node, `args` and `keywords` are required, but they can be empty lists.

```

>>> print(ast.dump(ast.parse('func(a, b=c, *d, **e)
Expression(
  body=Call(
    func=Name(id='func', ctx=Load()),
    args=[
      Name(id='a', ctx=Load()),
      Starred(
        value=Name(id='d', ctx=Load()),
        ctx=Load())],
    keywords=[
      keyword(
        arg='b',
        value=Name(id='c', ctx=Load())),
      keyword(
        value=Name(id='e', ctx=Load()))]))

```

```

class ast.keyword(arg, value)

```

A keyword argument to a function call or class definition. `arg` is a raw string of the parameter name, `value` is a node to pass in.

*class ast.IfExp(`test`, `body`, `orelse`)*

An expression such as `a if b else c`. Each field holds a single node, so in the following example, all three are **Name** nodes.

```
>>> print(ast.dump(ast.parse('a if b else c', mode='Expression(
    body=IfExp(
        test=Name(id='b', ctx=Load()),
        body=Name(id='a', ctx=Load()),
        orelse=Name(id='c', ctx=Load()))))
```

*class ast.Attribute(`value`, `attr`, `ctx`)*

Attribute access, e.g. `d.keys`. `value` is a node, typically a **Name**. `attr` is a bare string giving the name of the attribute, and `ctx` is **Load**, **Store** or **Del** according to how the attribute is acted on.

```
>>> print(ast.dump(ast.parse('snake.colour', mode='Expression(
    body=Attribute(
        value=Name(id='snake', ctx=Load()),
        attr='colour',
        ctx=Load()))
```

*class ast.NamedExpr(`target`, `value`)*

A named expression. This AST node is produced by the assignment expressions operator (also known as the walrus operator). As opposed to the **Assign** node in which the first argument can be multiple nodes, in this case both `target` and `value` must be single nodes.

```
>>> print(ast.dump(ast.parse('(x := 4)', mode='eval')
Expression(
  body=NamedExpr(
    target=Name(id='x', ctx=Store()),
    value=Constant(value=4)))
```

## Subscripting

*class ast.Subscript(value, slice, ctx)*

A subscript, such as `l[1]`. `value` is the subscripted object (usually sequence or mapping). `slice` is an index, slice or key. It can be a **Tuple** and contain a **Slice**. `ctx` is **Load**, **Store** or **Del** according to the action performed with the subscript.

```
>>> print(ast.dump(ast.parse('l[1:2, 3]', mode='eval')
Expression(
  body=Subscript(
    value=Name(id='l', ctx=Load()),
    slice=Tuple(
      elts=[
        Slice(
          lower=Constant(value=1),
          upper=Constant(value=2)),
        Constant(value=3)],
      ctx=Load()),
    ctx=Load()))
```

*class ast.Slice(lower, upper, step)*

Regular slicing (on the form `lower:upper` or `lower:upper:step`). Can occur only inside the *slice* field of **Subscript**, either directly or as an element of **Tuple**.

```
>>> print(ast.dump(ast.parse('l[1:2]', mode='eval')
Expression(
  body=Subscript(
    value=Name(id='l', ctx=Load()),
    slice=Slice(
```

```

        lower=Constant (value=1) ,
        upper=Constant (value=2)) ,
    ctx=Load()) )

```

## Comprehensions

```

class ast.ListComp(elt, generators)
class ast.SetComp(elt, generators)
class ast.GeneratorExp(elt, generators)
class ast.DictComp(key, value, generators)

```

List and set comprehensions, generator expressions, and dictionary comprehensions. `elt` (or `key` and `value`) is a single node representing the part that will be evaluated for each item.

`generators` is a list of [comprehension](#) nodes.

```

>>> print(ast.dump(ast.parse('[x for x in numbers]'
Expression(
    body=ListComp(
        elt=Name(id='x', ctx=Load()),
        generators=[
            comprehension(
                target=Name(id='x', ctx=Store()),
                iter=Name(id='numbers', ctx=Load()),
                ifs=[],
                is_async=0)))
>>> print(ast.dump(ast.parse('{x: x**2 for x in num
Expression(
    body=DictComp(
        key=Name(id='x', ctx=Load()),
        value=BinOp(
            left=Name(id='x', ctx=Load()),
            op=Pow(),
            right=Constant(value=2)),
        generators=[
            comprehension(
                target=Name(id='x', ctx=Store()),

```

```

        iter=Name(id='numbers', ctx=Load())
        ifs=[],
        is_async=0)))
>>> print(ast.dump(ast.parse('{x for x in numbers}'))
Expression(
  body=SetComp(
    elt=Name(id='x', ctx=Load()),
    generators=[
      comprehension(
        target=Name(id='x', ctx=Store()),
        iter=Name(id='numbers', ctx=Load()),
        ifs=[],
        is_async=0)))

```

*class ast.comprehension(target, iter, ifs, is\_async)*

One for clause in a comprehension. `target` is the reference to use for each element - typically a **Name** or **Tuple** node. `iter` is the object to iterate over. `ifs` is a list of test expressions: each for clause can have multiple `ifs`.

`is_async` indicates a comprehension is asynchronous (using an `async for` instead of `for`). The value is an integer (0 or 1).

```

>>> print(ast.dump(ast.parse('[ord(c) for line in f
...                          indent=4)') # Multiple comprehens
Expression(
  body=ListComp(
    elt=Call(
      func=Name(id='ord', ctx=Load()),
      args=[
        Name(id='c', ctx=Load())],
      keywords=[]),
    generators=[
      comprehension(
        target=Name(id='line', ctx=Store()),
        iter=Name(id='file', ctx=Load()),
        ifs=[],
        is_async=0),

```

```

        comprehension(
            target=Name(id='c', ctx=Store()),
            iter=Name(id='line', ctx=Load()),
            ifs=[],
            is_async=0)))

>>> print(ast.dump(ast.parse('(n**2 for n in it if
...                             indent=4)) # generator comprehen
Expression(
    body=GeneratorExp(
        elt=BinOp(
            left=Name(id='n', ctx=Load()),
            op=Pow(),
            right=Constant(value=2)),
        generators=[
            comprehension(
                target=Name(id='n', ctx=Store()),
                iter=Name(id='it', ctx=Load()),
                ifs=[
                    Compare(
                        left=Name(id='n', ctx=Load(
                        ops=[
                            Gt()),
                        comparators=[
                            Constant(value=5)]),
                    Compare(
                        left=Name(id='n', ctx=Load(
                        ops=[
                            Lt()),
                        comparators=[
                            Constant(value=10)])),
                is_async=0)))

>>> print(ast.dump(ast.parse('[i async for i in soc
...                             indent=4)) # Async comprehension
Expression(
    body=ListComp(
        elt=Name(id='i', ctx=Load()),

```

```

generators=[
    comprehension(
        target=Name(id='i', ctx=Store()),
        iter=Name(id='soc', ctx=Load()),
        ifs=[],
        is_async=1)))

```

## Statements

*class* `ast.Assign(targets, value, type_comment)`

An assignment. `targets` is a list of nodes, and `value` is a single node.

Multiple nodes in `targets` represents assigning the same value to each. Unpacking is represented by putting a **Tuple** or **List** within `targets`.

`type_comment`

`type_comment` is an optional string with the type annotation as a comment.

```
>>> print(ast.dump(ast.parse('a = b = 1'), indent=4))
Module(
```

```

    body=[
        Assign(
            targets=[
                Name(id='a', ctx=Store()),
                Name(id='b', ctx=Store())],
            value=Constant(value=1)),
        type_ignores=[])]

```

```
>>> print(ast.dump(ast.parse('a,b = c'), indent=4))
Module(
```

```

    body=[
        Assign(
            targets=[
                Tuple(
                    elts=[

```

```

        Name(id='a', ctx=Store()),
        Name(id='b', ctx=Store())],
        ctx=Store())],
        value=Name(id='c', ctx=Load()))],
    type_ignores=[])

```

*class ast.AnnAssign(target, annotation, value, simple)*

An assignment with a type annotation. `target` is a single node and can be a **Name**, a **Attribute** or a **Subscript**. `annotation` is the annotation, such as a **Constant** or **Name** node. `value` is a single optional node. `simple` is a boolean integer set to True for a **Name** node in `target` that do not appear in between parenthesis and are hence pure names and not expressions.

```

>>> print(ast.dump(ast.parse('c: int'), indent=4))
Module(
  body=[
    AnnAssign(
      target=Name(id='c', ctx=Store()),
      annotation=Name(id='int', ctx=Load()),
      simple=1)],
  type_ignores=[])

```

```

>>> print(ast.dump(ast.parse('(a): int = 1'), indent=4))
Module(
  body=[
    AnnAssign(
      target=Name(id='a', ctx=Store()),
      annotation=Name(id='int', ctx=Load()),
      value=Constant(value=1),
      simple=0)],
  type_ignores=[])

```

```

>>> print(ast.dump(ast.parse('a.b: int'), indent=4))
Module(
  body=[
    AnnAssign(

```

```

        target=Attribute(
            value=Name(id='a', ctx=Load()),
            attr='b',
            ctx=Store()),
        annotation=Name(id='int', ctx=Load()),
        simple=0)],
    type_ignores=[])

>>> print(ast.dump(ast.parse('a[1]: int'), indent=4)
Module(
    body=[
        AnnAssign(
            target=Subscript(
                value=Name(id='a', ctx=Load()),
                slice=Constant(value=1),
                ctx=Store()),
            annotation=Name(id='int', ctx=Load()),
            simple=0)],
    type_ignores=[])

```

*class* ast.AugAssign(*target, op, value*)

Augmented assignment, such as `a += 1`. In the following example, `target` is a **Name** node for `x` (with the **Store** context), `op` is **Add**, and `value` is a **Constant** with value for 1.

The `target` attribute cannot be of class **Tuple** or **List**, unlike the targets of **Assign**.

```

>>> print(ast.dump(ast.parse('x += 2'), indent=4))
Module(
    body=[
        AugAssign(
            target=Name(id='x', ctx=Store()),
            op=Add(),
            value=Constant(value=2))],
    type_ignores=[])

```

### *class ast.Raise(exc, cause)*

A raise statement. `exc` is the exception object to be raised, normally a **Call** or **Name**, or `None` for a standalone raise. `cause` is the optional part for `y` in `raise x from y`.

```
>>> print(ast.dump(ast.parse('raise x from y'), indent=4))
Module(
  body=[
    Raise(
      exc=Name(id='x', ctx=Load()),
      cause=Name(id='y', ctx=Load()))],
  type_ignores=[])
```

### *class ast.Assert(test, msg)*

An assertion. `test` holds the condition, such as a **Compare** node. `msg` holds the failure message.

```
>>> print(ast.dump(ast.parse('assert x,y'), indent=4))
Module(
  body=[
    Assert(
      test=Name(id='x', ctx=Load()),
      msg=Name(id='y', ctx=Load()))],
  type_ignores=[])
```

### *class ast.Delete(targets)*

Represents a `del` statement. `targets` is a list of nodes, such as **Name**, **Attribute** or **Subscript** nodes.

```
>>> print(ast.dump(ast.parse('del x,y,z'), indent=4))
Module(
  body=[
    Delete(
      targets=[
        Name(id='x', ctx=Del()),
        Name(id='y', ctx=Del()),
        Name(id='z', ctx=Del())])],
  type_ignores=[])
```

```
type_ignores=[])
```

*class ast.Pass*

A pass statement.

```
>>> print(ast.dump(ast.parse('pass'), indent=4))
Module(
  body=[
    Pass()],
  type_ignores=[])
```

Other statements which are only applicable inside functions or loops are described in other sections.

## Imports

*class ast.Import(names)*

An import statement. *names* is a list of **alias** nodes.

```
>>> print(ast.dump(ast.parse('import x,y,z'), indent=4))
Module(
  body=[
    Import(
      names=[
        alias(name='x'),
        alias(name='y'),
        alias(name='z')]),
  type_ignores=[])
```

*class ast.ImportFrom(module, names, level)*

Represents from x import y. *module* is a raw string of the ‘from’ name, without any leading dots, or None for statements such as from . import foo. *level* is an integer holding the level of the relative import (0 means absolute import).

```
>>> print(ast.dump(ast.parse('from y import x,y,z'), indent=4))
Module(
```

```

body=[
    ImportFrom(
        module='y',
        names=[
            alias(name='x'),
            alias(name='y'),
            alias(name='z')],
        level=0)],
type_ignores=[])

```

*class ast.alias(name, asname)*

Both parameters are raw strings of the names. `asname` can be `None` if the regular name is to be used.

```

>>> print(ast.dump(ast.parse('from ..foo.bar import
Module(
    body=[
        ImportFrom(
            module='foo.bar',
            names=[
                alias(name='a', asname='b'),
                alias(name='c')],
            level=2)],
        type_ignores=[]))

```

## Control flow

### Note

Optional clauses such as `else` are stored as an empty list if they're not present.

*class ast.If(test, body, or\_else)*

An `if` statement. `test` holds a single node, such as a **Compare** node. `body` and `or_else` each hold a list of nodes.

`elif` clauses don't have a special representation in the AST,

but rather appear as extra **If** nodes within the `orelse` section of the previous one.

```
>>> print(ast.dump(ast.parse("""
... if x:
...     ...
... elif y:
...     ...
... else:
...     ...
... """), indent=4))
Module(
  body=[
    If(
      test=Name(id='x', ctx=Load()),
      body=[
        Expr(
          value=Constant(value=Ellipsis))
      orelse=[
        If(
          test=Name(id='y', ctx=Load()),
          body=[
            Expr(
              value=Constant(value=El
            orelse=[
              Expr(
                value=Constant(value=El
          type_ignores=[]])
```

*class ast.For(target, iter, body, orelse, type\_comment)*

A for loop. `target` holds the variable(s) the loop assigns to, as a single **Name**, **Tuple** or **List** node. `iter` holds the item to be looped over, again as a single node. `body` and `orelse` contain lists of nodes to execute. Those in `orelse` are executed if the loop finishes normally, rather than via a `break` statement.

`type_comment`

`type_comment` is an optional string with the type annotation as a comment.

```
>>> print(ast.dump(ast.parse("""
... for x in y:
...     ...
... else:
...     ...
... """), indent=4))
Module(
  body=[
    For(
      target=Name(id='x', ctx=Store()),
      iter=Name(id='y', ctx=Load()),
      body=[
        Expr(
          value=Constant(value=Ellipsis))
      orelse=[
        Expr(
          value=Constant(value=Ellipsis))
      type_ignores=[])
```

*class ast.While(test, body, orelse)*

A while loop. `test` holds the condition, such as a [Compare](#) node.

```
>> print(ast.dump(ast.parse("""
... while x:
...     ...
... else:
...     ...
... """), indent=4))
Module(
  body=[
    While(
      test=Name(id='x', ctx=Load()),
      body=[
        Expr(
```

```

                                value=Constant (value=Ellipsis))
        orelse=[
            Expr (
                value=Constant (value=Ellipsis))
        type_ignores=[]])

```

*class ast.Break*

*class ast.Continue*

The break and continue statements.

```

>>> print (ast.dump (ast.parse ("""\

              name='e',
              body=[
                Expr(
                  value=Constant(value=El
      orelse=[
        Expr(
          value=Constant(value=Ellipsis))
      finalbody=[
```

```

Expr (
    value=Constant (value=Ellipsis)
type_ignores=[])

```

*class* ast.TryStar(*body*, *handlers*, *orelse*, *finalbody*)

try blocks which are followed by `except*` clauses. The attributes are the same as for **Try** but the **ExceptionHandler** nodes in `handlers` are interpreted as `except*` blocks rather than `except`.

```

>>> print (ast.dump (ast.parse ("\"
... try:
...     ...
... except* Exception:
...     ...
... \"\"\"), indent=4))
Module (
  body=[
    TryStar (
      body=[
        Expr (
          value=Constant (value=Ellipsis)
        handlers=[
          ExceptionHandler (
            type=Name (id='Exception', ctx=L
            body=[
              Expr (
                value=Constant (value=El
            orelse=[],
            finalbody=[])]),
        type_ignores=[])

```

*class* ast.ExceptionHandler(*type*, *name*, *body*)

A single `except` clause. `type` is the exception type it will match, typically a **Name** node (or `None` for a catch-all `except:` clause). `name` is a raw string for the name to hold the exception, or `None` if the clause doesn't have `as foo`. `body` is a list of nodes.

```
>>> print(ast.dump(ast.parse("""\
... try:
...     a + 1
... except TypeError:
...     pass
... """), indent=4))
Module(
  body=[
    Try(
      body=[
        Expr(
          value=BinOp(
            left=Name(id='a', ctx=Load()),
            op=Add(),
            right=Constant(value=1))),
        handlers=[
          ExceptHandler(
            type=Name(id='TypeError', ctx=Load()),
            body=[
              Pass()])],
          orelse=[],
          finalbody=[])],
    type_ignores=[])
```

*class* `ast.With(items, body, type_comment)`

A `with` block. `items` is a list of `withitem` nodes representing the context managers, and `body` is the indented block inside the context.

`type_comment`

`type_comment` is an optional string with the type annotation as a comment.

*class* `ast.withitem(context_expr, optional_vars)`

A single context manager in a `with` block. `context_expr` is the context manager, often a `Call` node.

`optional_vars` is a `Name`, `Tuple` or `List` for the `as foo` part, or `None` if that isn't used.

```
>>> print(ast.dump(ast.parse("""\
... with a as b, c as d:
...     something(b, d)
... """), indent=4))
Module(
  body=[
    With(
      items=[
        withitem(
          context_expr=Name(id='a', ctx=L
          optional_vars=Name(id='b', ctx=
        withitem(
          context_expr=Name(id='c', ctx=L
          optional_vars=Name(id='d', ctx=
      body=[
        Expr(
          value=Call(
            func=Name(id='something', c
            args=[
              Name(id='b', ctx=Load()
              Name(id='d', ctx=Load()
            keywords=[])))]),
      type_ignores=[])
```

## Pattern matching

*class* ast.Match(*subject*, *cases*)

A match statement. *subject* holds the subject of the match (the object that is being matched against the cases) and *cases* contains an iterable of **match\_case** nodes with the different cases.

*class* ast.match\_case(*pattern*, *guard*, *body*)

A single case pattern in a match statement. *pattern* contains the match pattern that the subject will be matched against. Note that the **AST** nodes produced for patterns differ from those produced for expressions, even when they share the same syntax.

The `guard` attribute contains an expression that will be evaluated if the pattern matches the subject.

`body` contains a list of nodes to execute if the pattern matches and the result of evaluating the guard expression is `true`.

```
>>> print(ast.dump(ast.parse("""
... match x:
...     case [x] if x>0:
...         ...
...     case tuple():
...         ...
... """), indent=4))
Module(
  body=[
    Match(
      subject=Name(id='x', ctx=Load()),
      cases=[
        match_case(
          pattern=MatchSequence(
            patterns=[
              MatchAs(name='x')]),
          guard=Compare(
            left=Name(id='x', ctx=Load()),
            ops=[
              Gt()],
            comparators=[
              Constant(value=0)]),
          body=[
            Expr(
              value=Constant(value=El
match_case(
  pattern=MatchClass(
    cls=Name(id='tuple', ctx=Lo
    patterns=[],
    kwd_attrs=[],
    kwd_patterns=[]),
    body=[
```

```

Expr (
    value=Constant (value=El
type_ignores=[])

```

*class ast.MatchValue(value)*

A match literal or value pattern that compares by equality. *value* is an expression node. Permitted value nodes are restricted as described in the match statement documentation. This pattern succeeds if the match subject is equal to the evaluated value.

```

>>> print(ast.dump(ast.parse("""
... match x:
...     case "Relevant":
...         ...
... """), indent=4))
Module(
  body=[
    Match(
      subject=Name(id='x', ctx=Load()),
      cases=[
        match_case(
          pattern=MatchValue(
            value=Constant(value='Relev
          body=[
            Expr(
              value=Constant(value=El
      type_ignores=[])

```

*class ast.MatchSingleton(value)*

A match literal pattern that compares by identity. *value* is the singleton to be compared against: `None`, `True`, or `False`. This pattern succeeds if the match subject is the given constant.

```

>>> print(ast.dump(ast.parse("""
... match x:
...     case None:

```

```

...
... """, indent=4))
Module(
    body=[
        Match(
            subject=Name(id='x', ctx=Load()),
            cases=[
                match_case(
                    pattern=MatchSingleton(value=No
                    body=[
                        Expr(
                            value=Constant(value=El
            type_ignores=[]))

```

*class ast.MatchSequence(patterns)*

A match sequence pattern. `patterns` contains the patterns to be matched against the subject elements if the subject is a sequence. Matches a variable length sequence if one of the subpatterns is a `MatchStar` node, otherwise matches a fixed length sequence.

```

>>> print(ast.dump(ast.parse("""
... match x:
...     case [1, 2]:
...         ...
... """, indent=4))
Module(
    body=[
        Match(
            subject=Name(id='x', ctx=Load()),
            cases=[
                match_case(
                    pattern=MatchSequence(
                        patterns=[
                            MatchValue(
                                value=Constant(valu
                            MatchValue(
                                value=Constant(valu

```

```

        body=[
            Expr (
                value=Constant (value=El
type_ignores=[])

```

*class* ast.MatchStar(*name*)

Matches the rest of the sequence in a variable length match sequence pattern. If *name* is not *None*, a list containing the remaining sequence elements is bound to that name if the overall sequence pattern is successful.

```

>>> print(ast.dump(ast.parse("""
... match x:
...     case [1, 2, *rest]:
...         ...
...     case [*_]:
...         ...
... """), indent=4))
Module (
    body=[
        Match (
            subject=Name (id='x', ctx=Load()),
            cases=[
                match_case (
                    pattern=MatchSequence (
                        patterns=[
                            MatchValue (
                                value=Constant (valu
                            MatchValue (
                                value=Constant (valu
                            MatchStar (name='rest') ]
                    body=[
                        Expr (
                            value=Constant (value=El
                match_case (
                    pattern=MatchSequence (
                        patterns=[
                            MatchStar() ]),

```

```

        body=[
            Expr (
                value=Constant (value=El
type_ignores=[])

```

*class ast.MatchMapping(keys, patterns, rest)*

A match mapping pattern. *keys* is a sequence of expression nodes. *patterns* is a corresponding sequence of pattern nodes. *rest* is an optional name that can be specified to capture the remaining mapping elements. Permitted key expressions are restricted as described in the match statement documentation.

This pattern succeeds if the subject is a mapping, all evaluated key expressions are present in the mapping, and the value corresponding to each key matches the corresponding subpattern. If *rest* is not *None*, a dict containing the remaining mapping elements is bound to that name if the overall mapping pattern is successful.

```

>>> print (ast.dump (ast.parse ("\"
... match x:
...     case {1: _, 2: _}:
...         ...
...     case {**rest}:
...         ...
... \"\"\"), indent=4))
Module(
  body=[
    Match(
      subject=Name(id='x', ctx=Load()),
      cases=[
        match_case(
          pattern=MatchMapping(
            keys=[
              Constant(value=1),
              Constant(value=2)],
            patterns=[
              MatchAs(),

```

```

MatchAs ( ) ] ) ,
body = [
    Expr (
        value = Constant ( value = El
match_case (
    pattern = MatchMapping ( keys = [ ] , p
    body = [
        Expr (
            value = Constant ( value = El
type_ignores = [ ] )

```

*class* ast.MatchClass(*cls*, *patterns*, *kwd\_attrs*, *kwd\_patterns*)

A match class pattern. *cls* is an expression giving the nominal class to be matched. *patterns* is a sequence of pattern nodes to be matched against the class defined sequence of pattern matching attributes. *kwd\_attrs* is a sequence of additional attributes to be matched (specified as keyword arguments in the class pattern), *kwd\_patterns* are the corresponding patterns (specified as keyword values in the class pattern).

This pattern succeeds if the subject is an instance of the nominated class, all positional patterns match the corresponding class-defined attributes, and any specified keyword attributes match their corresponding pattern.

Note: classes may define a property that returns self in order to match a pattern node against the instance being matched. Several builtin types are also matched that way, as described in the match statement documentation.

```

>>> print (ast.dump (ast.parse (" "
... match x:
...     case Point2D (0, 0):
...         ...
...     case Point3D (x=0, y=0, z=0):
...         ...
... """), indent=4))
Module (

```

```

body=[
    Match(
        subject=Name(id='x', ctx=Load()),
        cases=[
            match_case(
                pattern=MatchClass(
                    cls=Name(id='Point2D', ctx=
patterns=[
                    MatchValue(
                        value=Constant(valu
                    MatchValue(
                        value=Constant(valu
                    kwd_attrs=[],
                    kwd_patterns=[]),
                body=[

                        MatchValue(
                            value=Constant(valu
                body=[
                    Expr(
                        value=Constant(value=El
        type_ignores=[]))

```

*class ast.MatchAs(pattern, name)*

A match “as-pattern”, capture pattern or wildcard pattern. `pattern` contains the match pattern that the subject will be matched against. If the pattern is `None`, the node represents a capture pattern (i.e a bare name) and will always succeed.

The `name` attribute contains the name that will be bound if the pattern is successful. If `name` is `None`, `pattern` must also be `None` and the node represents the wildcard pattern.

```
>>> print(ast.dump(ast.parse("""
... match x:
...     case [x] as y:
...         ...
...     case _:
...         ...
... """), indent=4))
Module(
  body=[
    Match(
      subject=Name(id='x', ctx=Load()),
      cases=[
        match_case(
          pattern=MatchAs(
            pattern=MatchSequence(
              patterns=[
                MatchAs(name='x')])
            name='y'),
          body=[
            Expr(
              value=Constant(value=El
match_case(
  pattern=MatchAs(),
  body=[
    Expr(
      value=Constant(value=El
type_ignores=[])
```

*class* `ast.MatchOr(patterns)`

A match “or-pattern”. An or-pattern matches each of its

subpatterns in turn to the subject, until one succeeds. The or-pattern is then deemed to succeed. If none of the subpatterns succeed the or-pattern fails. The `patterns` attribute contains a list of match pattern nodes that will be matched against the subject.

```
>>> print(ast.dump(ast.parse("""
... match x:
...     case [x] | (y):
...         ...
... """), indent=4))
Module(
  body=[
    Match(
      subject=Name(id='x', ctx=Load()),
      cases=[
        match_case(
          pattern=MatchOr(
            patterns=[
              MatchSequence(
                patterns=[
                  MatchAs(name='x'),
                  MatchAs(name='y')]
                ),
              body=[
                Expr(
                  value=Constant(value=El
type_ignores=[])
```

## Function and class definitions

*class* `ast.FunctionDef(name, args, body, decorator_list, returns, type_comment)`

A function definition.

- `name` is a raw string of the function name.
- `args` is an **arguments** node.
- `body` is the list of nodes inside the function.
- `decorator_list` is the list of decorators to be applied, stored outermost first (i.e. the first in the list

will be applied last).

- `returns` is the return annotation.

`type_comment`

`type_comment` is an optional string with the type annotation as a comment.

*class* `ast.Lambda(args, body)`

`lambda` is a minimal function definition that can be used inside an expression. Unlike `FunctionDef`, `body` holds a single node.

```
>>> print(ast.dump(ast.parse('lambda x,y: ...'), in
Module(
    body=[
        Expr(
            value=Lambda(
                args=arguments(
                    posonlyargs=[],
                    args=[
                        arg(arg='x'),
                        arg(arg='y')],
                    kwonlyargs=[],
                    kw_defaults=[],
                    defaults=[]),
                body=Constant(value=Ellipsis))),
        type_ignores=[])
```

*class* `ast.arguments(posonlyargs, args, vararg, kwonlyargs, kw_defaults, kwarg, defaults)`

The arguments for a function.

- `posonlyargs`, `args` and `kwonlyargs` are lists of `arg` nodes.
- `vararg` and `kwarg` are single `arg` nodes, referring to the `*args`, `**kwargs` parameters.
- `kw_defaults` is a list of default values for keyword-only arguments. If one is `None`, the corresponding

argument is required.

- `defaults` is a list of default values for arguments that can be passed positionally. If there are fewer defaults, they correspond to the last `n` arguments.

*class* `ast.arg(arg, annotation, type_comment)`

A single argument in a list. `arg` is a raw string of the argument name, `annotation` is its annotation, such as a **Str** or **Name** node.

`type_comment`

`type_comment` is an optional string with the type annotation as a comment

```
>>> print(ast.dump(ast.parse("""\
... @decorator1
... @decorator2
... def f(a: 'annotation', b=1, c=2, *d, e, f=3, **
...     pass
... """), indent=4))
Module(
  body=[
    FunctionDef(
      name='f',
      args=arguments(
        posonlyargs=[],
        args=[
          arg(
            arg='a',
            annotation=Constant(value='
            arg(arg='b'),
            arg(arg='c')],
            vararg=arg(arg='d'),
            kwonlyargs=[
              arg(arg='e'),
              arg(arg='f')],
            kw_defaults=[
              None,
```

```

        Constant(value=3)],
        kwarg=arg(arg='g'),
        defaults=[
            Constant(value=1),
            Constant(value=2)]),
    body=[
        Pass()],
    decorator_list=[
        Name(id='decorator1', ctx=Load()),
        Name(id='decorator2', ctx=Load())],
    returns=Constant(value='return annotation'),
    type_ignores=[])

```

*class ast.Return(value)*

A return statement.

```

>>> print(ast.dump(ast.parse('return 4'), indent=4))
Module(
    body=[
        Return(
            value=Constant(value=4))],
    type_ignores=[])

```

*class ast.Yield(value)*

*class ast.YieldFrom(value)*

A yield or yield from expression. Because these are expressions, they must be wrapped in a **Expr** node if the value sent back is not used.

```

>>> print(ast.dump(ast.parse('yield x'), indent=4))
Module(
    body=[
        Expr(
            value=Yield(
                value=Name(id='x', ctx=Load())))],
    type_ignores=[])

```

```

>>> print(ast.dump(ast.parse('yield from x'), inden

```

```
Module(
    body=[
        Expr(
            value=YieldFrom(
                value=Name(id='x', ctx=Load()))],
    type_ignores=[])
```

*class ast.Global(names)*

*class ast.Nonlocal(names)*

**global and nonlocal statements.** *names* is a list of raw strings.

```
>>> print(ast.dump(ast.parse('global x,y,z'), indent=4))
Module(
    body=[
        Global(
            names=[
                'x',
                'y',
                'z'])],
    type_ignores=[])
```

```
>>> print(ast.dump(ast.parse('nonlocal x,y,z'), indent=4))
Module(
    body=[
        Nonlocal(
            names=[
                'x',
                'y',
                'z'])],
    type_ignores=[])
```

*class ast.ClassDef(name, bases, keywords, body, decorator\_list)*

**A class definition.**

- *name* is a raw string for the class name
- *bases* is a list of nodes for explicitly specified base classes.

- `keywords` is a list of **keyword** nodes, principally for ‘metaclass’. Other keywords will be passed to the metaclass, as per [PEP-3115](https://peps.python.org/pep-3115/) [https://peps.python.org/pep-3115/].
- `body` is a list of nodes representing the code within the class definition.
- `decorator_list` is a list of nodes, as in **FunctionDef**.

```
>>> print(ast.dump(ast.parse("""\
... @decorator1
... @decorator2
... class Foo(base1, base2, metaclass=meta):
...     pass
... """, indent=4))
Module(
  body=[
    ClassDef(
      name='Foo',
      bases=[
        Name(id='base1', ctx=Load()),
        Name(id='base2', ctx=Load())],
      keywords=[
        keyword(
          arg='metaclass',
          value=Name(id='meta', ctx=Load(
body=[
  Pass()],
decorator_list=[
  Name(id='decorator1', ctx=Load()),
  Name(id='decorator2', ctx=Load())])
type_ignores=[])
```

## Async and await

*class ast.AsyncFunctionDef(name, args, body, decorator\_list, returns, type\_comment)*

An `async def` function definition. Has the same fields as

## FunctionDef.

*class ast.Await(value)*

An `await` expression. `value` is what it waits for. Only valid in the body of an **AsyncFunctionDef**.

```
>>> print(ast.dump(ast.parse("""\n... async def f():\n...     await other_func()\n... """), indent=4))\nModule(\n  body=[\n    AsyncFunctionDef(\n      name='f',\n      args=arguments(\n        posonlyargs=[],\n        args=[],\n        kwonlyargs=[],\n        kw_defaults=[],\n        defaults=[]),\n      body=[\n        Expr(\n          value=Await(\n            value=Call(\n              func=Name(id='other_func', c\n              args=[],\n              keywords=[]))),\n          decorator_list=[]],\n      type_ignores=[])
```

*class ast.AsyncFor(target, iter, body, or\_else, type\_comment)*

*class ast.AsyncWith(items, body, type\_comment)*

async for loops and async with context managers. They have the same fields as **For** and **With**, respectively. Only valid in the body of an **AsyncFunctionDef**.

## Note

When a string is parsed by `ast.parse()`, operator nodes (subclasses of `ast.operator`, `ast.unaryop`, `ast.cmpop`, `ast.boolop` and `ast.expr_context`) on the returned tree will be singletons. Changes to one will be reflected in all other occurrences of the same value (e.g. `ast.Add`).

## ast Helpers

Apart from the node classes, the `ast` module defines these utility functions and classes for traversing abstract syntax trees:

```
ast.parse(source, filename='<unknown>', mode='exec', *,
type_comments=False, feature_version=None)
```

Parse the source into an AST node. Equivalent to `compile(source, filename, mode, ast.PyCF_ONLY_AST)`.

If `type_comments=True` is given, the parser is modified to check and return type comments as specified by [PEP 484](https://peps.python.org/pep-0484/) [https://peps.python.org/pep-0484/] and [PEP 526](https://peps.python.org/pep-0526/) [https://peps.python.org/pep-0526/]. This is equivalent to adding `ast.PyCF_TYPE_COMMENTS` to the flags passed to `compile()`. This will report syntax errors for misplaced type comments. Without this flag, type comments will be ignored, and the `type_comment` field on selected AST nodes will always be `None`. In addition, the locations of `# type: ignore` comments will be returned as the `type_ignores` attribute of `Module` (otherwise it is always an empty list).

In addition, if `mode` is `'func_type'`, the input syntax is modified to correspond to [PEP 484](https://peps.python.org/pep-0484/) [https://peps.python.org/pep-0484/] “signature type comments”, e.g. `(str, int) -> List[str]`.

Also, setting `feature_version` to a tuple (major, minor) will attempt to parse using that Python version’s grammar. Currently `major` must equal to 3. For example, setting `feature_version=(3, 4)` will allow the use of `async` and `await` as variable names. The lowest supported

version is (3, 4); the highest is `sys.version_info[0:2]`.

If source contains a null character ('0'), `ValueError` is raised.

### Warning

Note that successfully parsing source code into an AST object doesn't guarantee that the source code provided is valid Python code that can be executed as the compilation step can raise further `SyntaxError` exceptions. For instance, the source `return 42` generates a valid AST node for a return statement, but it cannot be compiled alone (it needs to be inside a function node).

In particular, `ast.parse()` won't do any scoping checks, which the compilation step does.

### Warning

It is possible to crash the Python interpreter with a sufficiently large/complex string due to stack depth limitations in Python's AST compiler.

*Changed in version 3.8:* Added `type_comments`, `mode='func_type'` and `feature_version`.

`ast.unparse(ast_obj)`

Unparse an `ast.AST` object and generate a string with code that would produce an equivalent `ast.AST` object if parsed back with `ast.parse()`.

### Warning

The produced code string will not necessarily be equal to the original code that generated the `ast.AST` object (without any compiler optimizations, such as constant tuples/frozensets).

## Warning

Trying to unparse a highly complex expression would result with `RecursionError`.

*New in version 3.9.*

`ast.literal_eval(node_or_string)`

Evaluate an expression node or a string containing only a Python literal or container display. The string or node provided may only consist of the following Python literal structures: strings, bytes, numbers, tuples, lists, dicts, sets, booleans, `None` and `Ellipsis`.

This can be used for evaluating strings containing Python values without the need to parse the values oneself. It is not capable of evaluating arbitrarily complex expressions, for example involving operators or indexing.

This function had been documented as “safe” in the past without defining what that meant. That was misleading. This is specifically designed not to execute Python code, unlike the more general `eval()`. There is no namespace, no name lookups, or ability to call out. But it is not free from attack: A relatively small input can lead to memory exhaustion or to C stack exhaustion, crashing the process. There is also the possibility for excessive CPU consumption denial of service on some inputs. Calling it on untrusted data is thus not recommended.

## Warning

It is possible to crash the Python interpreter due to stack depth limitations in Python’s AST compiler.

It can raise `ValueError`, `TypeError`, `SyntaxError`, `MemoryError` and `RecursionError` depending on the malformed input.

*Changed in version 3.2:* Now allows bytes and set literals.

*Changed in version 3.9:* Now supports creating empty sets with `'set () '`.

*Changed in version 3.10:* For string inputs, leading spaces and tabs are now stripped.

`ast.get_docstring(node, clean=True)`

Return the docstring of the given *node* (which must be a **FunctionDef**, **AsyncFunctionDef**, **ClassDef**, or **Module** node), or `None` if it has no docstring. If *clean* is true, clean up the docstring's indentation with `inspect.cleandoc()`.

*Changed in version 3.5:* **AsyncFunctionDef** is now supported.

`ast.get_source_segment(source, node, *, padded=False)`

Get source code segment of the *source* that generated *node*. If some location information (**lineno**, **end\_lineno**, **col\_offset**, or **end\_col\_offset**) is missing, return `None`.

If *padded* is `True`, the first line of a multi-line statement will be padded with spaces to match its original position.

*New in version 3.8.*

`ast.fix_missing_locations(node)`

When you compile a node tree with `compile()`, the compiler expects **lineno** and **col\_offset** attributes for every node that supports them. This is rather tedious to fill in for generated nodes, so this helper adds these attributes recursively where not already set, by setting them to the values of the parent node. It works recursively starting at *node*.

`ast.increment_lineno(node, n=1)`

Increment the line number and end line number of each node

in the tree starting at *node* by *n*. This is useful to “move code” to a different location in a file.

`ast.copy_location(new_node, old_node)`

Copy source location (`lineno`, `col_offset`, `end_lineno`, and `end_col_offset`) from *old\_node* to *new\_node* if possible, and return *new\_node*.

`ast.iter_fields(node)`

Yield a tuple of (`fieldname`, `value`) for each field in `node._fields` that is present on *node*.

`ast.iter_child_nodes(node)`

Yield all direct child nodes of *node*, that is, all fields that are nodes and all items of fields that are lists of nodes.

`ast.walk(node)`

Recursively yield all descendant nodes in the tree starting at *node* (including *node* itself), in no specified order. This is useful if you only want to modify nodes in place and don’t care about the context.

`class ast.NodeVisitor`

A node visitor base class that walks the abstract syntax tree and calls a visitor function for every node found. This function may return a value which is forwarded by the `visit()` method.

This class is meant to be subclassed, with the subclass adding visitor methods.

`visit(node)`

Visit a node. The default implementation calls the method called `self.visit_classname` where *classname* is the name of the node class, or `generic_visit()` if that method doesn’t exist.

`generic_visit(node)`

This visitor calls `visit()` on all children of the node.

Note that child nodes of nodes that have a custom visitor method won't be visited unless the visitor calls `generic_visit()` or visits them itself.

Don't use the `NodeVisitor` if you want to apply changes to nodes during traversal. For this a special visitor exists (`NodeTransformer`) that allows modifications.

*Deprecated since version 3.8:* Methods `visit_Num()`, `visit_Str()`, `visit_Bytes()`, `visit_NameConstant()` and `visit_Ellipsis()` are deprecated now and will not be called in future Python versions. Add the `visit_Constant()` method to handle all constant nodes.

*class* `ast.NodeTransformer`

A `NodeVisitor` subclass that walks the abstract syntax tree and allows modification of nodes.

The `NodeTransformer` will walk the AST and use the return value of the visitor methods to replace or remove the old node. If the return value of the visitor method is `None`, the node will be removed from its location, otherwise it is replaced with the return value. The return value may be the original node in which case no replacement takes place.

Here is an example transformer that rewrites all occurrences of name lookups (`foo`) to `data['foo']`:

```
class RewriteName(NodeTransformer):

    def visit_Name(self, node):
        return Subscript(
            value=Name(id='data', ctx=Load()),
            slice=Constant(value=node.id),
            ctx=node.ctx
        )
```

Keep in mind that if the node you're operating on has child nodes you must either transform the child nodes yourself or call the `generic_visit()` method for the node first.

For nodes that were part of a collection of statements (that applies to all statement nodes), the visitor may also return a list of nodes rather than just a single node.

If `NodeTransformer` introduces new nodes (that weren't part of original tree) without giving them location information (such as `lineno`), `fix_missing_locations()` should be called with the new sub-tree to recalculate the location information:

```
tree = ast.parse('foo', mode='eval')
new_tree = fix_missing_locations(RewriteName().visit(tree))
```

Usually you use the transformer like this:

```
node = YourTransformer().visit(node)
```

```
ast.dump(node, annotate_fields=True, include_attributes=False, *,
indent=None)
```

Return a formatted dump of the tree in *node*. This is mainly useful for debugging purposes. If *annotate\_fields* is true (by default), the returned string will show the names and the values for fields. If *annotate\_fields* is false, the result string will be more compact by omitting unambiguous field names. Attributes such as line numbers and column offsets are not dumped by default. If this is wanted, *include\_attributes* can be set to true.

If *indent* is a non-negative integer or string, then the tree will be pretty-printed with that indent level. An indent level of 0, negative, or "" will only insert newlines. `None` (the default) selects the single line representation. Using a positive integer *indent* indents that many spaces per level. If *indent* is a string (such as "\t"), that string is used to indent each level.

*Changed in version 3.9:* Added the *indent* option.

# Compiler Flags

The following flags may be passed to `compile()` in order to change effects on the compilation of a program:

`ast.PyCF_ALLOW_TOP_LEVEL_AWAIT`

Enables support for top-level `await`, `async for`, `async with` and `async comprehensions`.

*New in version 3.8.*

`ast.PyCF_ONLY_AST`

Generates and returns an abstract syntax tree instead of returning a compiled code object.

`ast.PyCF_TYPE_COMMENTS`

Enables support for [PEP 484](https://peps.python.org/pep-0484/) [https://peps.python.org/pep-0484/] and [PEP 526](https://peps.python.org/pep-0526/) [https://peps.python.org/pep-0526/] style type comments (`# type: <type>`, `# type: ignore <stuff>`).

*New in version 3.8.*

## Command-Line Usage

*New in version 3.9.*

The `ast` module can be executed as a script from the command line. It is as simple as:

```
python -m ast [-m <mode>] [-a] [infile]
```

The following options are accepted:

`-h, --help`

Show the help message and exit.

`-m <mode>`

`--mode <mode>`

Specify what kind of code must be compiled, like the *mode* argument in `parse()`.

`--no-type-comments`

Don't parse type comments.

`-a, --include-attributes`

Include attributes such as line numbers and column offsets.

`-i <indent>`

`--indent <indent>`

Indentation of nodes in AST (number of spaces).

If `infile` is specified its contents are parsed to AST and dumped to stdout. Otherwise, the content is read from stdin.

[LibCST](https://libcst.readthedocs.io/) [https://libcst.readthedocs.io/] parses code as a Concrete Syntax Tree that looks like an ast tree and keeps all formatting details. It's useful for building automated refactoring (codemod) applications and linters.

[Parso](https://parso.readthedocs.io/) [https://parso.readthedocs.io/] is a Python parser that supports error recovery and round-trip parsing for different Python versions (in multiple Python versions). Parso is also able to list

multiple syntax errors in your python file.

# `symtable` — Access to the compiler's symbol tables

**Source code:** [Lib/symtable.py](https://github.com/python/cpython/tree/3.11/Lib/symtable.py) [https://github.com/python/cpython/tree/3.11/Lib/symtable.py]

---

Symbol tables are generated by the compiler from AST just before bytecode is generated. The symbol table is responsible for calculating the scope of every identifier in the code. `symtable` provides an interface to examine these tables.

## Generating Symbol Tables

`symtable.symtable(code, filename, compile_type)`

Return the toplevel `SymbolTable` for the Python source *code*. *filename* is the name of the file containing the code. *compile\_type* is like the *mode* argument to `compile()`.

## Examining Symbol Tables

`class symtable.SymbolTable`

A namespace table for a block. The constructor is not public.

`get_type()`

Return the type of the symbol table. Possible values are 'class', 'module', and 'function'.

`get_id()`

Return the table's identifier.

`get_name()`

Return the table's name. This is the name of the class if the table is for a class, the name of the function if the table is for a function, or 'top' if the table is global (`get_type()` returns 'module').

`get_lineno()`

Return the number of the first line in the block this table represents.

`is_optimized()`

Return `True` if the locals in this table can be optimized.

`is_nested()`

Return `True` if the block is a nested class or function.

`has_children()`

Return `True` if the block has nested namespaces within it. These can be obtained with `get_children()`.

`get_identifiers()`

Return a view object containing the names of symbols in the table. See the [documentation of view objects](#).

`lookup(name)`

Lookup *name* in the table and return a `Symbol` instance.

`get_symbols()`

Return a list of `Symbol` instances for names in the table.

`get_children()`

Return a list of the nested symbol tables.

*class* symtable.Function

A namespace for a function or method. This class inherits **SymbolTable**.

get\_parameters()

Return a tuple containing names of parameters to this function.

get\_locals()

Return a tuple containing names of locals in this function.

get\_globals()

Return a tuple containing names of globals in this function.

get\_nonlocals()

Return a tuple containing names of nonlocals in this function.

get\_frees()

Return a tuple containing names of free variables in this function.

*class* symtable.Class

A namespace of a class. This class inherits **SymbolTable**.

get\_methods()

Return a tuple containing the names of methods declared in the class.

*class* symtable.Symbol

An entry in a **SymbolTable** corresponding to an identifier in the source. The constructor is not public.

get\_name()

Return the symbol's name.

`is_referenced()`

Return `True` if the symbol is used in its block.

`is_imported()`

Return `True` if the symbol is created from an import statement.

`is_parameter()`

Return `True` if the symbol is a parameter.

`is_global()`

Return `True` if the symbol is global.

`is_nonlocal()`

Return `True` if the symbol is nonlocal.

`is_declared_global()`

Return `True` if the symbol is declared global with a global statement.

`is_local()`

Return `True` if the symbol is local to its block.

`is_annotated()`

Return `True` if the symbol is annotated.

*New in version 3.6.*

`is_free()`

Return `True` if the symbol is referenced in its block, but not assigned to.

`is_assigned()`

Return `True` if the symbol is assigned to in its block.

### `is_namespace()`

Return `True` if name binding introduces new namespace.

If the name is used as the target of a function or class statement, this will be true.

For example:

```
>>> table = symtable.symtable("def some_func() :  
>>> table.lookup("some_func").is_namespace()  
True
```

Note that a single name can be bound to multiple objects. If the result is `True`, the name may also be bound to other objects, like an int or list, that does not introduce a new namespace.

### `get_namespaces()`

Return a list of namespaces bound to this name.

### `get_namespace()`

Return the namespace bound to this name. If more than one or no namespace is bound to this name, a `ValueError` is raised.

# token — Constants used with Python parse trees

**Source code:** [Lib/token.py](https://github.com/python/cpython/tree/3.11/Lib/token.py) [https://github.com/python/cpython/tree/3.11/Lib/token.py]

---

This module provides constants which represent the numeric values of leaf nodes of the parse tree (terminal tokens). Refer to the file `Grammar/Tokens` in the Python distribution for the definitions of the names in the context of the language grammar. The specific numeric values which the names map to may change between Python versions.

The module also provides a mapping from numeric codes to names and some functions. The functions mirror definitions in the Python C header files.

`token.tok_name`

Dictionary mapping the numeric values of the constants defined in this module back to name strings, allowing more human-readable representation of parse trees to be generated.

`token.ISTERMINAL(x)`

Return `True` for terminal token values.

`token.ISNONTERMINAL(x)`

Return `True` for non-terminal token values.

`token.ISEOF(x)`

Return `True` if `x` is the marker indicating the end of input.

The token constants are:

token.ENDMARKER

token.NAME

token.NUMBER

token.STRING

token.NEWLINE

token.INDENT

token.DEDENT

token.LPAR

Token value for " ( ".

token.RPAR

Token value for " ) ".

token.LSQB

Token value for " [ ".

token.RSQB

Token value for " ] ".

token.COLON

Token value for " : ".

token.COMMA

Token value for " , ".

token.SEMI

Token value for " ; ".

token.PLUS

Token value for "+".

token.MINUS

Token value for "-".

token.STAR

Token value for "\*".

token.SLASH

Token value for "/".

token.VBAR

Token value for "|".

token.AMPER

Token value for "&".

token.LESS

Token value for "<".

token.GREATER

Token value for ">".

token.EQUAL

Token value for "=".

token.DOT

Token value for ".".

token.PERCENT

Token value for "%".

token.LBRACE

Token value for "{".

token.RBRACE

Token value for " } ".

token.EQEQUAL

Token value for "==".

token.NOTEQUAL

Token value for "!=".

token.LESSEQUAL

Token value for "<=".

token.GREATEREQUAL

Token value for ">=".

token.TILDE

Token value for "~".

token.CIRCUMFLEX

Token value for "^".

token.OP

token.AWAIT

token.ASYNC

token.TYPE\_IGNORE

token.TYPE\_COMMENT

token.SOFT\_KEYWORD

token.ERRORTOKEN

token.N\_TOKENS

token.NT\_OFFSET

The following token type values aren't used by the C tokenizer but are needed for the **tokenize** module.

token.COMMENT

Token value used to indicate a comment.

token.NL

Token value used to indicate a non-terminating newline. The

**NEWLINE** token indicates the end of a logical line of Python code; **NL** tokens are generated when a logical line of code is continued over multiple physical lines.

#### `token.ENCODING`

Token value that indicates the encoding used to decode the source bytes into text. The first token returned by `tokenize.tokenize()` will always be an `ENCODING` token.

#### `token.TYPE_COMMENT`

Token value indicating that a type comment was recognized. Such tokens are only produced when `ast.parse()` is invoked with `type_comments=True`.

*Changed in version 3.5:* Added **AWAIT** and **ASYNC** tokens.

*Changed in version 3.7:* Added **COMMENT**, **NL** and **ENCODING** tokens.

*Changed in version 3.7:* Removed **AWAIT** and **ASYNC** tokens. “async” and “await” are now tokenized as **NAME** tokens.

*Changed in version 3.8:* Added **TYPE\_COMMENT**, **TYPE\_IGNORE**, **COLONEQUAL**. Added **AWAIT** and **ASYNC** tokens back (they’re needed to support parsing older Python versions for `ast.parse()` with `feature_version` set to 6 or lower).

# keyword — Testing for Python keywords

**Source code:** [Lib/keyword.py](https://github.com/python/cpython/tree/3.11/Lib/keyword.py) [https://github.com/python/cpython/tree/3.11/Lib/keyword.py]

---

This module allows a Python program to determine if a string is a [keyword](#) or [soft keyword](#).

`keyword.iskeyword(s)`

Return `True` if `s` is a Python [keyword](#).

`keyword.kwlist`

Sequence containing all the [keywords](#) defined for the interpreter. If any keywords are defined to only be active when particular `__future__` statements are in effect, these will be included as well.

`keyword.issoftkeyword(s)`

Return `True` if `s` is a Python [soft keyword](#).

*New in version 3.9.*

`keyword.softkwlist`

Sequence containing all the [soft keywords](#) defined for the interpreter. If any soft keywords are defined to only be active when particular `__future__` statements are in effect, these will be included as well.

*New in version 3.9.*

# tokenize — Tokenizer for Python source

**Source code:** [Lib/tokenize.py](https://github.com/python/cpython/tree/3.11/Lib/tokenize.py) [https://github.com/python/cpython/tree/3.11/Lib/tokenize.py]

---

The `tokenize` module provides a lexical scanner for Python source code, implemented in Python. The scanner in this module returns comments as tokens as well, making it useful for implementing “pretty-printers”, including colorizers for on-screen displays.

To simplify token stream handling, all `operator` and `delimiter` tokens and `Ellipsis` are returned using the generic `OP` token type. The exact type can be determined by checking the `exact_type` property on the `named tuple` returned from `tokenize.tokenize()`.

## Warning

Note that the functions in this module are only designed to parse syntactically valid Python code (code that does not raise when parsed using `ast.parse()`). The behavior of the functions in this module is **undefined** when providing invalid Python code and it can change at any point.

## Tokenizing Input

The primary entry point is a `generator`:

```
tokenize.tokenize(readline)
```

The `tokenize()` generator requires one argument, *readline*, which must be a callable object which provides the same

interface as the `io.IOBase.readline()` method of file objects. Each call to the function should return one line of input as bytes.

The generator produces 5-tuples with these members: the token type; the token string; a 2-tuple `(srow, scol)` of ints specifying the row and column where the token begins in the source; a 2-tuple `(erow, ecol)` of ints specifying the row and column where the token ends in the source; and the line on which the token was found. The line passed (the last tuple item) is the *physical* line. The 5 tuple is returned as a **named tuple** with the field names: `type` `string` `start` `end` `line`.

The returned **named tuple** has an additional property named `exact_type` that contains the exact operator type for **OP** tokens. For all other token types `exact_type` equals the named tuple `type` field.

*Changed in version 3.1:* Added support for named tuples.

*Changed in version 3.3:* Added support for `exact_type`.

**tokenize()** determines the source encoding of the file by looking for a UTF-8 BOM or encoding cookie, according to **PEP 263** [<https://peps.python.org/pep-0263/>].

`tokenize.generate_tokens(readline)`

Tokenize a source reading unicode strings instead of bytes.

Like **tokenize()**, the *readline* argument is a callable returning a single line of input. However, **generate\_tokens()** expects *readline* to return a str object rather than bytes.

The result is an iterator yielding named tuples, exactly like **tokenize()**. It does not yield an **ENCODING** token.

All constants from the **token** module are also exported from **tokenize**.

Another function is provided to reverse the tokenization process. This is useful for creating tools that tokenize a script, modify the token stream, and write back the modified script.

`tokenize.untokenize(iterable)`

Converts tokens back into Python source code. The *iterable* must return sequences with at least two elements, the token type and the token string. Any additional sequence elements are ignored.

The reconstructed script is returned as a single string. The result is guaranteed to tokenize back to match the input so that the conversion is lossless and round-trips are assured. The guarantee applies only to the token type and token string as the spacing between tokens (column positions) may change.

It returns bytes, encoded using the `ENCODING` token, which is the first token sequence output by `tokenize()`. If there is no encoding token in the input, it returns a str instead.

`tokenize()` needs to detect the encoding of source files it tokenizes. The function it uses to do this is available:

`tokenize.detect_encoding(readline)`

The `detect_encoding()` function is used to detect the encoding that should be used to decode a Python source file. It requires one argument, *readline*, in the same way as the `tokenize()` generator.

It will call *readline* a maximum of twice, and return the encoding used (as a string) and a list of any lines (not decoded from bytes) it has read in.

It detects the encoding from the presence of a UTF-8 BOM or an encoding cookie as specified in [PEP 263](https://peps.python.org/pep-0263/) [https://peps.python.org/pep-0263/]. If both a BOM and a cookie are present, but disagree, a `SyntaxError` will be raised. Note that if the BOM is found, `'utf-8-sig'` will be returned as an encoding.

If no encoding is specified, then the default of `'utf-8'` will be returned.

Use `open()` to open Python source files: it uses `detect_encoding()` to detect the file encoding.

`tokenize.open(filename)`

Open a file in read only mode using the encoding detected by `detect_encoding()`.

*New in version 3.2.*

*exception* `tokenize.TokenError`

Raised when either a docstring or expression that may be split over several lines is not completed anywhere in the file, for example:

```
"""Beginning of  
docstring
```

or:

```
[1,  
 2,  
 3
```

Note that unclosed single-quoted strings do not cause an error to be raised. They are tokenized as `ERRORTOKEN`, followed by the tokenization of their contents.

## Command-Line Usage

*New in version 3.3.*

The `tokenize` module can be executed as a script from the command line. It is as simple as:

```
python -m tokenize [-e] [filename.py]
```

The following options are accepted:

`-h, --help`

show this help message and exit

`-e, --exact`

display token names using the exact type

If `filename.py` is specified its contents are tokenized to stdout. Otherwise, tokenization is performed on stdin.

## Examples

Example of a script rewriter that transforms float literals into Decimal objects:

```
from tokenize import tokenize, untokenize, NUMBER, STRING
from io import BytesIO
```

```
def decistmt(s):
    """Substitute Decimals for floats in a string of statements"""

    >>> from decimal import Decimal
    >>> s = 'print(+21.3e-5*-.1234/81.7) '
    >>> decistmt(s)
    "print (+Decimal ('21.3e-5')*-Decimal ('.1234')/Decimal ('81.7'))"
```

The format of the exponent is inherited from the platform. Known cases are "e-007" (Windows) and "e-07" (not Windows). We're only showing 12 digits, and the 13th isn't close to the rest of the output should be platform-independent.

```
>>> exec(s) #doctest: +ELLIPSIS
-3.21716034272e-0...7
```

Output from calculations with Decimal should be identical on all platforms.

```
>>> exec(decistmt(s))
-3.217160342717258261933904529E-7
"""
result = []
g = tokenize(BytesIO(s.encode('utf-8')).readline) #
for toknum, tokval, _, _, _ in g:
    if toknum == NUMBER and '.' in tokval: # replac
        result.extend([
            (NAME, 'Decimal'),
            (OP, '('),
            (STRING, repr(tokval)),
            (OP, ')')
        ])
    else:
        result.append((toknum, tokval))
return untokenize(result).decode('utf-8')
```

Example of tokenizing from the command line. The script:

```
def say_hello():
    print("Hello, World!")
```

```
say_hello()
```

will be tokenized to the following output where the first column is the range of the line/column coordinates where the token is found, the second column is the name of the token, and the final column is the value of the token (if any)

```
$ python -m tokenize hello.py
0,0-0,0:      ENCODING      'utf-8'
1,0-1,3:      NAME          'def'
1,4-1,13:     NAME          'say_hello'
1,13-1,14:    OP            '('
1,14-1,15:    OP            ')'
1,15-1,16:    OP            ':'
1,16-1,17:    NEWLINE      '\n'
2,0-2,4:      INDENT       '    '
2,4-2,9:      NAME          'print'
```

2,9-2,10:	OP	'('
2,10-2,25:	STRING	'"Hello, World!"'
2,25-2,26:	OP	')'
2,26-2,27:	NEWLINE	'\n'
3,0-3,1:	NL	'\n'
4,0-4,0:	DEDENT	''
4,0-4,9:	NAME	'say_hello'
4,9-4,10:	OP	'('
4,10-4,11:	OP	')'
4,11-4,12:	NEWLINE	'\n'
5,0-5,0:	ENDMARKER	''

The exact token type names can be displayed using the **-e** option:

```
$ python -m tokenize -e hello.py
0,0-0,0:      ENCODING      'utf-8'
1,0-1,3:      NAME          'def'
1,4-1,13:     NAME          'say_hello'
1,13-1,14:    LPAR          '('
1,14-1,15:    RPAR          ')'
1,15-1,16:    COLON         ':'
1,16-1,17:    NEWLINE      '\n'
2,0-2,4:      INDENT        '    '
2,4-2,9:      NAME          'print'
2,9-2,10:     LPAR          '('
2,10-2,25:    STRING        '"Hello, World!"'
2,25-2,26:    RPAR          ')'
2,26-2,27:    NEWLINE      '\n'
3,0-3,1:      NL           '\n'
4,0-4,0:      DEDENT        ''
4,0-4,9:      NAME          'say_hello'
4,9-4,10:     LPAR          '('
4,10-4,11:    RPAR          ')'
4,11-4,12:    NEWLINE      '\n'
5,0-5,0:      ENDMARKER    ''
```

Example of tokenizing a file programmatically, reading unicode strings instead of bytes with **generate\_tokens()**:

```
import tokenize
```

```
with tokenize.open('hello.py') as f:  
    tokens = tokenize.generate_tokens(f.readline)  
    for token in tokens:  
        print(token)
```

Or reading bytes directly with `tokenize()`:

```
import tokenize
```

```
with open('hello.py', 'rb') as f:  
    tokens = tokenize.tokenize(f.readline)  
    for token in tokens:  
        print(token)
```

# tabnanny — Detection of ambiguous indentation

**Source code:** [Lib/tabnanny.py](https://github.com/python/cpython/tree/3.11/Lib/tabnanny.py) [https://github.com/python/cpython/tree/3.11/Lib/tabnanny.py]

---

For the time being this module is intended to be called as a script. However it is possible to import it into an IDE and use the function `check()` described below.

## Note

The API provided by this module is likely to change in future releases; such changes may not be backward compatible.

`tabnanny.check(file_or_dir)`

If *file\_or\_dir* is a directory and not a symbolic link, then recursively descend the directory tree named by *file\_or\_dir*, checking all `.py` files along the way. If *file\_or\_dir* is an ordinary Python source file, it is checked for whitespace related problems. The diagnostic messages are written to standard output using the `print()` function.

`tabnanny.verbose`

Flag indicating whether to print verbose messages. This is incremented by the `-v` option if called as a script.

`tabnanny.filename_only`

Flag indicating whether to print only the filenames of files containing whitespace related problems. This is set to true by the `-q` option if called as a script.

*exception* `tabnanny.NannyNag`

Raised by `process_tokens()` if detecting an ambiguous indent. Captured and handled in `check()`.

`tabnanny.process_tokens(tokens)`

This function is used by `check()` to process tokens generated by the `tokenize` module.

**See also**

**Module** `tokenize`

Lexical scanner for Python source code.

# pyclbr — Python module browser support

**Source code:** [Lib/pyclbr.py](https://github.com/python/cpython/tree/3.11/Lib/pyclbr.py) [https://github.com/python/cpython/tree/3.11/Lib/pyclbr.py]

---

The **pyclbr** module provides limited information about the functions, classes, and methods defined in a Python-coded module. The information is sufficient to implement a module browser. The information is extracted from the Python source code rather than by importing the module, so this module is safe to use with untrusted code. This restriction makes it impossible to use this module with modules not implemented in Python, including all standard and optional extension modules.

`pyclbr.readmodule(module, path = None)`

Return a dictionary mapping module-level class names to class descriptors. If possible, descriptors for imported base classes are included. Parameter *module* is a string with the name of the module to read; it may be the name of a module within a package. If given, *path* is a sequence of directory paths prepended to `sys.path`, which is used to locate the module source code.

This function is the original interface and is only kept for back compatibility. It returns a filtered version of the following.

`pyclbr.readmodule_ex(module, path = None)`

Return a dictionary-based tree containing a function or class descriptors for each function and class defined in the module with a `def` or `class` statement. The returned dictionary maps module-level function and class names to their descriptors. Nested objects are entered into the children

dictionary of their parent. As with `readmodule`, *module* names the module to be read and *path* is prepended to `sys.path`. If the module being read is a package, the returned dictionary has a key `'__path__'` whose value is a list containing the package search path.

*New in version 3.7:* Descriptors for nested definitions. They are accessed through the new `children` attribute. Each has a new `parent` attribute.

The descriptors returned by these functions are instances of `Function` and `Class` classes. Users are not expected to create instances of these classes.

## Function Objects

Class **`Function`** instances describe functions defined by `def` statements. They have the following attributes:

`Function.file`

Name of the file in which the function is defined.

`Function.module`

The name of the module defining the function described.

`Function.name`

The name of the function.

`Function.lineno`

The line number in the file where the definition starts.

`Function.parent`

For top-level functions, `None`. For nested functions, the parent.

*New in version 3.7.*

`Function.children`

A dictionary mapping names to descriptors for nested functions and classes.

*New in version 3.7.*

Function.is\_async

True for functions that are defined with the `async` prefix, False otherwise.

*New in version 3.10.*

## Class Objects

Class **Class** instances describe classes defined by class statements. They have the same attributes as Functions and two more.

Class.file

Name of the file in which the class is defined.

Class.module

The name of the module defining the class described.

Class.name

The name of the class.

Class.lineno

The line number in the file where the definition starts.

Class.parent

For top-level classes, None. For nested classes, the parent.

*New in version 3.7.*

Class.children

A dictionary mapping names to descriptors for nested functions and classes.

*New in version 3.7.*

## Class.super

A list of **Class** objects which describe the immediate base classes of the class being described. Classes which are named as superclasses but which are not discoverable by `readmodule_ex()` are listed as a string with the class name instead of as **Class** objects.

## Class.methods

A dictionary mapping method names to line numbers. This can be derived from the newer children dictionary, but remains for back-compatibility.

# py\_compile — Compile Python source files

**Source code:** [Lib/py\\_compile.py](#) [[https://github.com/python/cpython/tree/3.11/Lib/py\\_compile.py](https://github.com/python/cpython/tree/3.11/Lib/py_compile.py)]

---

The `py_compile` module provides a function to generate a byte-code file from a source file, and another function used when the module source file is invoked as a script.

Though not often needed, this function can be useful when installing modules for shared use, especially if some of the users may not have permission to write the byte-code cache files in the directory containing the source code.

*exception* `py_compile.PyCompileError`

Exception raised when an error occurs while attempting to compile the file.

`py_compile.compile(file, cfile=None, dfile=None, doraise=False, optimize=-1, invalidation_mode=PycInvalidationMode.TIMESTAMP, quiet=0)`

Compile a source file to byte-code and write out the byte-code cache file. The source code is loaded from the file named *file*. The byte-code is written to *cfile*, which defaults to the [PEP 3147](#) [<https://peps.python.org/pep-3147/>]/[PEP 488](#) [<https://peps.python.org/pep-0488/>] path, ending in `.pyc`. For example, if *file* is `/foo/bar/baz.py` *cfile* will default to `/foo/bar/__pycache__/baz.cpython-32.pyc` for Python 3.2. If *dfile* is specified, it is used instead of *file* as the name of the source file from which source lines are obtained for display in exception tracebacks. If *doraise* is true, a `PyCompileError` is raised when an error is encountered while compiling *file*. If *doraise* is false (the default), an error string is written to

`sys.stderr`, but no exception is raised. This function returns the path to byte-compiled file, i.e. whatever *cfile* value was used.

The *doraise* and *quiet* arguments determine how errors are handled while compiling file. If *quiet* is 0 or 1, and *doraise* is false, the default behaviour is enabled: an error string is written to `sys.stderr`, and the function returns `None` instead of a path. If *doraise* is true, a `PyCompileError` is raised instead. However if *quiet* is 2, no message is written, and *doraise* has no effect.

If the path that *cfile* becomes (either explicitly specified or computed) is a symlink or non-regular file, `FileExistsError` will be raised. This is to act as a warning that import will turn those paths into regular files if it is allowed to write byte-compiled files to those paths. This is a side-effect of import using file renaming to place the final byte-compiled file into place to prevent concurrent file writing issues.

*optimize* controls the optimization level and is passed to the built-in `compile()` function. The default of `-1` selects the optimization level of the current interpreter.

*invalidation\_mode* should be a member of the `PycInvalidationMode` enum and controls how the generated bytecode cache is invalidated at runtime. The default is `PycInvalidationMode.CHECKED_HASH` if the `SOURCE_DATE_EPOCH` environment variable is set, otherwise the default is `PycInvalidationMode.TIMESTAMP`.

*Changed in version 3.2:* Changed default value of *cfile* to be [PEP 3147](https://peps.python.org/pep-3147/) [https://peps.python.org/pep-3147/] -compliant. Previous default was `file + 'c' ('o' if optimization was enabled)`. Also added the *optimize* parameter.

*Changed in version 3.4:* Changed code to use `importlib` for the byte-code cache file writing. This means file creation/writing semantics now match what `importlib` does, e.g. permissions, write-and-move semantics, etc. Also added the

caveat that `FileExistsError` is raised if `cfile` is a symlink or non-regular file.

*Changed in version 3.7:* The `invalidation_mode` parameter was added as specified in [PEP 552](https://peps.python.org/pep-0552/) [https://peps.python.org/pep-0552/]. If the `SOURCE_DATE_EPOCH` environment variable is set, `invalidation_mode` will be forced to `PycInvalidationMode.CHECKED_HASH`.

*Changed in version 3.7.2:* The `SOURCE_DATE_EPOCH` environment variable no longer overrides the value of the `invalidation_mode` argument, and determines its default value instead.

*Changed in version 3.8:* The `quiet` parameter was added.

`class py_compile.PycInvalidationMode`

An enumeration of possible methods the interpreter can use to determine whether a bytecode file is up to date with a source file. The `.pyc` file indicates the desired invalidation mode in its header. See [Cached bytecode invalidation](#) for more information on how Python invalidates `.pyc` files at runtime.

*New in version 3.7.*

**TIMESTAMP**

The `.pyc` file includes the timestamp and size of the source file, which Python will compare against the metadata of the source file at runtime to determine if the `.pyc` file needs to be regenerated.

**CHECKED\_HASH**

The `.pyc` file includes a hash of the source file content, which Python will compare against the source at runtime to determine if the `.pyc` file needs to be regenerated.

**UNCHECKED\_HASH**

Like `CHECKED_HASH`, the `.pyc` file includes a hash of the source file content. However, Python will at runtime assume the `.pyc` file is up to date and not validate the `.pyc` against the source file at all.

This option is useful when the `.pycs` are kept up to date by some system external to Python like a build system.

## Command-Line Interface

This module can be invoked as a script to compile several source files. The files named in *filenames* are compiled and the resulting bytecode is cached in the normal manner. This program does not search a directory structure to locate source files; it only compiles files named explicitly. The exit status is nonzero if one of the files could not be compiled.

<file> ... <fileN>

-

Positional arguments are files to compile. If - is the only parameter, the list of files is taken from standard input.

-q, --quiet

Suppress errors output.

*Changed in version 3.2:* Added support for -.

*Changed in version 3.10:* Added support for `-q`.

See also

Module `compileall`

Utilities to compile all Python source files in a directory tree.

# compileall — Byte-compile Python libraries

**Source code:** [Lib/compileall.py](https://github.com/python/cpython/tree/3.11/Lib/compileall.py) [https://github.com/python/cpython/tree/3.11/Lib/compileall.py]

---

This module provides some utility functions to support installing Python libraries. These functions compile Python source files in a directory tree. This module can be used to create the cached byte-code files at library installation time, which makes them available for use even by users who don't have write permission to the library directories.

**Availability:** not Emscripten, not WASI.

This module does not work or is not available on WebAssembly platforms `wasm32-emscripten` and `wasm32-wasi`. See [WebAssembly platforms](#) for more information.

## Command-line use

This module can work as a script (using **python -m compileall**) to compile Python sources.

directory ...

file ...

Positional arguments are files to compile or directories that contain source files, traversed recursively. If no argument is given, behave as if the command line was `-l <directories from sys.path>`.

-l

Do not recurse into subdirectories, only compile source code files directly contained in the named or implied directories.

-f

Force rebuild even if timestamps are up-to-date.

-q

Do not print the list of files compiled. If passed once, error messages will still be printed. If passed twice (-qq), all output is suppressed.

-d destdir

Directory prepended to the path to each file being compiled. This will appear in compilation time tracebacks, and is also compiled in to the byte-code file, where it will be used in tracebacks and other messages in cases where the source file does not exist at the time the byte-code file is executed.

-s strip\_prefix

-p prepend\_prefix

Remove (-s) or append (-p) the given prefix of paths recorded in the .pyc files. Cannot be combined with -d.

-x regex

regex is used to search the full path to each file considered for compilation, and if the regex produces a match, the file is skipped.

-i list

Read the file list and add each line that it contains to the list of files and directories to compile. If list is -, read lines from stdin.

-b

Write the byte-code files to their legacy locations and names, which may overwrite byte-code files created by another version of Python. The default is to write files to their [PEP 3147](https://peps.python.org/pep-3147/) [https://peps.python.org/pep-3147/] locations and names, which allows byte-code files from multiple versions of Python

to coexist.

**-r**

Control the maximum recursion level for subdirectories. If this is given, then **-l** option will not be taken into account. **python -m compileall <directory> -r 0** is equivalent to **python -m compileall <directory> -l**.

**-j N**

Use *N* workers to compile the files within the given directory. If 0 is used, then the result of `os.cpu_count()` will be used.

**--invalidation-mode [timestamp|checked-hash|unchecked-hash]**

Control how the generated byte-code files are invalidated at runtime. The `timestamp` value, means that `.pyc` files with the source timestamp and size embedded will be generated. The `checked-hash` and `unchecked-hash` values cause hash-based pycs to be generated. Hash-based pycs embed a hash of the source file contents rather than a timestamp. See [Cached bytecode invalidation](#) for more information on how Python validates bytecode cache files at runtime. The default is `timestamp` if the `SOURCE_DATE_EPOCH` environment variable is not set, and `checked-hash` if the `SOURCE_DATE_EPOCH` environment variable is set.

**-o level**

Compile with the given optimization level. May be used multiple times to compile for multiple levels at a time (for example, `compileall -o 1 -o 2`).

**-e dir**

Ignore symlinks pointing outside the given directory.

**--hardlink-dupes**

If two `.pyc` files with different optimization level have the same content, use hard links to consolidate duplicate files.

*Changed in version 3.2:* Added the `-i`, `-b` and `-h` options.

*Changed in version 3.5:* Added the `-j`, `-r`, and `-qq` options. `-q` option was changed to a multilevel value. `-b` will always produce a byte-code file ending in `.pyc`, never `.pyo`.

*Changed in version 3.7:* Added the `--invalidation-mode` option.

*Changed in version 3.9:* Added the `-s`, `-p`, `-e` and `--hardlink-dupes` options. Raised the default recursion limit from 10 to `sys.getrecursionlimit()`. Added the possibility to specify the `-o` option multiple times.

There is no command-line option to control the optimization level used by the `compile()` function, because the Python interpreter itself already provides the option: **`python -O -m compileall`**.

Similarly, the `compile()` function respects the `sys.pycache_prefix` setting. The generated bytecode cache will only be useful if `compile()` is run with the same `sys.pycache_prefix` (if any) that will be used at runtime.

## Public functions

`compileall.compile_dir(dir, maxlevels=sys.getrecursionlimit(), ddir=None, force=False, rx=None, quiet=0, legacy=False, optimize=-1, workers=1, invalidation_mode=None, *, stripdir=None, prependdir=None, limit_sl_dest=None, hardlink_dupes=False)`

Recursively descend the directory tree named by *dir*, compiling all `.py` files along the way. Return a true value if all the files compiled successfully, and a false value otherwise.

The *maxlevels* parameter is used to limit the depth of the recursion; it defaults to `sys.getrecursionlimit()`.

If *ddir* is given, it is prepended to the path to each file being compiled for use in compilation time tracebacks, and is also compiled in to the byte-code file, where it will be used in

tracebacks and other messages in cases where the source file does not exist at the time the byte-code file is executed.

If *force* is true, modules are re-compiled even if the timestamps are up to date.

If *rx* is given, its `search` method is called on the complete path to each file considered for compilation, and if it returns a true value, the file is skipped. This can be used to exclude files matching a regular expression, given as a [re.Pattern](#) object.

If *quiet* is `False` or `0` (the default), the filenames and other information are printed to standard out. Set to `1`, only errors are printed. Set to `2`, all output is suppressed.

If *legacy* is true, byte-code files are written to their legacy locations and names, which may overwrite byte-code files created by another version of Python. The default is to write files to their [PEP 3147](https://peps.python.org/pep-3147/) [https://peps.python.org/pep-3147/] locations and names, which allows byte-code files from multiple versions of Python to coexist.

*optimize* specifies the optimization level for the compiler. It is passed to the built-in `compile()` function. Accepts also a sequence of optimization levels which lead to multiple compilations of one `.py` file in one call.

The argument *workers* specifies how many workers are used to compile files in parallel. The default is to not use multiple workers. If the platform can't use multiple workers and *workers* argument is given, then sequential compilation will be used as a fallback. If *workers* is `0`, the number of cores in the system is used. If *workers* is lower than `0`, a `ValueError` will be raised.

*invalidation\_mode* should be a member of the `py_compile.PycInvalidationMode` enum and controls how the generated pycs are invalidated at runtime.

The *stripdir*, *prependdir* and *limit\_sl\_dest* arguments correspond

to the `-s`, `-p` and `-e` options described above. They may be specified as `str` or `os.PathLike`.

If `hardlink_dupes` is true and two `.pyc` files with different optimization level have the same content, use hard links to consolidate duplicate files.

*Changed in version 3.2:* Added the `legacy` and `optimize` parameter.

*Changed in version 3.5:* Added the `workers` parameter.

*Changed in version 3.5:* `quiet` parameter was changed to a multilevel value.

*Changed in version 3.5:* The `legacy` parameter only writes out `.pyc` files, not `.pyo` files no matter what the value of `optimize` is.

*Changed in version 3.6:* Accepts a `path-like object`.

*Changed in version 3.7:* The `invalidation_mode` parameter was added.

*Changed in version 3.7.2:* The `invalidation_mode` parameter's default value is updated to `None`.

*Changed in version 3.8:* Setting `workers` to 0 now chooses the optimal number of cores.

*Changed in version 3.9:* Added `stripdir`, `prependdir`, `limit_sl_dest` and `hardlink_dupes` arguments. Default value of `maxlevels` was changed from 10 to `sys.getrecursionlimit()`

```
compileall.compile_file(fullname, ddir=None, force=False,
rx=None, quiet=0, legacy=False, optimize=-1,
invalidation_mode=None, *, stripdir=None, prependdir=None,
limit_sl_dest=None, hardlink_dupes=False)
```

Compile the file with path `fullname`. Return a true value if the file compiled successfully, and a false value otherwise.

If *ddir* is given, it is prepended to the path to the file being compiled for use in compilation time tracebacks, and is also compiled in to the byte-code file, where it will be used in tracebacks and other messages in cases where the source file does not exist at the time the byte-code file is executed.

If *rx* is given, its `search` method is passed the full path name to the file being compiled, and if it returns a true value, the file is not compiled and `True` is returned. This can be used to exclude files matching a regular expression, given as a [re.Pattern](#) object.

If *quiet* is `False` or `0` (the default), the filenames and other information are printed to standard out. Set to `1`, only errors are printed. Set to `2`, all output is suppressed.

If *legacy* is true, byte-code files are written to their legacy locations and names, which may overwrite byte-code files created by another version of Python. The default is to write files to their [PEP 3147](https://peps.python.org/pep-3147/) [https://peps.python.org/pep-3147/] locations and names, which allows byte-code files from multiple versions of Python to coexist.

*optimize* specifies the optimization level for the compiler. It is passed to the built-in `compile()` function. Accepts also a sequence of optimization levels which lead to multiple compilations of one `.py` file in one call.

*invalidation\_mode* should be a member of the [py\\_compile.PycInvalidationMode](#) enum and controls how the generated pycs are invalidated at runtime.

The *stripdir*, *prependdir* and *limit\_sl\_dest* arguments correspond to the `-s`, `-p` and `-e` options described above. They may be specified as `str` or [os.PathLike](#).

If *hardlink\_dupes* is true and two `.pyc` files with different optimization level have the same content, use hard links to consolidate duplicate files.

*New in version 3.2.*

*Changed in version 3.5:* *quiet* parameter was changed to a multilevel value.

*Changed in version 3.5:* The *legacy* parameter only writes out `.pyc` files, not `.pyo` files no matter what the value of *optimize* is.

*Changed in version 3.7:* The *invalidation\_mode* parameter was added.

*Changed in version 3.7.2:* The *invalidation\_mode* parameter's default value is updated to `None`.

*Changed in version 3.9:* Added *stripdir*, *prependdir*, *limit\_sl\_dest* and *hardlink\_dupes* arguments.

```
compileall.compile_path(skip_curdir=True, maxlevels=0,  
force=False, quiet=0, legacy=False, optimize=-1,  
invalidation_mode=None)
```

Byte-compile all the `.py` files found along `sys.path`. Return a true value if all the files compiled successfully, and a false value otherwise.

If *skip\_curdir* is true (the default), the current directory is not included in the search. All other parameters are passed to the [compile\\_dir\(\)](#) function. Note that unlike the other compile functions, `maxlevels` defaults to 0.

*Changed in version 3.2:* Added the *legacy* and *optimize* parameter.

*Changed in version 3.5:* *quiet* parameter was changed to a multilevel value.

*Changed in version 3.5:* The *legacy* parameter only writes out `.pyc` files, not `.pyo` files no matter what the value of *optimize* is.

*Changed in version 3.7:* The *invalidation\_mode* parameter was added.

*Changed in version 3.7.2:* The `invalidation_mode` parameter's default value is updated to `None`.

To force a recompile of all the `.py` files in the `Lib/` subdirectory and all its subdirectories:

```
import compileall

compileall.compile_dir('Lib/', force=True)

# Perform same compilation, excluding files in .svn dire
import re
compileall.compile_dir('Lib/', rx=re.compile(r'[/\\][.]s

# pathlib.Path objects can also be used.
import pathlib
compileall.compile_dir(pathlib.Path('Lib/'), force=True)
```

## See also

### Module `py_compile`

Byte-compile a single source file.

# dis — Disassembler for Python bytecode

**Source code:** [Lib/dis.py](https://github.com/python/cpython/tree/3.11/Lib/dis.py) [https://github.com/python/cpython/tree/3.11/Lib/dis.py]

---

The **dis** module supports the analysis of CPython **bytecode** by disassembling it. The CPython bytecode which this module takes as an input is defined in the file `Include/opcode.h` and used by the compiler and the interpreter.

**CPython implementation detail:** Bytecode is an implementation detail of the CPython interpreter. No guarantees are made that bytecode will not be added, removed, or changed between versions of Python. Use of this module should not be considered to work across Python VMs or Python releases.

*Changed in version 3.6:* Use 2 bytes for each instruction. Previously the number of bytes varied by instruction.

*Changed in version 3.10:* The argument of jump, exception handling and loop instructions is now the instruction offset rather than the byte offset.

*Changed in version 3.11:* Some instructions are accompanied by one or more inline cache entries, which take the form of **CACHE** instructions. These instructions are hidden by default, but can be shown by passing `show_caches=True` to any **dis** utility. Furthermore, the interpreter now adapts the bytecode to specialize it for different runtime conditions. The adaptive bytecode can be shown by passing `adaptive=True`.

Example: Given the function **myfunc()**:

```
def myfunc(alist):
```

```
return len(alist)
```

the following command can be used to display the disassembly of **myfunc()**:

```
>>> dis.dis(myfunc)
2              0 RESUME              0

3              2 LOAD_GLOBAL        1 (NULL + len)
              14 LOAD_FAST          0 (alist)
              16 PRECALL            1
              20 CALL              1
              30 RETURN_VALUE
```

(The “2” is a line number).

## Bytecode analysis

*New in version 3.4.*

The bytecode analysis API allows pieces of Python code to be wrapped in a **Bytecode** object that provides easy access to details of the compiled code.

```
class dis.Bytecode(x, *, first_line=None, current_offset=None,
show_caches=False, adaptive=False)
```

Analyse the bytecode corresponding to a function, generator, asynchronous generator, coroutine, method, string of source code, or a code object (as returned by **compile()**).

This is a convenience wrapper around many of the functions listed below, most notably **get\_instructions()**, as iterating over a **Bytecode** instance yields the bytecode operations as **Instruction** instances.

If *first\_line* is not `None`, it indicates the line number that should be reported for the first source line in the disassembled code. Otherwise, the source line information (if any) is taken directly from the disassembled code object.

If *current\_offset* is not `None`, it refers to an instruction offset in the disassembled code. Setting this means `dis()` will display a “current instruction” marker against the specified opcode.

If *show\_caches* is `True`, `dis()` will display inline cache entries used by the interpreter to specialize the bytecode.

If *adaptive* is `True`, `dis()` will display specialized bytecode that may be different from the original bytecode.

*classmethod* `from_traceback(tb, *, show_caches=False)`

Construct a `Bytecode` instance from the given traceback, setting *current\_offset* to the instruction responsible for the exception.

*codeobj*

The compiled code object.

*first\_line*

The first source line of the code object (if available)

`dis()`

Return a formatted view of the bytecode operations (the same as printed by `dis.dis()`, but returned as a multi-line string).

`info()`

Return a formatted multi-line string with detailed information about the code object, like `code_info()`.

*Changed in version 3.7:* This can now handle coroutine and asynchronous generator objects.

*Changed in version 3.11:* Added the *show\_caches* and *adaptive* parameters.

Example:

```
>>> bytecode = dis.Bytecode(myfunc)
>>> for instr in bytecode:
...     print(instr.opname)
...
RESUME
LOAD_GLOBAL
LOAD_FAST
PRECALL
CALL
RETURN_VALUE
```

## Analysis functions

The **dis** module also defines the following analysis functions that convert the input directly to the desired output. They can be useful if only a single operation is being performed, so the intermediate analysis object isn't useful:

`dis.code_info(x)`

Return a formatted multi-line string with detailed code object information for the supplied function, generator, asynchronous generator, coroutine, method, source code string or code object.

Note that the exact contents of code info strings are highly implementation dependent and they may change arbitrarily across Python VMs or Python releases.

*New in version 3.2.*

*Changed in version 3.7:* This can now handle coroutine and asynchronous generator objects.

`dis.show_code(x, *, file=None)`

Print detailed code object information for the supplied function, method, source code string or code object to *file* (or `sys.stdout` if *file* is not specified).

This is a convenient shorthand for `print(code_info(x),`

`file=file)`, intended for interactive exploration at the interpreter prompt.

*New in version 3.2.*

*Changed in version 3.4:* Added `file` parameter.

`dis.dis(x=None, *, file=None, depth=None, show_caches=False, adaptive=False)`

Disassemble the `x` object. `x` can denote either a module, a class, a method, a function, a generator, an asynchronous generator, a coroutine, a code object, a string of source code or a byte sequence of raw bytecode. For a module, it disassembles all functions. For a class, it disassembles all methods (including class and static methods). For a code object or sequence of raw bytecode, it prints one line per bytecode instruction. It also recursively disassembles nested code objects (the code of comprehensions, generator expressions and nested functions, and the code used for building nested classes). Strings are first compiled to code objects with the `compile()` built-in function before being disassembled. If no object is provided, this function disassembles the last traceback.

The disassembly is written as text to the supplied `file` argument if provided and to `sys.stdout` otherwise.

The maximal depth of recursion is limited by `depth` unless it is `None`. `depth=0` means no recursion.

If `show_caches` is `True`, this function will display inline cache entries used by the interpreter to specialize the bytecode.

If `adaptive` is `True`, this function will display specialized bytecode that may be different from the original bytecode.

*Changed in version 3.4:* Added `file` parameter.

*Changed in version 3.7:* Implemented recursive disassembling and added `depth` parameter.

*Changed in version 3.7:* This can now handle coroutine and asynchronous generator objects.

*Changed in version 3.11:* Added the *show\_caches* and *adaptive* parameters.

```
dis.distb(tb=None, *, file=None, show_caches=False,  
adaptive=False)
```

Disassemble the top-of-stack function of a traceback, using the last traceback if none was passed. The instruction causing the exception is indicated.

The disassembly is written as text to the supplied *file* argument if provided and to `sys.stdout` otherwise.

*Changed in version 3.4:* Added *file* parameter.

*Changed in version 3.11:* Added the *show\_caches* and *adaptive* parameters.

```
dis.disassemble(code, lasti=-1, *, file=None, show_caches=False,  
adaptive=False)
```

```
dis.disco(code, lasti=-1, *, file=None, show_caches=False,  
adaptive=False)
```

Disassemble a code object, indicating the last instruction if *lasti* was provided. The output is divided in the following columns:

1. the line number, for the first instruction of each line
2. the current instruction, indicated as `-->`,
3. a labelled instruction, indicated with `>>`,
4. the address of the instruction,
5. the operation code name,
6. operation parameters, and
7. interpretation of the parameters in parentheses.

The parameter interpretation recognizes local and global variable names, constant values, branch targets, and compare operators.

The disassembly is written as text to the supplied *file* argument if provided and to `sys.stdout` otherwise.

*Changed in version 3.4:* Added *file* parameter.

*Changed in version 3.11:* Added the *show\_caches* and *adaptive* parameters.

`dis.get_instructions(x, *, first_line=None, show_caches=False, adaptive=False)`

Return an iterator over the instructions in the supplied function, method, source code string or code object.

The iterator generates a series of **Instruction** named tuples giving the details of each operation in the supplied code.

If *first\_line* is not `None`, it indicates the line number that should be reported for the first source line in the disassembled code. Otherwise, the source line information (if any) is taken directly from the disassembled code object.

The *show\_caches* and *adaptive* parameters work as they do in **`dis()`**.

*New in version 3.4.*

*Changed in version 3.11:* Added the *show\_caches* and *adaptive* parameters.

`dis.findlinestarts(code)`

This generator function uses the `co_lines` method of the code object *code* to find the offsets which are starts of lines in the source code. They are generated as `(offset, lineno)` pairs.

*Changed in version 3.6:* Line numbers can be decreasing. Before, they were always increasing.

*Changed in version 3.10:* The **PEP 626** [<https://peps.python.org/>]

pep-0626/] `co_lines` method is used instead of the `co_firstlineno` and `co_notab` attributes of the code object.

`dis.findlabels(code)`

Detect all offsets in the raw compiled bytecode string *code* which are jump targets, and return a list of these offsets.

`dis.stack_effect(opcode, oparg=None, *, jump=None)`

Compute the stack effect of *opcode* with argument *oparg*.

If the code has a jump target and *jump* is `True`, `stack_effect()` will return the stack effect of jumping. If *jump* is `False`, it will return the stack effect of not jumping. And if *jump* is `None` (default), it will return the maximal stack effect of both cases.

*New in version 3.4.*

*Changed in version 3.8:* Added *jump* parameter.

## Python Bytecode Instructions

The `get_instructions()` function and `Bytecode` class provide details of bytecode instructions as `Instruction` instances:

*class* `dis.Instruction`

Details for a bytecode operation

`opcode`

numeric code for operation, corresponding to the opcode values listed below and the bytecode values in the [Opcode collections](#).

`opname`

human readable name for operation

arg

numeric argument to operation (if any), otherwise  
None

argval

resolved arg value (if any), otherwise None

argrepr

human readable description of operation argument (if  
any), otherwise an empty string.

offset

start index of operation within bytecode sequence

starts\_line

line started by this opcode (if any), otherwise None

is\_jump\_target

True if other code jumps to here, otherwise False

positions

**dis.Positions** object holding the start and end  
locations that are covered by this instruction.

*New in version 3.4.*

*Changed in version 3.11:* Field `positions` is added.

*class* `dis.Positions`

In case the information is not available, some fields might be  
None.

lineno

end\_lineno

col\_offset

end\_col\_offset

*New in version 3.11.*

The Python compiler currently generates the following bytecode instructions.

## General instructions

### NOP

Do nothing code. Used as a placeholder by the bytecode optimizer, and to generate line tracing events.

### POP\_TOP

Removes the top-of-stack (TOS) item.

### COPY(*i*)

Push the *i*-th item to the top of the stack. The item is not removed from its original location.

*New in version 3.11.*

### SWAP(*i*)

Swap TOS with the item at position *i*.

*New in version 3.11.*

### CACHE

Rather than being an actual instruction, this opcode is used to mark extra space for the interpreter to cache useful data directly in the bytecode itself. It is automatically hidden by all `dis` utilities, but can be viewed with `show_caches=True`.

Logically, this space is part of the preceding instruction. Many opcodes expect to be followed by an exact number of caches, and will instruct the interpreter to skip over them at runtime.

Populated caches can look like arbitrary instructions, so great

care should be taken when reading or modifying raw, adaptive bytecode containing quickened data.

*New in version 3.11.*

## Unary operations

Unary operations take the top of the stack, apply the operation, and push the result back on the stack.

### UNARY\_POSITIVE

Implements `TOS = +TOS`.

### UNARY\_NEGATIVE

Implements `TOS = -TOS`.

### UNARY\_NOT

Implements `TOS = not TOS`.

### UNARY\_INVERT

Implements `TOS = ~TOS`.

### GET\_ITER

Implements `TOS = iter(TOS)`.

### GET\_YIELD\_FROM\_ITER

If `TOS` is a [generator iterator](#) or [coroutine](#) object it is left as is. Otherwise, implements `TOS = iter(TOS)`.

*New in version 3.5.*

## Binary and in-place operations

Binary operations remove the top of the stack (`TOS`) and the second top-most stack item (`TOS1`) from the stack. They perform the operation, and put the result back on the stack.

In-place operations are like binary operations, in that they remove `TOS` and `TOS1`, and push the result back on the stack, but the

operation is done in-place when TOS1 supports it, and the resulting TOS may be (but does not have to be) the original TOS1.

### **BINARY\_OP(*op*)**

Implements the binary and in-place operators (depending on the value of *op*).

*New in version 3.11.*

### **BINARY\_SUBSCR**

Implements `TOS = TOS1[TOS]`.

### **STORE\_SUBSCR**

Implements `TOS1[TOS] = TOS2`.

### **DELETE\_SUBSCR**

Implements `del TOS1[TOS]`.

## **Coroutine opcodes**

### **GET\_AWAITABLE(*where*)**

Implements `TOS = get_awaitable(TOS)`, where `get_awaitable(o)` returns `o` if `o` is a coroutine object or a generator object with the `CO_ITERABLE_COROUTINE` flag, or resolves `o.__await__`.

If the `where` operand is nonzero, it indicates where the instruction occurs:

- 1 After a call to `__aenter__`
- 2 After a call to `__aexit__`

*New in version 3.5.*

*Changed in version 3.11:* Previously, this instruction did not have an `oparg`.

### **GET\_AITER**

Implements `TOS = TOS.__aiter__()`.

*New in version 3.5.*

*Changed in version 3.7:* Returning awaitable objects from `__aiter__` is no longer supported.

## GET\_ANEXT

Pushes `get_awaitable(TOS.__anext__())` to the stack. See `GET_AWAITABLE` for details about `get_awaitable`.

*New in version 3.5.*

## END\_ASYNC\_FOR

Terminates an **async for** loop. Handles an exception raised when awaiting a next item. The stack contains the async iterable in TOS1 and the raised exception in TOS. Both are popped. If the exception is not **StopAsyncIteration**, it is re-raised.

*New in version 3.8.*

*Changed in version 3.11:* Exception representation on the stack now consist of one, not three, items.

## BEFORE\_ASYNC\_WITH

Resolves `__aenter__` and `__aexit__` from the object on top of the stack. Pushes `__aexit__` and result of `__aenter__()` to the stack.

*New in version 3.5.*

## Miscellaneous opcodes

### PRINT\_EXPR

Implements the expression statement for the interactive mode. TOS is removed from the stack and printed. In non-interactive mode, an expression statement is terminated with **POP\_TOP**.

### SET\_ADD(*i*)

Calls `set.add(TOS1[-i], TOS)`. Used to implement set comprehensions.

### LIST\_APPEND(*i*)

Calls `list.append(TOS1[-i], TOS)`. Used to implement list comprehensions.

### MAP\_ADD(*i*)

Calls `dict.__setitem__(TOS1[-i], TOS1, TOS)`. Used to implement dict comprehensions.

*New in version 3.1.*

*Changed in version 3.8:* Map value is TOS and map key is TOS1. Before, those were reversed.

For all of the [SET\\_ADD](#), [LIST\\_APPEND](#) and [MAP\\_ADD](#) instructions, while the added value or key/value pair is popped off, the container object remains on the stack so that it is available for further iterations of the loop.

### RETURN\_VALUE

Returns with TOS to the caller of the function.

### YIELD\_VALUE

Pops TOS and yields it from a [generator](#).

### SETUP\_ANNOTATIONS

Checks whether `__annotations__` is defined in `locals()`, if not it is set up to an empty dict. This opcode is only emitted if a class or module body contains [variable annotations](#) statically.

*New in version 3.6.*

### IMPORT\_STAR

Loads all symbols not starting with `'_'` directly from the module TOS to the local namespace. The module is popped

after loading all names. This opcode implements `from module import *`.

## POP\_EXCEPT

Pops a value from the stack, which is used to restore the exception state.

*Changed in version 3.11:* Exception representation on the stack now consist of one, not three, items.

## RERAISE

Re-raises the exception currently on top of the stack. If `oparg` is non-zero, pops an additional value from the stack which is used to set `f_lasti` of the current frame.

*New in version 3.9.*

*Changed in version 3.11:* Exception representation on the stack now consist of one, not three, items.

## PUSH\_EXC\_INFO

Pops a value from the stack. Pushes the current exception to the top of the stack. Pushes the value originally popped back to the stack. Used in exception handlers.

*New in version 3.11.*

## CHECK\_EXC\_MATCH

Performs exception matching for `except`. Tests whether the TOS1 is an exception matching TOS. Pops TOS and pushes the boolean result of the test.

*New in version 3.11.*

## CHECK\_EG\_MATCH

Performs exception matching for `except*`. Applies `split(TOS)` on the exception group representing TOS1.

In case of a match, pops two items from the stack and pushes the non-matching subgroup (`None` in case of full match) followed by the matching subgroup. When there is no match, pops one item (the match type) and pushes `None`.

*New in version 3.11.*

#### PREP\_RERAISE\_STAR

Combines the raised and reraised exceptions list from TOS, into an exception group to propagate from a try-except\* block. Uses the original exception group from TOS1 to reconstruct the structure of reraised exceptions. Pops two items from the stack and pushes the exception to reraise or `None` if there isn't one.

*New in version 3.11.*

#### WITH\_EXCEPT\_START

Calls the function in position 4 on the stack with arguments (type, val, tb) representing the exception at the top of the stack. Used to implement the call `context_manager.__exit__(*exc_info())` when an exception has occurred in a `with` statement.

*New in version 3.9.*

*Changed in version 3.11:* The `__exit__` function is in position 4 of the stack rather than 7. Exception representation on the stack now consist of one, not three, items.

#### LOAD\_ASSERTION\_ERROR

Pushes `AssertionError` onto the stack. Used by the `assert` statement.

*New in version 3.9.*

#### LOAD\_BUILD\_CLASS

Pushes `builtins.__build_class__()` onto the stack. It is later called to construct a class.

## BEFORE\_WITH(*delta*)

This opcode performs several operations before a with block starts. First, it loads `__exit__()` from the context manager and pushes it onto the stack for later use by `WITH_EXCEPT_START`. Then, `__enter__()` is called. Finally, the result of calling the `__enter__()` method is pushed onto the stack.

*New in version 3.11.*

## GET\_LEN

Push `len(TOS)` onto the stack.

*New in version 3.10.*

## MATCH\_MAPPING

If TOS is an instance of `collections.abc.Mapping` (or, more technically: if it has the `Py_TPFLAGS_MAPPING` flag set in its `tp_flags`), push `True` onto the stack. Otherwise, push `False`.

*New in version 3.10.*

## MATCH\_SEQUENCE

If TOS is an instance of `collections.abc.Sequence` and is *not* an instance of `str/bytes/bytearray` (or, more technically: if it has the `Py_TPFLAGS_SEQUENCE` flag set in its `tp_flags`), push `True` onto the stack. Otherwise, push `False`.

*New in version 3.10.*

## MATCH\_KEYS

TOS is a tuple of mapping keys, and TOS1 is the match subject. If TOS1 contains all of the keys in TOS, push a `tuple` containing the corresponding values. Otherwise, push `None`.

*New in version 3.10.*

*Changed in version 3.11:* Previously, this instruction also pushed a boolean value indicating success (`True`) or failure (`False`).

### STORE\_NAME(*namei*)

Implements `name = TOS`. *namei* is the index of *name* in the attribute **co\_names** of the code object. The compiler tries to use **STORE\_FAST** or **STORE\_GLOBAL** if possible.

### DELETE\_NAME(*namei*)

Implements `del name`, where *namei* is the index into **co\_names** attribute of the code object.

### UNPACK\_SEQUENCE(*count*)

Unpacks TOS into *count* individual values, which are put onto the stack right-to-left.

### UNPACK\_EX(*counts*)

Implements assignment with a starred target: Unpacks an iterable in TOS into individual values, where the total number of values can be smaller than the number of items in the iterable: one of the new values will be a list of all leftover items.

The low byte of *counts* is the number of values before the list value, the high byte of *counts* the number of values after it. The resulting values are put onto the stack right-to-left.

### STORE\_ATTR(*namei*)

Implements `TOS.name = TOS1`, where *namei* is the index of name in **co\_names**.

### DELETE\_ATTR(*namei*)

Implements `del TOS.name`, using *namei* as index into **co\_names**.

STORE\_GLOBAL(*namei*)

Works as [STORE\\_NAME](#), but stores the name as a global.

DELETE\_GLOBAL(*namei*)

Works as [DELETE\\_NAME](#), but deletes a global name.

LOAD\_CONST(*consti*)

Pushes `co_consts[consti]` onto the stack.

LOAD\_NAME(*namei*)

Pushes the value associated with `co_names[namei]` onto the stack.

BUILD\_TUPLE(*count*)

Creates a tuple consuming *count* items from the stack, and pushes the resulting tuple onto the stack.

BUILD\_LIST(*count*)

Works as [BUILD\\_TUPLE](#), but creates a list.

BUILD\_SET(*count*)

Works as [BUILD\\_TUPLE](#), but creates a set.

BUILD\_MAP(*count*)

Pushes a new dictionary object onto the stack. Pops  $2 * \text{count}$  items so that the dictionary holds *count* entries: `{..., TOS3: TOS2, TOS1: TOS}`.

*Changed in version 3.5:* The dictionary is created from stack items instead of creating an empty dictionary pre-sized to hold *count* items.

BUILD\_CONST\_KEY\_MAP(*count*)

The version of [BUILD\\_MAP](#) specialized for constant keys. Pops the top element on the stack which contains a tuple of

keys, then starting from `TOS1`, pops *count* values to form values in the built dictionary.

*New in version 3.6.*

### `BUILD_STRING(count)`

Concatenates *count* strings from the stack and pushes the resulting string onto the stack.

*New in version 3.6.*

### `LIST_TO_TUPLE`

Pops a list from the stack and pushes a tuple containing the same values.

*New in version 3.9.*

### `LIST_EXTEND(i)`

Calls `list.extend(TOS1[-i], TOS)`. Used to build lists.

*New in version 3.9.*

### `SET_UPDATE(i)`

Calls `set.update(TOS1[-i], TOS)`. Used to build sets.

*New in version 3.9.*

### `DICT_UPDATE(i)`

Calls `dict.update(TOS1[-i], TOS)`. Used to build dicts.

*New in version 3.9.*

### `DICT_MERGE(i)`

Like `DICT_UPDATE` but raises an exception for duplicate keys.

*New in version 3.9.*

## LOAD\_ATTR(*namei*)

Replaces TOS with `getattr(TOS, co_names[namei])`.

## COMPARE\_OP(*opname*)

Performs a Boolean operation. The operation name can be found in `cmp_op[opname]`.

## IS\_OP(*invert*)

Performs `is` comparison, or `is not` if `invert` is 1.

*New in version 3.9.*

## CONTAINS\_OP(*invert*)

Performs `in` comparison, or `not in` if `invert` is 1.

*New in version 3.9.*

## IMPORT\_NAME(*namei*)

Imports the module `co_names[namei]`. TOS and TOS1 are popped and provide the *fromlist* and *level* arguments of `\_\_import\_\_\(\)`. The module object is pushed onto the stack. The current namespace is not affected: for a proper import statement, a subsequent `STORE\_FAST` instruction modifies the namespace.

## IMPORT\_FROM(*namei*)

Loads the attribute `co_names[namei]` from the module found in TOS. The resulting object is pushed onto the stack, to be subsequently stored by a `STORE\_FAST` instruction.

## JUMP\_FORWARD(*delta*)

Increments bytecode counter by *delta*.

## JUMP\_BACKWARD(*delta*)

Decrements bytecode counter by *delta*. Checks for interrupts.

*New in version 3.11.*

`JUMP_BACKWARD_NO_INTERRUPT(delta)`

Decrements bytecode counter by *delta*. Does not check for interrupts.

*New in version 3.11.*

`POP_JUMP_FORWARD_IF_TRUE(delta)`

If TOS is true, increments the bytecode counter by *delta*. TOS is popped.

*New in version 3.11.*

`POP_JUMP_BACKWARD_IF_TRUE(delta)`

If TOS is true, decrements the bytecode counter by *delta*. TOS is popped.

*New in version 3.11.*

`POP_JUMP_FORWARD_IF_FALSE(delta)`

If TOS is false, increments the bytecode counter by *delta*. TOS is popped.

*New in version 3.11.*

`POP_JUMP_BACKWARD_IF_FALSE(delta)`

If TOS is false, decrements the bytecode counter by *delta*. TOS is popped.

*New in version 3.11.*

`POP_JUMP_FORWARD_IF_NOT_NONE(delta)`

If TOS is not `None`, increments the bytecode counter by *delta*. TOS is popped.

*New in version 3.11.*

### POP\_JUMP\_BACKWARD\_IF\_NOT\_NONE(*delta*)

If TOS is not `None`, decrements the bytecode counter by *delta*. TOS is popped.

*New in version 3.11.*

### POP\_JUMP\_FORWARD\_IF\_NONE(*delta*)

If TOS is `None`, increments the bytecode counter by *delta*. TOS is popped.

*New in version 3.11.*

### POP\_JUMP\_BACKWARD\_IF\_NONE(*delta*)

If TOS is `None`, decrements the bytecode counter by *delta*. TOS is popped.

*New in version 3.11.*

### JUMP\_IF\_TRUE\_OR\_POP(*delta*)

If TOS is true, increments the bytecode counter by *delta* and leaves TOS on the stack. Otherwise (TOS is false), TOS is popped.

*New in version 3.1.*

*Changed in version 3.11:* The oparg is now a relative delta rather than an absolute target.

### JUMP\_IF\_FALSE\_OR\_POP(*delta*)

If TOS is false, increments the bytecode counter by *delta* and leaves TOS on the stack. Otherwise (TOS is true), TOS is popped.

*New in version 3.1.*

*Changed in version 3.11:* The oparg is now a relative delta rather than an absolute target.

## FOR\_ITER(*delta*)

TOS is an [iterator](#). Call its `__next__()` method. If this yields a new value, push it on the stack (leaving the iterator below it). If the iterator indicates it is exhausted, TOS is popped, and the byte code counter is incremented by *delta*.

## LOAD\_GLOBAL(*namei*)

Loads the global named `co_names[namei>>1]` onto the stack.

*Changed in version 3.11:* If the low bit of `namei` is set, then a `NULL` is pushed to the stack before the global variable.

## LOAD\_FAST(*var\_num*)

Pushes a reference to the local `co_varnames[var_num]` onto the stack.

## STORE\_FAST(*var\_num*)

Stores TOS into the local `co_varnames[var_num]`.

## DELETE\_FAST(*var\_num*)

Deletes local `co_varnames[var_num]`.

## MAKE\_CELL(*i*)

Creates a new cell in slot `i`. If that slot is nonempty then that value is stored into the new cell.

*New in version 3.11.*

## LOAD\_CLOSURE(*i*)

Pushes a reference to the cell contained in slot `i` of the “fast locals” storage. The name of the variable is `co_fastlocalnames[i]`.

Note that `LOAD_CLOSURE` is effectively an alias for `LOAD_FAST`. It exists to keep bytecode a little more readable.

*Changed in version 3.11:* `i` is no longer offset by the length of `co_varnames`.

### LOAD\_DEREF(*i*)

Loads the cell contained in slot `i` of the “fast locals” storage. Pushes a reference to the object the cell contains on the stack.

*Changed in version 3.11:* `i` is no longer offset by the length of `co_varnames`.

### LOAD\_CLASSDEREF(*i*)

Much like [LOAD\\_DEREF](#) but first checks the locals dictionary before consulting the cell. This is used for loading free variables in class bodies.

*New in version 3.4.*

*Changed in version 3.11:* `i` is no longer offset by the length of `co_varnames`.

### STORE\_DEREF(*i*)

Stores TOS into the cell contained in slot `i` of the “fast locals” storage.

*Changed in version 3.11:* `i` is no longer offset by the length of `co_varnames`.

### DELETE\_DEREF(*i*)

Empties the cell contained in slot `i` of the “fast locals” storage. Used by the [del](#) statement.

*New in version 3.2.*

*Changed in version 3.11:* `i` is no longer offset by the length of `co_varnames`.

### COPY\_FREE\_VARS(*n*)

Copies the `n` free variables from the closure into the frame.

Removes the need for special code on the caller's side when calling closures.

*New in version 3.11.*

### `RAISE_VARARGS(argc)`

Raises an exception using one of the 3 forms of the `raise` statement, depending on the value of *argc*:

- 0: `raise` (re-raise previous exception)
- 1: `raise TOS` (raise exception instance or type at TOS)
- 2: `raise TOS1 from TOS` (raise exception instance or type at TOS1 with `__cause__` set to TOS)

### `CALL(argc)`

Calls a callable object with the number of arguments specified by *argc*, including the named arguments specified by the preceding [KW\\_NAMES](#), if any. On the stack are (in ascending order), either:

- `NULL`
- The callable
- The positional arguments
- The named arguments

or:

- The callable
- `self`
- The remaining positional arguments
- The named arguments

*argc* is the total of the positional and named arguments, excluding `self` when a `NULL` is not present.

`CALL` pops all arguments and the callable object off the stack, calls the callable object with those arguments, and pushes the return value returned by the callable object.

*New in version 3.11.*

### CALL\_FUNCTION\_EX(*flags*)

Calls a callable object with variable set of positional and keyword arguments. If the lowest bit of *flags* is set, the top of the stack contains a mapping object containing additional keyword arguments. Before the callable is called, the mapping object and iterable object are each “unpacked” and their contents passed in as keyword and positional arguments respectively. CALL\_FUNCTION\_EX pops all arguments and the callable object off the stack, calls the callable object with those arguments, and pushes the return value returned by the callable object.

*New in version 3.6.*

### LOAD\_METHOD(*namei*)

Loads a method named `co_names[namei]` from the TOS object. TOS is popped. This bytecode distinguishes two cases: if TOS has a method with the correct name, the bytecode pushes the unbound method and TOS. TOS will be used as the first argument (`self`) by **CALL** when calling the unbound method. Otherwise, `NULL` and the object return by the attribute lookup are pushed.

*New in version 3.7.*

### PRECALL(*argc*)

Prefixes **CALL**. Logically this is a no op. It exists to enable effective specialization of calls. *argc* is the number of arguments as described in **CALL**.

*New in version 3.11.*

### PUSH\_NULL

Pushes a `NULL` to the stack. Used in the call sequence to match the `NULL` pushed by **LOAD\_METHOD** for non-method calls.

*New in version 3.11.*

## KW\_NAMES(*i*)

Prefixes **PRECALL**. Stores a reference to `co_consts[consti]` into an internal variable for use by **CALL**. `co_consts[consti]` must be a tuple of strings.

*New in version 3.11.*

## MAKE\_FUNCTION(*flags*)

Pushes a new function object on the stack. From bottom to top, the consumed stack must consist of values if the argument carries a specified flag value

- `0x01` a tuple of default values for positional-only and positional-or-keyword parameters in positional order
- `0x02` a dictionary of keyword-only parameters' default values
- `0x04` a tuple of strings containing parameters' annotations
- `0x08` a tuple containing cells for free variables, making a closure
- the code associated with the function (at TOS)

*Changed in version 3.10:* Flag value `0x04` is a tuple of strings instead of dictionary

*Changed in version 3.11:* Qualified name at TOS was removed.

## BUILD\_SLICE(*argc*)

Pushes a slice object on the stack. *argc* must be 2 or 3. If it is 2, `slice(TOS1, TOS)` is pushed; if it is 3, `slice(TOS2, TOS1, TOS)` is pushed. See the **slice()** built-in function for more information.

## EXTENDED\_ARG(*ext*)

Prefixes any opcode which has an argument too big to fit into the default one byte. *ext* holds an additional byte which act as

higher bits in the argument. For each opcode, at most three prefixal `EXTENDED_ARG` are allowed, forming an argument from two-byte to four-byte.

### `FORMAT_VALUE(flags)`

Used for implementing formatted literal strings (f-strings). Pops an optional *fmt\_spec* from the stack, then a required *value*. *flags* is interpreted as follows:

- `(flags & 0x03) == 0x00`: *value* is formatted as-is.
- `(flags & 0x03) == 0x01`: call `str()` on *value* before formatting it.
- `(flags & 0x03) == 0x02`: call `repr()` on *value* before formatting it.
- `(flags & 0x03) == 0x03`: call `ascii()` on *value* before formatting it.
- `(flags & 0x04) == 0x04`: pop *fmt\_spec* from the stack and use it, else use an empty *fmt\_spec*.

Formatting is performed using `PyObject_Format()`. The result is pushed on the stack.

*New in version 3.6.*

### `MATCH_CLASS(count)`

TOS is a tuple of keyword attribute names, TOS1 is the class being matched against, and TOS2 is the match subject. *count* is the number of positional sub-patterns.

Pop TOS, TOS1, and TOS2. If TOS2 is an instance of TOS1 and has the positional and keyword attributes required by *count* and TOS, push a tuple of extracted attributes. Otherwise, push `None`.

*New in version 3.10.*

*Changed in version 3.11:* Previously, this instruction also pushed a boolean value indicating success (`True`) or failure (`False`).

## RESUME(*where*)

A no-op. Performs internal tracing, debugging and optimization checks.

The `where` operand marks where the RESUME occurs:

- 0 The start of a function
- 1 After a `yield` expression
- 2 After a `yield from` expression
- 3 After an `await` expression

*New in version 3.11.*

## RETURN\_GENERATOR

Create a generator, coroutine, or async generator from the current frame. Clear the current frame and return the newly created generator.

*New in version 3.11.*

## SEND

Sends `None` to the sub-generator of this generator. Used in `yield from` and `await` statements.

*New in version 3.11.*

## ASYNC\_GEN\_WRAP

Wraps the value on top of the stack in an `async_generator_wrapped_value`. Used to yield in async generators.

*New in version 3.11.*

## HAVE\_ARGUMENT

This is not really an opcode. It identifies the dividing line between opcodes which don't use their argument and those that do (`< HAVE_ARGUMENT` and `>= HAVE_ARGUMENT`,

respectively).

*Changed in version 3.6:* Now every instruction has an argument, but opcodes `< HAVE_ARGUMENT` ignore it. Before, only opcodes `>= HAVE_ARGUMENT` had an argument.

## Opcode collections

These collections are provided for automatic introspection of bytecode instructions:

`dis.opname`

Sequence of operation names, indexable using the bytecode.

`dis.opmap`

Dictionary mapping operation names to bytecodes.

`dis.cmp_op`

Sequence of all compare operation names.

`dis.hasconst`

Sequence of bytecodes that access a constant.

`dis.hasfree`

Sequence of bytecodes that access a free variable (note that ‘free’ in this context refers to names in the current scope that are referenced by inner scopes or names in outer scopes that are referenced from this scope. It does *not* include references to global or builtin scopes).

`dis.hasname`

Sequence of bytecodes that access an attribute by name.

`dis.hasjrel`

Sequence of bytecodes that have a relative jump target.

`dis.hasjabs`

Sequence of bytecodes that have an absolute jump target.

`dis.haslocal`

Sequence of bytecodes that access a local variable.

`dis.hascompare`

Sequence of bytecodes of Boolean operations.

# `pickletools` — Tools for pickle developers

**Source code:** [Lib/pickletools.py](https://github.com/python/cpython/tree/3.11/Lib/pickletools.py) [https://github.com/python/cpython/tree/3.11/Lib/pickletools.py]

---

This module contains various constants relating to the intimate details of the `pickle` module, some lengthy comments about the implementation, and a few useful functions for analyzing pickled data. The contents of this module are useful for Python core developers who are working on the `pickle`; ordinary users of the `pickle` module probably won't find the `pickletools` module relevant.

## Command line usage

*New in version 3.2.*

When invoked from the command line, `python -m pickletools` will disassemble the contents of one or more pickle files. Note that if you want to see the Python object stored in the pickle rather than the details of pickle format, you may want to use `-m pickle` instead. However, when the pickle file that you want to examine comes from an untrusted source, `-m pickletools` is a safer option because it does not execute pickle bytecode.

For example, with a tuple `(1, 2)` pickled in file `x.pickle`:

```
$ python -m pickle x.pickle
(1, 2)
```

```
$ python -m pickletools x.pickle
0: \x80 PROTO      3
2: K      BININT1   1
```

```
4: K      BININT1      2
6: \x86  TUPLE2
7: q      BININPUT     0
9: .      STOP
```

highest protocol among opcodes = 2

## Command line options

**-a, --annotate**

Annotate each line with a short opcode description.

**-o, --output = <file>**

Name of a file where the output should be written.

**-l, --indentlevel = <num>**

The number of blanks by which to indent a new MARK level.

**-m, --memo**

When multiple objects are disassembled, preserve memo between disassemblies.

**-p, --preamble = <preamble>**

When more than one pickle file are specified, print given preamble before each disassembly.

## Programmatic Interface

`pickletools.dis(pickle, out=None, memo=None, indentlevel=4, annotate=0)`

Outputs a symbolic disassembly of the pickle to the file-like object *out*, defaulting to `sys.stdout`. *pickle* can be a string or a file-like object. *memo* can be a Python dictionary that will be used as the pickle's memo; it can be used to perform disassemblies across multiple pickles created by the same pickler. Successive levels, indicated by MARK opcodes in the stream, are indented by *indentlevel* spaces. If a nonzero value is given to *annotate*, each opcode in the output is annotated

with a short description. The value of *annotate* is used as a hint for the column where annotation should start.

*New in version 3.2:* The *annotate* argument.

`pickletools.genops(pickle)`

Provides an [iterator](#) over all of the opcodes in a pickle, returning a sequence of (*opcode*, *arg*, *pos*) triples. *opcode* is an instance of an **OpcodeInfo** class; *arg* is the decoded value, as a Python object, of the opcode's argument; *pos* is the position at which this opcode is located. *pickle* can be a string or a file-like object.

`pickletools.optimize(picklestring)`

Returns a new equivalent pickle string after eliminating unused `PUT` opcodes. The optimized pickle is shorter, takes less transmission time, requires less storage space, and unpickles more efficiently.

# MS Windows Specific Services

This chapter describes modules that are only available on MS Windows platforms.

- **msvcrt** — Useful routines from the MS VC++ runtime
  - File Operations
  - Console I/O
  - Other Functions
- **winreg** — Windows registry access
  - Functions
  - Constants
    - HKEY\_\* Constants
    - Access Rights
    - 64-bit Specific
    - Value Types
  - Registry Handle Objects
- **winsound** — Sound-playing interface for Windows

# msvcrt — Useful routines from the MS VC++ runtime

---

These functions provide access to some useful capabilities on Windows platforms. Some higher-level modules use these functions to build the Windows implementations of their services. For example, the `getpass` module uses this in the implementation of the `getpass()` function.

Further documentation on these functions can be found in the Platform API documentation.

The module implements both the normal and wide char variants of the console I/O api. The normal API deals only with ASCII characters and is of limited use for internationalized applications. The wide char API should be used where ever possible.

*Changed in version 3.3:* Operations in this module now raise `OSError` where `IOError` was raised.

## File Operations

`msvcrt.locking(fd, mode, nbytes)`

Lock part of a file based on file descriptor *fd* from the C runtime. Raises `OSError` on failure. The locked region of the file extends from the current file position for *nbytes* bytes, and may continue beyond the end of the file. *mode* must be one of the `LK_*` constants listed below. Multiple regions in a file may be locked at the same time, but may not overlap. Adjacent regions are not merged; they must be unlocked individually.

Raises an `auditing event` `msvcrt.locking` with arguments *fd*, *mode*, *nbytes*.

`msvcrt.LK_LOCK`

`msvcrt.LK_RLCK`

Locks the specified bytes. If the bytes cannot be locked, the program immediately tries again after 1 second. If, after 10 attempts, the bytes cannot be locked, `OSError` is raised.

`msvcrt.LK_NBLCK`

`msvcrt.LK_NBRLOCK`

Locks the specified bytes. If the bytes cannot be locked, `OSError` is raised.

`msvcrt.LK_UNLOCK`

Unlocks the specified bytes, which must have been previously locked.

`msvcrt.setmode(fd, flags)`

Set the line-end translation mode for the file descriptor *fd*. To set it to text mode, *flags* should be `os.O_TEXT`; for binary, it should be `os.O_BINARY`.

`msvcrt.open_oshandle(handle, flags)`

Create a C runtime file descriptor from the file handle *handle*. The *flags* parameter should be a bitwise OR of `os.O_APPEND`, `os.O_RDONLY`, and `os.O_TEXT`. The returned file descriptor may be used as a parameter to `os.fdopen()` to create a file object.

Raises an `auditing event` `msvcrt.open_oshandle` with arguments *handle*, *flags*.

`msvcrt.get_oshandle(fd)`

Return the file handle for the file descriptor *fd*. Raises `OSError` if *fd* is not recognized.

Raises an `auditing event` `msvcrt.get_oshandle` with argument *fd*.

# Console I/O

`msvcrt.kbhit()`

Return `True` if a keypress is waiting to be read.

`msvcrt.getch()`

Read a keypress and return the resulting character as a byte string. Nothing is echoed to the console. This call will block if a keypress is not already available, but will not wait for `Enter` to be pressed. If the pressed key was a special function key, this will return `'\000'` or `'\xe0'`; the next call will return the keycode. The `Control-C` keypress cannot be read with this function.

`msvcrt.getwch()`

Wide char variant of `getch()`, returning a Unicode value.

`msvcrt.getche()`

Similar to `getch()`, but the keypress will be echoed if it represents a printable character.

`msvcrt.getwche()`

Wide char variant of `getche()`, returning a Unicode value.

`msvcrt.putch(char)`

Print the byte string *char* to the console without buffering.

`msvcrt.putwch(unicode_char)`

Wide char variant of `putch()`, accepting a Unicode value.

`msvcrt.ungetch(char)`

Cause the byte string *char* to be “pushed back” into the console buffer; it will be the next character read by `getch()` or `getche()`.

`msvcrt.ungetwch(unicode_char)`

Wide char variant of `ungetch()`, accepting a Unicode value.

## Other Functions

`msvcrt.heapmin()`

Force the `malloc()` heap to clean itself up and return unused blocks to the operating system. On failure, this raises `OSError`.

# winreg — Windows registry access

---

These functions expose the Windows registry API to Python. Instead of using an integer as the registry handle, a [handle object](#) is used to ensure that the handles are closed correctly, even if the programmer neglects to explicitly close them.

*Changed in version 3.3:* Several functions in this module used to raise a [WindowsError](#), which is now an alias of [OSError](#).

## Functions

This module offers the following functions:

`winreg.CloseKey(hkey)`

Closes a previously opened registry key. The *hkey* argument specifies a previously opened key.

### Note

If *hkey* is not closed using this method (or via [hkey.Close\(\)](#)), it is closed when the *hkey* object is destroyed by Python.

`winreg.ConnectRegistry(computer_name, key)`

Establishes a connection to a predefined registry handle on another computer, and returns a [handle object](#).

*computer\_name* is the name of the remote computer, of the form `r"\\computername"`. If `None`, the local computer is used.

key is the predefined handle to connect to.

The return value is the handle of the opened key. If the function fails, an **OSError** exception is raised.

Raises an **auditing event** `winreg.ConnectRegistry` with arguments `computer_name`, `key`.

*Changed in version 3.3:* See [above](#).

`winreg.CreateKey(key, sub_key)`

Creates or opens the specified key, returning a **handle object**.

key is an already open key, or one of the predefined **HKEY\_\* constants**.

sub\_key is a string that names the key this method opens or creates.

If key is one of the predefined keys, sub\_key may be `None`. In that case, the handle returned is the same key handle passed in to the function.

If the key already exists, this function opens the existing key.

The return value is the handle of the opened key. If the function fails, an **OSError** exception is raised.

Raises an **auditing event** `winreg.CreateKey` with arguments `key`, `sub_key`, `access`.

Raises an **auditing event** `winreg.OpenKey/result` with argument `key`.

*Changed in version 3.3:* See [above](#).

`winreg.CreateKeyEx(key, sub_key, reserved=0, access=KEY_WRITE)`

Creates or opens the specified key, returning a **handle object**.

key is an already open key, or one of the predefined **HKEY\_\* constants**.

*sub\_key* is a string that names the key this method opens or creates.

*reserved* is a reserved integer, and must be zero. The default is zero.

*access* is an integer that specifies an access mask that describes the desired security access for the key. Default is [KEY\\_WRITE](#). See [Access Rights](#) for other allowed values.

If *key* is one of the predefined keys, *sub\_key* may be `None`. In that case, the handle returned is the same key handle passed in to the function.

If the key already exists, this function opens the existing key.

The return value is the handle of the opened key. If the function fails, an [OSError](#) exception is raised.

Raises an [auditing event](#) `winreg.CreateKey` with arguments `key`, `sub_key`, `access`.

Raises an [auditing event](#) `winreg.OpenKey/result` with argument `key`.

*New in version 3.2.*

*Changed in version 3.3:* See [above](#).

`winreg.DeleteKey(key, sub_key)`

Deletes the specified key.

*key* is an already open key, or one of the predefined [HKEY\\_\\* constants](#).

*sub\_key* is a string that must be a subkey of the key identified by the *key* parameter. This value must not be `None`, and the key may not have subkeys.

*This method can not delete keys with subkeys.*

If the method succeeds, the entire key, including all of its

values, is removed. If the method fails, an **OSError** exception is raised.

Raises an **auditing event** `winreg.DeleteKey` with arguments `key`, `sub_key`, `access`.

*Changed in version 3.3:* See [above](#).

```
winreg.DeleteKeyEx(key, sub_key, access=KEY_WOW64_64KEY,  
reserved=0)
```

Deletes the specified key.

`key` is an already open key, or one of the predefined **HKEY\_\* constants**.

`sub_key` is a string that must be a subkey of the key identified by the `key` parameter. This value must not be `None`, and the key may not have subkeys.

`reserved` is a reserved integer, and must be zero. The default is zero.

`access` is an integer that specifies an access mask that describes the desired security access for the key. Default is **KEY\_WOW64\_64KEY**. On 32-bit Windows, the WOW64 constants are ignored. See [Access Rights](#) for other allowed values.

*This method can not delete keys with subkeys.*

If the method succeeds, the entire key, including all of its values, is removed. If the method fails, an **OSError** exception is raised.

On unsupported Windows versions, **NotImplementedError** is raised.

Raises an **auditing event** `winreg.DeleteKey` with arguments `key`, `sub_key`, `access`.

*New in version 3.2.*

*Changed in version 3.3: See [above](#).*

`winreg.DeleteValue(key, value)`

Removes a named value from a registry key.

*key* is an already open key, or one of the predefined [HKEY\\_\\* constants](#).

*value* is a string that identifies the value to remove.

Raises an [auditing event](#) `winreg.DeleteValue` with arguments `key`, `value`.

`winreg.EnumKey(key, index)`

Enumerates subkeys of an open registry key, returning a string.

*key* is an already open key, or one of the predefined [HKEY\\_\\* constants](#).

*index* is an integer that identifies the index of the key to retrieve.

The function retrieves the name of one subkey each time it is called. It is typically called repeatedly until an [OSError](#) exception is raised, indicating, no more values are available.

Raises an [auditing event](#) `winreg.EnumKey` with arguments `key`, `index`.

*Changed in version 3.3: See [above](#).*

`winreg.EnumValue(key, index)`

Enumerates values of an open registry key, returning a tuple.

*key* is an already open key, or one of the predefined [HKEY\\_\\* constants](#).

*index* is an integer that identifies the index of the value to retrieve.

The function retrieves the name of one subkey each time it is called. It is typically called repeatedly, until an [OSError](#) exception is raised, indicating no more values.

The result is a tuple of 3 items:

#### **Indexing**

---

A string that identifies the value name

---

An object that holds the value data, and whose type depends on the underlying registry type

---

An integer that identifies the type of the value data (see table in docs for [SetValueEx\(\)](#))

---

Raises an [auditing event](#) `winreg.EnumValue` with arguments `key`, `index`.

*Changed in version 3.3:* See [above](#).

### `winreg.ExpandEnvironmentStrings(str)`

Expands environment variable placeholders `%NAME%` in strings like [REG\\_EXPAND\\_SZ](#):

```
>>> ExpandEnvironmentStrings('%windir%')
'C:\\Windows'
```

Raises an [auditing event](#)

`winreg.ExpandEnvironmentStrings` with argument `str`.

### `winreg.FlushKey(key)`

Writes all the attributes of a key to the registry.

`key` is an already open key, or one of the predefined [HKEY\\_\\* constants](#).

It is not necessary to call [FlushKey\(\)](#) to change a key. Registry changes are flushed to disk by the registry using its lazy flusher. Registry changes are also flushed to disk at system shutdown. Unlike [CloseKey\(\)](#), the [FlushKey\(\)](#) method returns only when all the data has been written to the

registry. An application should only call **FlushKey()** if it requires absolute certainty that registry changes are on disk.

### Note

If you don't know whether a **FlushKey()** call is required, it probably isn't.

**winreg.LoadKey(*key*, *sub\_key*, *file\_name*)**

Creates a subkey under the specified key and stores registration information from a specified file into that subkey.

*key* is a handle returned by **ConnectRegistry()** or one of the constants **HKEY\_USERS** or **HKEY\_LOCAL\_MACHINE**.

*sub\_key* is a string that identifies the subkey to load.

*file\_name* is the name of the file to load registry data from. This file must have been created with the **SaveKey()** function. Under the file allocation table (FAT) file system, the filename may not have an extension.

A call to **LoadKey()** fails if the calling process does not have the **SE\_RESTORE\_PRIVILEGE** privilege. Note that privileges are different from permissions – see the [RegLoadKey documentation](https://msdn.microsoft.com/en-us/library/ms724889%28v=VS.85%29.aspx) [https://msdn.microsoft.com/en-us/library/ms724889%28v=VS.85%29.aspx] for more details.

If *key* is a handle returned by **ConnectRegistry()**, then the path specified in *file\_name* is relative to the remote computer.

Raises an [auditing event](#) winreg.LoadKey with arguments *key*, *sub\_key*, *file\_name*.

**winreg.OpenKey(*key*, *sub\_key*, *reserved*=0, *access*=KEY\_READ)**

**winreg.OpenKeyEx(*key*, *sub\_key*, *reserved*=0, *access*=KEY\_READ)**

Opens the specified key, returning a [handle object](#).

*key* is an already open key, or one of the predefined [HKEY\\_\\* constants](#).

*sub\_key* is a string that identifies the sub\_key to open.

*reserved* is a reserved integer, and must be zero. The default is zero.

*access* is an integer that specifies an access mask that describes the desired security access for the key. Default is [KEY\\_READ](#). See [Access Rights](#) for other allowed values.

The result is a new handle to the specified key.

If the function fails, [OSError](#) is raised.

Raises an [auditing event](#) `winreg.OpenKey` with arguments `key`, `sub_key`, `access`.

Raises an [auditing event](#) `winreg.OpenKey/result` with argument `key`.

*Changed in version 3.2:* Allow the use of named arguments.

*Changed in version 3.3:* See [above](#).

`winreg.QueryInfoKey(key)`

Returns information about a key, as a tuple.

*key* is an already open key, or one of the predefined [HKEY\\_\\* constants](#).

The result is a tuple of 3 items:

**~~Meaning~~**

---

An integer giving the number of sub keys this key has.

---

An integer giving the number of values this key has.

---

An integer giving when the key was last modified (if available) as 100's of nanoseconds since Jan 1, 1601.

---

Raises an [auditing event](#) `winreg.QueryInfoKey` with argument `key`.

`winreg.QueryValue(key, sub_key)`

Retrieves the unnamed value for a key, as a string.

*key* is an already open key, or one of the predefined [HKEY\\_\\* constants](#).

*sub\_key* is a string that holds the name of the subkey with which the value is associated. If this parameter is `None` or empty, the function retrieves the value set by the [SetValue\(\)](#) method for the key identified by *key*.

Values in the registry have name, type, and data components. This method retrieves the data for a key's first value that has a `NULL` name. But the underlying API call doesn't return the type, so always use [QueryValueEx\(\)](#) if possible.

Raises an [auditing event](#) `winreg.QueryValue` with arguments `key`, `sub_key`, `value_name`.

`winreg.QueryValueEx(key, value_name)`

Retrieves the type and data for a specified value name associated with an open registry key.

*key* is an already open key, or one of the predefined [HKEY\\_\\* constants](#).

*value\_name* is a string indicating the value to query.

The result is a tuple of 2 items:

### **Maxing**

---

The value of the registry item.

---

An integer giving the registry type for this value (see table in docs for [SetValueEx\(\)](#))

---

Raises an [auditing event](#) `winreg.QueryValue` with arguments `key`, `sub_key`, `value_name`.

`winreg.SaveKey(key, file_name)`

Saves the specified key, and all its subkeys to the specified

file.

*key* is an already open key, or one of the predefined [HKEY\\_\\* constants](#).

*file\_name* is the name of the file to save registry data to. This file cannot already exist. If this filename includes an extension, it cannot be used on file allocation table (FAT) file systems by the [LoadKey\(\)](#) method.

If *key* represents a key on a remote computer, the path described by *file\_name* is relative to the remote computer. The caller of this method must possess the **SeBackupPrivilege** security privilege. Note that privileges are different than permissions – see the [Conflicts Between User Rights and Permissions documentation](#) [<https://msdn.microsoft.com/en-us/library/ms724878%28v=VS.85%29.aspx>] for more details.

This function passes `NULL` for *security\_attributes* to the API.

Raises an [auditing event](#) `winreg.SaveKey` with arguments *key*, *file\_name*.

`winreg.SetValue(key, sub_key, type, value)`

Associates a value with a specified key.

*key* is an already open key, or one of the predefined [HKEY\\_\\* constants](#).

*sub\_key* is a string that names the subkey with which the value is associated.

*type* is an integer that specifies the type of the data. Currently this must be [REG\\_SZ](#), meaning only strings are supported. Use the [SetValueEx\(\)](#) function for support for other data types.

*value* is a string that specifies the new value.

If the key specified by the *sub\_key* parameter does not exist, the `SetValue` function creates it.

Value lengths are limited by available memory. Long values (more than 2048 bytes) should be stored as files with the filenames stored in the configuration registry. This helps the registry perform efficiently.

The key identified by the *key* parameter must have been opened with **KEY\_SET\_VALUE** access.

Raises an **auditing event** `winreg.SetValue` with arguments *key*, *sub\_key*, *type*, *value*.

`winreg.SetValueEx(key, value_name, reserved, type, value)`

Stores data in the value field of an open registry key.

*key* is an already open key, or one of the predefined **HKEY\_\* constants**.

*value\_name* is a string that names the subkey with which the value is associated.

*reserved* can be anything – zero is always passed to the API.

*type* is an integer that specifies the type of the data. See **Value Types** for the available types.

*value* is a string that specifies the new value.

This method can also set additional value and type information for the specified key. The key identified by the *key* parameter must have been opened with **KEY\_SET\_VALUE** access.

To open the key, use the **CreateKey()** or **OpenKey()** methods.

Value lengths are limited by available memory. Long values (more than 2048 bytes) should be stored as files with the filenames stored in the configuration registry. This helps the registry perform efficiently.

Raises an **auditing event** `winreg.SetValue` with arguments

key, sub\_key, type, value.

### winreg.DisableReflectionKey(key)

Disables registry reflection for 32-bit processes running on a 64-bit operating system.

key is an already open key, or one of the predefined [HKEY\\_\\* constants](#).

Will generally raise [NotImplementedError](#) if executed on a 32-bit operating system.

If the key is not on the reflection list, the function succeeds but has no effect. Disabling reflection for a key does not affect reflection of any subkeys.

Raises an [auditing event](#) winreg.DisableReflectionKey with argument key.

### winreg.EnableReflectionKey(key)

Restores registry reflection for the specified disabled key.

key is an already open key, or one of the predefined [HKEY\\_\\* constants](#).

Will generally raise [NotImplementedError](#) if executed on a 32-bit operating system.

Restoring reflection for a key does not affect reflection of any subkeys.

Raises an [auditing event](#) winreg.EnableReflectionKey with argument key.

### winreg.QueryReflectionKey(key)

Determines the reflection state for the specified key.

key is an already open key, or one of the predefined [HKEY\\_\\* constants](#).

Returns `True` if reflection is disabled.

Will generally raise `NotImplementedError` if executed on a 32-bit operating system.

Raises an `auditing event` `winreg.QueryReflectionKey` with argument `key`.

## Constants

The following constants are defined for use in many `_winreg` functions.

### **HKEY\_\* Constants**

`winreg.HKEY_CLASSES_ROOT`

Registry entries subordinate to this key define types (or classes) of documents and the properties associated with those types. Shell and COM applications use the information stored under this key.

`winreg.HKEY_CURRENT_USER`

Registry entries subordinate to this key define the preferences of the current user. These preferences include the settings of environment variables, data about program groups, colors, printers, network connections, and application preferences.

`winreg.HKEY_LOCAL_MACHINE`

Registry entries subordinate to this key define the physical state of the computer, including data about the bus type, system memory, and installed hardware and software.

`winreg.HKEY_USERS`

Registry entries subordinate to this key define the default user configuration for new users on the local computer and the user configuration for the current user.

`winreg.HKEY_PERFORMANCE_DATA`

Registry entries subordinate to this key allow you to access performance data. The data is not actually stored in the registry; the registry functions cause the system to collect the data from its source.

winreg.HKEY\_CURRENT\_CONFIG

Contains information about the current hardware profile of the local computer system.

winreg.HKEY\_DYN\_DATA

This key is not used in versions of Windows after 98.

## Access Rights

For more information, see [Registry Key Security and Access](https://msdn.microsoft.com/en-us/library/ms724878%28v=VS.85%29.aspx) [https://msdn.microsoft.com/en-us/library/ms724878%28v=VS.85%29.aspx].

winreg.KEY\_ALL\_ACCESS

Combines the STANDARD\_RIGHTS\_REQUIRED, [KEY\\_QUERY\\_VALUE](#), [KEY\\_SET\\_VALUE](#), [KEY\\_CREATE\\_SUB\\_KEY](#), [KEY\\_ENUMERATE\\_SUB\\_KEYS](#), [KEY\\_NOTIFY](#), and [KEY\\_CREATE\\_LINK](#) access rights.

winreg.KEY\_WRITE

Combines the STANDARD\_RIGHTS\_WRITE, [KEY\\_SET\\_VALUE](#), and [KEY\\_CREATE\\_SUB\\_KEY](#) access rights.

winreg.KEY\_READ

Combines the STANDARD\_RIGHTS\_READ, [KEY\\_QUERY\\_VALUE](#), [KEY\\_ENUMERATE\\_SUB\\_KEYS](#), and [KEY\\_NOTIFY](#) values.

winreg.KEY\_EXECUTE

Equivalent to [KEY\\_READ](#).

winreg.KEY\_QUERY\_VALUE

Required to query the values of a registry key.

winreg.KEY\_SET\_VALUE

Required to create, delete, or set a registry value.

winreg.KEY\_CREATE\_SUB\_KEY

Required to create a subkey of a registry key.

winreg.KEY\_ENUMERATE\_SUB\_KEYS

Required to enumerate the subkeys of a registry key.

winreg.KEY\_NOTIFY

Required to request change notifications for a registry key or for subkeys of a registry key.

winreg.KEY\_CREATE\_LINK

Reserved for system use.

## 64-bit Specific

For more information, see [Accessing an Alternate Registry View](https://msdn.microsoft.com/en-us/library/aa384129(v=VS.85).aspx)

[[https://msdn.microsoft.com/en-us/library/aa384129\(v=VS.85\).aspx](https://msdn.microsoft.com/en-us/library/aa384129(v=VS.85).aspx)].

winreg.KEY\_WOW64\_64KEY

Indicates that an application on 64-bit Windows should operate on the 64-bit registry view. On 32-bit Windows, this constant is ignored.

winreg.KEY\_WOW64\_32KEY

Indicates that an application on 64-bit Windows should operate on the 32-bit registry view. On 32-bit Windows, this constant is ignored.

## Value Types

For more information, see [Registry Value Types](https://msdn.microsoft.com/en-us/library/ms724884%28v=VS.85%29.aspx) [<https://msdn.microsoft.com/en-us/library/ms724884%28v=VS.85%29.aspx>].

winreg.REG\_BINARY

Binary data in any form.

winreg.REG\_DWORD

32-bit number.

winreg.REG\_DWORD\_LITTLE\_ENDIAN

A 32-bit number in little-endian format. Equivalent to [REG\\_DWORD](#).

winreg.REG\_DWORD\_BIG\_ENDIAN

A 32-bit number in big-endian format.

winreg.REG\_EXPAND\_SZ

Null-terminated string containing references to environment variables (%PATH%).

winreg.REG\_LINK

A Unicode symbolic link.

winreg.REG\_MULTI\_SZ

A sequence of null-terminated strings, terminated by two null characters. (Python handles this termination automatically.)

winreg.REG\_NONE

No defined value type.

winreg.REG\_QWORD

A 64-bit number.

*New in version 3.6.*

winreg.REG\_QWORD\_LITTLE\_ENDIAN

A 64-bit number in little-endian format. Equivalent to [REG\\_QWORD](#).

*New in version 3.6.*

winreg.REG\_RESOURCE\_LIST

A device-driver resource list.

winreg.REG\_FULL\_RESOURCE\_DESCRIPTOR

A hardware setting.

winreg.REG\_RESOURCE\_REQUIREMENTS\_LIST

A hardware resource list.

winreg.REG\_SZ

A null-terminated string.

## Registry Handle Objects

This object wraps a Windows HKEY object, automatically closing it when the object is destroyed. To guarantee cleanup, you can call either the `Close()` method on the object, or the `CloseKey()` function.

All registry functions in this module return one of these objects.

All registry functions in this module which accept a handle object also accept an integer, however, use of the handle object is encouraged.

Handle objects provide semantics for `__bool__()` – thus

```
if handle:
    print("Yes")
```

will print `Yes` if the handle is currently valid (has not been closed or detached).

The object also support comparison semantics, so handle objects will compare true if they both reference the same underlying Windows handle value.

Handle objects can be converted to an integer (e.g., using the built-in `int()` function), in which case the underlying Windows handle

value is returned. You can also use the `Detach()` method to return the integer handle, and also disconnect the Windows handle from the handle object.

### `PyHKEY.Close()`

Closes the underlying Windows handle.

If the handle is already closed, no error is raised.

### `PyHKEY.Detach()`

Detaches the Windows handle from the handle object.

The result is an integer that holds the value of the handle before it is detached. If the handle is already detached or closed, this will return zero.

After calling this function, the handle is effectively invalidated, but the handle is not closed. You would call this function when you need the underlying Win32 handle to exist beyond the lifetime of the handle object.

Raises an [auditing event](#) `winreg.PyHKEY.Detach` with argument `key`.

### `PyHKEY.__enter__()`

### `PyHKEY.__exit__(*exc_info)`

The HKEY object implements `__enter__()` and `__exit__()` and thus supports the context protocol for the `with` statement:

```
with OpenKey(HKEY_LOCAL_MACHINE, "foo") as key:
    ... # work with key
```

will automatically close `key` when control leaves the `with` block.

# winsound — Sound-playing interface for Windows

---

The **winsound** module provides access to the basic sound-playing machinery provided by Windows platforms. It includes functions and several constants.

`winsound.Beep(frequency, duration)`

Beep the PC's speaker. The *frequency* parameter specifies frequency, in hertz, of the sound, and must be in the range 37 through 32,767. The *duration* parameter specifies the number of milliseconds the sound should last. If the system is not able to beep the speaker, **RuntimeError** is raised.

`winsound.PlaySound(sound, flags)`

Call the underlying **PlaySound()** function from the Platform API. The *sound* parameter may be a filename, a system sound alias, audio data as a **bytes-like object**, or `None`. Its interpretation depends on the value of *flags*, which can be a bitwise ORed combination of the constants described below. If the *sound* parameter is `None`, any currently playing waveform sound is stopped. If the system indicates an error, **RuntimeError** is raised.

`winsound.MessageBeep(type = MB_OK)`

Call the underlying **MessageBeep()** function from the Platform API. This plays a sound as specified in the registry. The *type* argument specifies which sound to play; possible values are `-1`, `MB_ICONASTERISK`, `MB_ICONEXCLAMATION`, `MB_ICONHAND`, `MB_ICONQUESTION`, and `MB_OK`, all described below. The value `-1` produces a “simple beep”; this is the final fallback if a sound cannot be played otherwise. If the system indicates

an error, `RuntimeError` is raised.

#### `winsound.SND_FILENAME`

The *sound* parameter is the name of a WAV file. Do not use with `SND_ALIAS`.

#### `winsound.SND_ALIAS`

The *sound* parameter is a sound association name from the registry. If the registry contains no such name, play the system default sound unless `SND_NODEFAULT` is also specified. If no default sound is registered, raise `RuntimeError`. Do not use with `SND_FILENAME`.

All Win32 systems support at least the following; most systems support many more:

<del>Corresponding Control</del>	Control Panel Sound name
<del>Asterisk</del>	Asterisk'
<del>Exclamation</del>	Exclamation'
<del>Exit Window</del>	Exit Window'
<del>Critical Stop</del>	Critical Stop'
<del>Question</del>	Question'

For example:

```
import winsound
# Play Windows exit sound.
winsound.PlaySound("SystemExit", winsound.SND_ALIAS)

# Probably play Windows default sound, if any is registered.
# "*" probably isn't the registered name of any sound.
winsound.PlaySound("*", winsound.SND_ALIAS)
```

#### `winsound.SND_LOOP`

Play the sound repeatedly. The `SND_ASYNC` flag must also be used to avoid blocking. Cannot be used with `SND_MEMORY`.

#### `winsound.SND_MEMORY`

The *sound* parameter to `PlaySound()` is a memory image of

a WAV file, as a [bytes-like object](#).

### **Note**

This module does not support playing from a memory image asynchronously, so a combination of this flag and [SND\\_ASYNC](#) will raise [RuntimeError](#).

`winsound.SND_PURGE`

Stop playing all instances of the specified sound.

### **Note**

This flag is not supported on modern Windows platforms.

`winsound.SND_ASYNC`

Return immediately, allowing sounds to play asynchronously.

`winsound.SND_NODEFAULT`

If the specified sound cannot be found, do not play the system default sound.

`winsound.SND_NOSTOP`

Do not interrupt sounds currently playing.

`winsound.SND_NOWAIT`

Return immediately if the sound driver is busy.

### **Note**

This flag is not supported on modern Windows platforms.

`winsound.MB_ICONASTERISK`

Play the `SystemDefault` sound.

winsound.MB\_ICONEXCLAMATION

Play the SystemExclamation sound.

winsound.MB\_ICONHAND

Play the SystemHand sound.

winsound.MB\_ICONQUESTION

Play the SystemQuestion sound.

winsound.MB\_OK

Play the SystemDefault sound.

# Unix Specific Services

The modules described in this chapter provide interfaces to features that are unique to the Unix operating system, or in some cases to some or many variants of it. Here's an overview:

- **posix** — The most common POSIX system calls
  - Large File Support
  - Notable Module Contents
- **pwd** — The password database
- **grp** — The group database
- **termios** — POSIX style tty control
  - Example
- **tty** — Terminal control functions
- **pty** — Pseudo-terminal utilities
  - Example
- **fcntl** — The **fcntl** and **ioctl** system calls
- **resource** — Resource usage information
  - Resource Limits
  - Resource Usage
- **syslog** — Unix syslog library routines
  - Examples
    - Simple example

# posix — The most common POSIX system calls

---

This module provides access to operating system functionality that is standardized by the C Standard and the POSIX standard (a thinly disguised Unix interface).

**Do not import this module directly.** Instead, import the module `os`, which provides a *portable* version of this interface. On Unix, the `os` module provides a superset of the `posix` interface. On non-Unix operating systems the `posix` module is not available, but a subset is always available through the `os` interface. Once `os` is imported, there is *no* performance penalty in using it instead of `posix`. In addition, `os` provides some additional functionality, such as automatically calling `putenv()` when an entry in `os.environ` is changed.

Errors are reported as exceptions; the usual exceptions are given for type errors, while errors reported by the system calls raise `OSError`.

## Large File Support

Several operating systems (including AIX and Solaris) provide support for files that are larger than 2 GiB from a C programming model where `int` and `long` are 32-bit values. This is typically accomplished by defining the relevant size and offset types as 64-bit values. Such files are sometimes referred to as *large files*.

Large file support is enabled in Python when the size of an `off_t` is larger than a `long` and the `long long` is at least as large as an `off_t`. It may be necessary to configure and compile Python with certain compiler flags to enable this mode. For example, with Solaris 2.6 and 2.7 you need to do something like:

```
CFLAGS="\`getconf LFS_CFLAGS`" OPT="-g -O2 $CFLAGS" \  
./configure
```

On large-file-capable Linux systems, this might work:

```
CFLAGS='-D_LARGEFILE64_SOURCE -D_FILE_OFFSET_BITS=64' OF  
./configure
```

## Notable Module Contents

In addition to many functions described in the `os` module documentation, `posix` defines the following data item:

`posix.envIRON`

A dictionary representing the string environment at the time the interpreter was started. Keys and values are bytes on Unix and str on Windows. For example, `environ[b'HOME']` (`environ['HOME']` on Windows) is the pathname of your home directory, equivalent to `getenv("HOME")` in C.

Modifying this dictionary does not affect the string environment passed on by `execv()`, `popen()` or `system()`; if you need to change the environment, pass `environ` to `execve()` or add variable assignments and export statements to the command string for `system()` or `popen()`.

*Changed in version 3.2:* On Unix, keys and values are bytes.

### Note

The `os` module provides an alternate implementation of `environ` which updates the environment on modification. Note also that updating `os.environ` will render this dictionary obsolete. Use of the `os` module version of this is recommended over direct access to the `posix` module.

# pwd — The password database

---

This module provides access to the Unix user account and password database. It is available on all Unix versions.

**Availability:** not Emscripten, not WASI.

This module does not work or is not available on WebAssembly platforms `wasm32-emscripten` and `wasm32-wasi`. See [WebAssembly platforms](#) for more information.

Password database entries are reported as a tuple-like object, whose attributes correspond to the members of the `passwd` structure (Attribute field below, see `<pwd.h>`):

## Members

<code>pw_name</code>
<code>pw_passwd</code>
<code>pw_uid</code>
<code>pw_gid</code>
<code>pw_gecos</code>
<code>pw_dir</code>
<code>pw_shell</code>

The uid and gid items are integers, all others are strings.

**KeyError** is raised if the entry asked for cannot be found.

## Note

In traditional Unix the field `pw_passwd` usually contains a password encrypted with a DES derived algorithm (see module [crypt](#)). However most modern unices use a so-called *shadow password* system. On those unices the `pw_passwd` field only contains an asterisk ('\*') or the letter 'x' where the encrypted password is stored in a file `/etc/shadow` which is not world readable. Whether the `pw_passwd` field contains anything useful is

system-dependent. If available, the [spwd](#) module should be used where access to the encrypted password is required.

It defines the following items:

`pwd.getpwuid(uid)`

Return the password database entry for the given numeric user ID.

`pwd.getpwnam(name)`

Return the password database entry for the given user name.

`pwd.getpwall()`

Return a list of all available password database entries, in arbitrary order.

### See also

#### Module [grp](#)

An interface to the group database, similar to this.

#### Module [spwd](#)

An interface to the shadow password database, similar to this.

# grp — The group database

---

This module provides access to the Unix group database. It is available on all Unix versions.

**Availability:** not Emscripten, not WASI.

This module does not work or is not available on WebAssembly platforms `wasm32-emscripten` and `wasm32-wasi`. See [WebAssembly platforms](#) for more information.

Group database entries are reported as a tuple-like object, whose attributes correspond to the members of the `group` structure (Attribute field below, see `<grp.h>`):

## Members

---

<code>gr_name</code>	name of the group
<code>gr_passwd</code>	(optional) group password; often empty
<code>gr_gid</code>	numerical group ID
<code>gr_mem</code>	group member's user names

---

The `gid` is an integer, `name` and `password` are strings, and the `member` list is a list of strings. (Note that most users are not explicitly listed as members of the group they are in according to the password database. Check both databases to get complete membership information. Also note that a `gr_name` that starts with a `+` or `-` is likely to be a YP/NIS reference and may not be accessible via `getgrnam()` or `getgrgid().`)

It defines the following items:

`grp.getgrgid(id)`

Return the group database entry for the given numeric group ID. **KeyError** is raised if the entry asked for cannot be found.

*Changed in version 3.10:* `TypeError` is raised for non-integer arguments like floats or strings.

`grp.getgrnam(name)`

Return the group database entry for the given group name.  
`KeyError` is raised if the entry asked for cannot be found.

`grp.getgrall()`

Return a list of all available group entries, in arbitrary order.

An interface to the user database, similar to this.

#### Module `spwd`

An interface to the shadow password database, similar to this.

# `termios` — POSIX style tty control

---

This module provides an interface to the POSIX calls for tty I/O control. For a complete description of these calls, see [termios\(3\)](#) Unix manual page. It is only available for those Unix versions that support POSIX *termios* style tty I/O control configured during installation.

All functions in this module take a file descriptor *fd* as their first argument. This can be an integer file descriptor, such as returned by `sys.stdin.fileno()`, or a [file object](#), such as `sys.stdin` itself.

This module also defines all the constants needed to work with the functions provided here; these have the same name as their counterparts in C. Please refer to your system documentation for more information on using these terminal control interfaces.

The module defines the following functions:

`termios.tcgetattr(fd)`

Return a list containing the tty attributes for file descriptor *fd*, as follows: [*iflag*, *oflag*, *cflag*, *lflag*, *ispeed*, *ospeed*, *cc*] where *cc* is a list of the tty special characters (each a string of length 1, except the items with indices **VMIN** and **VTIME**, which are integers when these fields are defined). The interpretation of the flags and the speeds as well as the indexing in the *cc* array must be done using the symbolic constants defined in the [termios](#) module.

`termios.tcsetattr(fd, when, attributes)`

Set the tty attributes for file descriptor *fd* from the *attributes*, which is a list like the one returned by [tcgetattr\(\)](#). The *when* argument determines when the attributes are changed:

**TCSANOW** to change immediately, **TCSADRAIN** to change after transmitting all queued output, or **TCSAFLUSH** to change after transmitting all queued output and discarding all queued input.

`termios.tcsendbreak(fd, duration)`

Send a break on file descriptor *fd*. A zero *duration* sends a break for 0.25–0.5 seconds; a nonzero *duration* has a system dependent meaning.

`termios.tcdrain(fd)`

Wait until all output written to file descriptor *fd* has been transmitted.

`termios.tcflush(fd, queue)`

Discard queued data on file descriptor *fd*. The *queue* selector specifies which queue: **TCIFLUSH** for the input queue, **TCOFLUSH** for the output queue, or **TCIOFLUSH** for both queues.

`termios.tcflow(fd, action)`

Suspend or resume input or output on file descriptor *fd*. The *action* argument can be **TCOOFF** to suspend output, **TCOON** to restart output, **TCIOFF** to suspend input, or **TCION** to restart input.

`termios.tcgetwinsize(fd)`

Return a tuple (*ws\_row*, *ws\_col*) containing the tty window size for file descriptor *fd*. Requires **termios.TIOCGWINSZ** or **termios.TIOCGSIZE**.

*New in version 3.11.*

`termios.tcsetwinsize(fd, winsize)`

Set the tty window size for file descriptor *fd* from *winsize*, which is a two-item tuple (*ws\_row*, *ws\_col*) like the one returned by `tcgetwinsize()`. Requires at least one of the

pairs (`termios.TIOCGWINSZ`, `termios.TIOCSWINSZ`); (`termios.TIOCGSIZE`, `termios.TIOCSSIZE`) to be defined.

*New in version 3.11.*

## See also

### Module `tty`

Convenience functions for common terminal control operations.

## Example

Here's a function that prompts for a password with echoing turned off. Note the technique using a separate `tcgetattr()` call and a `try ... finally` statement to ensure that the old `tty` attributes are restored exactly no matter what happens:

```
def getpass(prompt="Password: "):
    import termios, sys
    fd = sys.stdin.fileno()
    old = termios.tcgetattr(fd)
    new = termios.tcgetattr(fd)
    new[3] = new[3] & ~termios.ECHO           # lflags
    try:
        termios.tcsetattr(fd, termios.TCSADRAIN, new)
        passwd = input(prompt)
    finally:
        termios.tcsetattr(fd, termios.TCSADRAIN, old)
    return passwd
```

# tty — Terminal control functions

**Source code:** [Lib/tty.py](https://github.com/python/cpython/tree/3.11/Lib/tty.py) [https://github.com/python/cpython/tree/3.11/Lib/tty.py]

---

The **tty** module defines functions for putting the tty into cbreak and raw modes.

Because it requires the **termios** module, it will work only on Unix.

The **tty** module defines the following functions:

`tty.setraw(fd, when = termios.TCSAFLUSH)`

Change the mode of the file descriptor *fd* to raw. If *when* is omitted, it defaults to **termios.TCSAFLUSH**, and is passed to **termios.tcsetattr()**.

`tty.setcbreak(fd, when = termios.TCSAFLUSH)`

Change the mode of file descriptor *fd* to cbreak. If *when* is omitted, it defaults to **termios.TCSAFLUSH**, and is passed to **termios.tcsetattr()**.

See also

**Module** **termios**

Low-level terminal control interface.

# pty — Pseudo-terminal utilities

**Source code:** [Lib/pty.py](https://github.com/python/cpython/tree/3.11/Lib/pty.py) [https://github.com/python/cpython/tree/3.11/Lib/pty.py]

---

The **pty** module defines operations for handling the pseudo-terminal concept: starting another process and being able to write to and read from its controlling terminal programmatically.

Pseudo-terminal handling is highly platform dependent. This code is mainly tested on Linux, FreeBSD, and macOS (it is supposed to work on other POSIX platforms but it's not been thoroughly tested).

The **pty** module defines the following functions:

`pty.fork()`

Fork. Connect the child's controlling terminal to a pseudo-terminal. Return value is `(pid, fd)`. Note that the child gets *pid* 0, and the *fd* is *invalid*. The parent's return value is the *pid* of the child, and *fd* is a file descriptor connected to the child's controlling terminal (and also to the child's standard input and output).

`pty.openpty()`

Open a new pseudo-terminal pair, using `os.openpty()` if possible, or emulation code for generic Unix systems. Return a pair of file descriptors `(master, slave)`, for the master and the slave end, respectively.

`pty.spawn(argv[, master_read[, stdin_read]])`

Spawn a process, and connect its controlling terminal with the current process's standard io. This is often used to baffle programs which insist on reading from the controlling terminal. It is expected that the process spawned behind the

pty will eventually terminate, and when it does *spawn* will return.

A loop copies STDIN of the current process to the child and data received from the child to STDOUT of the current process. It is not signaled to the child if STDIN of the current process closes down.

The functions *master\_read* and *stdin\_read* are passed a file descriptor which they should read from, and they should always return a byte string. In order to force spawn to return before the child process exits an empty byte array should be returned to signal end of file.

The default implementation for both functions will read and return up to 1024 bytes each time the function is called. The *master\_read* callback is passed the pseudoterminal's master file descriptor to read output from the child process, and *stdin\_read* is passed file descriptor 0, to read from the parent process's standard input.

Returning an empty byte string from either callback is interpreted as an end-of-file (EOF) condition, and that callback will not be called after that. If *stdin\_read* signals EOF the controlling terminal can no longer communicate with the parent process OR the child process. Unless the child process will quit without any input, *spawn* will then loop forever. If *master\_read* signals EOF the same behavior results (on linux at least).

Return the exit status value from `os.waitpid()` on the child process.

`waitstatus_to_exitcode()` can be used to convert the exit status into an exit code.

Raises an [auditing event](#) `pty.spawn` with argument `argv`.

*Changed in version 3.4:* `spawn()` now returns the status value from `os.waitpid()` on the child process.

# Example

The following program acts like the Unix command [\*script\(1\)\*](#), using a pseudo-terminal to record all input and output of a terminal session in a “typescript”.

```
import argparse
import os
import pty
import sys
import time

parser = argparse.ArgumentParser()
parser.add_argument('-a', dest='append', action='store_true')
parser.add_argument('-p', dest='use_python', action='store_true')
parser.add_argument('filename', nargs='?', default='typescript')
options = parser.parse_args()

shell = sys.executable if options.use_python else os.environ['SHELL']
filename = options.filename
mode = 'ab' if options.append else 'wb'

with open(filename, mode) as script:
    def read(fd):
        data = os.read(fd, 1024)
        script.write(data)
        return data

    print('Script started, file is', filename)
    script.write(('Script started on %s\n' % time.asctime()))

    pty.spawn(shell, read)

    script.write(('Script done on %s\n' % time.asctime()))
    print('Script done, file is', filename)
```

# fcntl — The fcntl and ioctl system calls

---

This module performs file control and I/O control on file descriptors. It is an interface to the `fcntl()` and `ioctl()` Unix routines. For a complete description of these calls, see [fcntl\(2\)](#) and [ioctl\(2\)](#) Unix manual pages.

**Availability:** not Emscripten, not WASI.

This module does not work or is not available on WebAssembly platforms `wasm32-emsripten` and `wasm32-wasi`. See [WebAssembly platforms](#) for more information.

All functions in this module take a file descriptor `fd` as their first argument. This can be an integer file descriptor, such as returned by `sys.stdin.fileno()`, or an `io.IOBase` object, such as `sys.stdin` itself, which provides a `fileno()` that returns a genuine file descriptor.

*Changed in version 3.3:* Operations in this module used to raise an `IOError` where they now raise an `OSError`.

*Changed in version 3.8:* The `fcntl` module now contains `F_ADD_SEALS`, `F_GET_SEALS`, and `F_SEAL_*` constants for sealing of `os.memfd_create()` file descriptors.

*Changed in version 3.9:* On macOS, the `fcntl` module exposes the `F_GETPATH` constant, which obtains the path of a file from a file descriptor. On Linux ( $\geq 3.15$ ), the `fcntl` module exposes the `F_OFD_GETLK`, `F_OFD_SETLK` and `F_OFD_SETLKW` constants, which are used when working with open file description locks.

*Changed in version 3.10:* On Linux  $\geq 2.6.11$ , the `fcntl` module exposes the `F_GETPIPE_SZ` and `F_SETPIPE_SZ` constants, which

allow to check and modify a pipe's size respectively.

*Changed in version 3.11:* On FreeBSD, the `fcntl` module exposes the `F_DUP2FD` and `F_DUP2FD_CLOEXEC` constants, which allow to duplicate a file descriptor, the latter setting `FD_CLOEXEC` flag in addition.

The module defines the following functions:

`fcntl.fcntl(fd, cmd, arg=0)`

Perform the operation *cmd* on file descriptor *fd* (file objects providing a `fileno()` method are accepted as well). The values used for *cmd* are operating system dependent, and are available as constants in the `fcntl` module, using the same names as used in the relevant C header files. The argument *arg* can either be an integer value, or a `bytes` object. With an integer value, the return value of this function is the integer return value of the C `fcntl()` call. When the argument is bytes it represents a binary structure, e.g. created by `struct.pack()`. The binary data is copied to a buffer whose address is passed to the C `fcntl()` call. The return value after a successful call is the contents of the buffer, converted to a `bytes` object. The length of the returned object will be the same as the length of the *arg* argument. This is limited to 1024 bytes. If the information returned in the buffer by the operating system is larger than 1024 bytes, this is most likely to result in a segmentation violation or a more subtle data corruption.

If the `fcntl()` fails, an `OSError` is raised.

Raises an `auditing event` `fcntl.fcntl` with arguments *fd*, *cmd*, *arg*.

`fcntl.ioctl(fd, request, arg=0, mutate_flag=True)`

This function is identical to the `fcntl()` function, except that the argument handling is even more complicated.

The *request* parameter is limited to values that can fit in 32-bits. Additional constants of interest for use as the *request*

argument can be found in the `termios` module, under the same names as used in the relevant C header files.

The parameter *arg* can be one of an integer, an object supporting the read-only buffer interface (like `bytes`) or an object supporting the read-write buffer interface (like `bytearray`).

In all but the last case, behaviour is as for the `fcntl()` function.

If a mutable buffer is passed, then the behaviour is determined by the value of the *mutate\_flag* parameter.

If it is false, the buffer's mutability is ignored and behaviour is as for a read-only buffer, except that the 1024 byte limit mentioned above is avoided – so long as the buffer you pass is at least as long as what the operating system wants to put there, things should work.

If *mutate\_flag* is true (the default), then the buffer is (in effect) passed to the underlying `ioctl()` system call, the latter's return code is passed back to the calling Python, and the buffer's new contents reflect the action of the `ioctl()`. This is a slight simplification, because if the supplied buffer is less than 1024 bytes long it is first copied into a static buffer 1024 bytes long which is then passed to `ioctl()` and copied back into the supplied buffer.

If the `ioctl()` fails, an `OSError` exception is raised.

An example:

```
>>> import array, fcntl, struct, termios, os
>>> os.getpgrp()
13341
>>> struct.unpack('h', fcntl.ioctl(0, termios.TIOCG
13341
>>> buf = array.array('h', [0])
>>> fcntl.ioctl(0, termios.TIOCGPGRP, buf, 1)
0
```

```
>>> buf
array('h', [13341])
```

Raises an [auditing event](#) `fcntl.ioctl` with arguments `fd`, `request`, `arg`.

`fcntl.flock(fd, operation)`

Perform the lock operation *operation* on file descriptor *fd* (file objects providing a [fileno\(\)](#) method are accepted as well). See the Unix manual [flock\(2\)](#) for details. (On some systems, this function is emulated using `fcntl()`.)

If the `flock()` fails, an [OSError](#) exception is raised.

Raises an [auditing event](#) `fcntl.flock` with arguments `fd`, `operation`.

`fcntl.lockf(fd, cmd, len=0, start=0, whence=0)`

This is essentially a wrapper around the `fcntl()` locking calls. *fd* is the file descriptor (file objects providing a [fileno\(\)](#) method are accepted as well) of the file to lock or unlock, and *cmd* is one of the following values:

- `LOCK_UN` – unlock
- `LOCK_SH` – acquire a shared lock
- `LOCK_EX` – acquire an exclusive lock

When *cmd* is `LOCK_SH` or `LOCK_EX`, it can also be bitwise ORed with `LOCK_NB` to avoid blocking on lock acquisition. If `LOCK_NB` is used and the lock cannot be acquired, an [OSError](#) will be raised and the exception will have an *errno* attribute set to `EACCES` or `EAGAIN` (depending on the operating system; for portability, check for both values). On at least some systems, `LOCK_EX` can only be used if the file descriptor refers to a file opened for writing.

*len* is the number of bytes to lock, *start* is the byte offset at which the lock starts, relative to *whence*, and *whence* is as with [io.IOBase.seek\(\)](#), specifically:

- 0 – relative to the start of the file (`os.SEEK_SET`)
- 1 – relative to the current buffer position (`os.SEEK_CUR`)
- 2 – relative to the end of the file (`os.SEEK_END`)

The default for *start* is 0, which means to start at the beginning of the file. The default for *len* is 0 which means to lock to the end of the file. The default for *whence* is also 0.

Raises an [auditing event](#) `fcntl.lockf` with arguments `fd`, `cmd`, `len`, `start`, `whence`.

Examples (all on a SVR4 compliant system):

```
import struct, fcntl, os

f = open(...)
rv = fcntl.fcntl(f, fcntl.F_SETFL, os.O_NDELAY)

lockdata = struct.pack('hhllhh', fcntl.F_WRLCK, 0, 0, 0, 0, 0)
rv = fcntl.fcntl(f, fcntl.F_SETLKW, lockdata)
```

Note that in the first example the return value variable *rv* will hold an integer value; in the second example it will hold a [bytes](#) object. The structure lay-out for the *lockdata* variable is system dependent — therefore using the [flock\(\)](#) call may be better.

**See also**

## Module [os](#)

If the locking flags [O\\_SHLOCK](#) and [O\\_EXLOCK](#) are present in the [os](#) module (on BSD only), the [os.open\(\)](#) function provides an alternative to the [lockf\(\)](#) and [flock\(\)](#) functions.

# resource — Resource usage information

---

This module provides basic mechanisms for measuring and controlling system resources utilized by a program.

**Availability:** not Emscripten, not WASI.

This module does not work or is not available on WebAssembly platforms `wasm32-emscripten` and `wasm32-wasi`. See [WebAssembly platforms](#) for more information.

Symbolic constants are used to specify particular system resources and to request usage information about either the current process or its children.

An **OSError** is raised on syscall failure.

*exception* resource.error

A deprecated alias of **OSError**.

*Changed in version 3.3:* Following [PEP 3151](https://peps.python.org/pep-3151/) [https://peps.python.org/pep-3151/], this class was made an alias of **OSError**.

## Resource Limits

Resources usage can be limited using the **setrlimit()** function described below. Each resource is controlled by a pair of limits: a soft limit and a hard limit. The soft limit is the current limit, and may be lowered or raised by a process over time. The soft limit can never exceed the hard limit. The hard limit can be lowered to any value greater than the soft limit, but not raised. (Only processes with the effective UID of the super-user can raise a hard limit.)

The specific resources that can be limited are system dependent. They are described in the [getrlimit\(2\)](#) man page. The resources listed below are supported when the underlying operating system supports them; resources which cannot be checked or controlled by the operating system are not defined in this module for those platforms.

`resource.RLIM_INFINITY`

Constant used to represent the limit for an unlimited resource.

`resource.getrlimit(resource)`

Returns a tuple (soft, hard) with the current soft and hard limits of *resource*. Raises **ValueError** if an invalid resource is specified, or **error** if the underlying system call fails unexpectedly.

`resource.setrlimit(resource, limits)`

Sets new limits of consumption of *resource*. The *limits* argument must be a tuple (soft, hard) of two integers describing the new limits. A value of **RLIM\_INFINITY** can be used to request a limit that is unlimited.

Raises **ValueError** if an invalid resource is specified, if the new soft limit exceeds the hard limit, or if a process tries to raise its hard limit. Specifying a limit of **RLIM\_INFINITY** when the hard or system limit for that resource is not unlimited will result in a **ValueError**. A process with the effective UID of super-user can request any valid limit value, including unlimited, but **ValueError** will still be raised if the requested limit exceeds the system imposed limit.

`setrlimit` may also raise **error** if the underlying system call fails.

VxWorks only supports setting **RLIMIT\_NOFILE**.

Raises an **auditing event** `resource.setrlimit` with arguments `resource, limits`.

`resource.prlimit(pid, resource[, limits])`

Combines `setrlimit()` and `getrlimit()` in one function and supports to get and set the resources limits of an arbitrary process. If *pid* is 0, then the call applies to the current process. *resource* and *limits* have the same meaning as in `setrlimit()`, except that *limits* is optional.

When *limits* is not given the function returns the *resource* limit of the process *pid*. When *limits* is given the *resource* limit of the process is set and the former resource limit is returned.

Raises `ProcessLookupError` when *pid* can't be found and `PermissionError` when the user doesn't have `CAP_SYS_RESOURCE` for the process.

Raises an `auditing event` `resource.prlimit` with arguments `pid`, `resource`, `limits`.

**Availability:** Linux  $\geq$  2.6.36 with glibc  $\geq$  2.13.

*New in version 3.4.*

These symbols define resources whose consumption can be controlled using the `setrlimit()` and `getrlimit()` functions described below. The values of these symbols are exactly the constants used by C programs.

The Unix man page for `getrlimit(2)` lists the available resources. Note that not all systems use the same symbol or same value to denote the same resource. This module does not attempt to mask platform differences — symbols not defined for a platform will not be available from this module on that platform.

`resource.RLIMIT_CORE`

The maximum size (in bytes) of a core file that the current process can create. This may result in the creation of a partial core file if a larger core would be required to contain the entire process image.

`resource.RLIMIT_CPU`

The maximum amount of processor time (in seconds) that a process can use. If this limit is exceeded, a **SIGXCPU** signal is sent to the process. (See the [signal](#) module documentation for information about how to catch this signal and do something useful, e.g. flush open files to disk.)

resource.RLIMIT\_FSIZE

The maximum size of a file which the process may create.

resource.RLIMIT\_DATA

The maximum size (in bytes) of the process's heap.

resource.RLIMIT\_STACK

The maximum size (in bytes) of the call stack for the current process. This only affects the stack of the main thread in a multi-threaded process.

resource.RLIMIT\_RSS

The maximum resident set size that should be made available to the process.

resource.RLIMIT\_NPROC

The maximum number of processes the current process may create.

resource.RLIMIT\_NOFILE

The maximum number of open file descriptors for the current process.

resource.RLIMIT\_OFILE

The BSD name for [RLIMIT\\_NOFILE](#).

resource.RLIMIT\_MEMLOCK

The maximum address space which may be locked in memory.

resource.RLIMIT\_VMEM

The largest area of mapped memory which the process may occupy.

resource.RLIMIT\_AS

The maximum area (in bytes) of address space which may be taken by the process.

resource.RLIMIT\_MSGQUEUE

The number of bytes that can be allocated for POSIX message queues.

**Availability:** Linux  $\geq$  2.6.8.

*New in version 3.4.*

resource.RLIMIT\_NICE

The ceiling for the process's nice level (calculated as  $20 - \text{rlim\_cur}$ ).

**Availability:** Linux  $\geq$  2.6.12.

*New in version 3.4.*

resource.RLIMIT\_RTPRIO

The ceiling of the real-time priority.

**Availability:** Linux  $\geq$  2.6.12.

*New in version 3.4.*

resource.RLIMIT\_RTTIME

The time limit (in microseconds) on CPU time that a process can spend under real-time scheduling without making a blocking syscall.

**Availability:** Linux  $\geq$  2.6.25.

*New in version 3.4.*

#### resource.RLIMIT\_SIGPENDING

The number of signals which the process may queue.

**Availability:** Linux  $\geq$  2.6.8.

*New in version 3.4.*

#### resource.RLIMIT\_SBSIZE

The maximum size (in bytes) of socket buffer usage for this user. This limits the amount of network memory, and hence the amount of mbufs, that this user may hold at any time.

**Availability:** FreeBSD.

*New in version 3.4.*

#### resource.RLIMIT\_SWAP

The maximum size (in bytes) of the swap space that may be reserved or used by all of this user id's processes. This limit is enforced only if bit 1 of the vm.overcommit sysctl is set.

Please see [tuning\(7\)](https://man.freebsd.org/cgi/man.cgi?query=tuning&sektion=7) [https://man.freebsd.org/cgi/man.cgi?query=tuning&sektion=7] for a complete description of this sysctl.

**Availability:** FreeBSD.

*New in version 3.4.*

#### resource.RLIMIT\_NPTS

The maximum number of pseudo-terminals created by this user id.

**Availability:** FreeBSD.

*New in version 3.4.*

#### resource.RLIMIT\_KQUEUES

The maximum number of kqueues this user id is allowed to create.

**Availability:** FreeBSD >= 11.

*New in version 3.10.*

## Resource Usage

These functions are used to retrieve resource usage information:

`resource.getrusage(who)`

This function returns an object that describes the resources consumed by either the current process or its children, as specified by the *who* parameter. The *who* parameter should be specified using one of the **RUSAGE\_\*** constants described below.

A simple example:

```
from resource import *
import time

# a non CPU-bound task
time.sleep(3)
print(getrusage(RUSAGE_SELF))

# a CPU-bound task
for i in range(10 ** 8):
    _ = 1 + 1
print(getrusage(RUSAGE_SELF))
```

The fields of the return value each describe how a particular system resource has been used, e.g. amount of time spent running in user mode or number of times the process was swapped out of main memory. Some values are dependent on the clock tick interval, e.g. the amount of memory the process is using.

For backward compatibility, the return value is also accessible as a tuple of 16 elements.

The fields **ru\_utime** and **ru\_stime** of the return value are

floating point values representing the amount of time spent executing in user mode and the amount of time spent executing in system mode, respectively. The remaining values are integers. Consult the [getrusage\(2\)](#) man page for detailed information about these values. A brief summary is presented here:

Resource
<code>timeutime</code>
time in user mode (float seconds)
<code>timesstime</code>
time in system mode (float seconds)
<code>maxrss</code>
maximum resident set size
<code>sharedrss</code>
shared memory size
<code>unsharedrss</code>
unshared memory size
<code>unsharedst</code>
unshared stack size
<code>pgfault</code>
page faults not requiring I/O
<code>pgmajflt</code>
page faults requiring I/O
<code>numswap</code>
number of swap outs
<code>blockio</code>
block operations
<code>blockop</code>
block operations
<code>msgsnd</code>
messages sent
<code>msgrcv</code>
messages received
<code>signals</code>
signals received
<code>voluntary</code>
voluntary context switches
<code>involuntary</code>
involuntary context switches

This function will raise a **ValueError** if an invalid *who* parameter is specified. It may also raise **error** exception in unusual circumstances.

```
resource.getpagesize()
```

Returns the number of bytes in a system page. (This need not be the same as the hardware page size.)

The following **RUSAGE\_\*** symbols are passed to the [getrusage\(\)](#) function to specify which processes information should be provided for.

```
resource.RUSAGE_SELF
```

Pass to [getrusage\(\)](#) to request resources consumed by the calling process, which is the sum of resources used by all

threads in the process.

resource.RUSAGE\_CHILDREN

Pass to `getrusage()` to request resources consumed by child processes of the calling process which have been terminated and waited for.

resource.RUSAGE\_BOTH

Pass to `getrusage()` to request resources consumed by both the current process and child processes. May not be available on all systems.

resource.RUSAGE\_THREAD

Pass to `getrusage()` to request resources consumed by the current thread. May not be available on all systems.

*New in version 3.2.*

# syslog — Unix syslog library routines

---

This module provides an interface to the Unix `syslog` library routines. Refer to the Unix manual pages for a detailed description of the `syslog` facility.

This module wraps the system `syslog` family of routines. A pure Python library that can speak to a syslog server is available in the `logging.handlers` module as `SysLogHandler`.

**Availability:** not Emscripten, not WASI.

This module does not work or is not available on WebAssembly platforms `wasm32-emscripten` and `wasm32-wasi`. See [WebAssembly platforms](#) for more information.

The module defines the following functions:

`syslog.syslog(message)`

`syslog.syslog(priority, message)`

Send the string *message* to the system logger. A trailing newline is added if necessary. Each message is tagged with a priority composed of a *facility* and a *level*. The optional *priority* argument, which defaults to `LOG_INFO`, determines the message priority. If the facility is not encoded in *priority* using logical-or (`LOG_INFO | LOG_USER`), the value given in the `openlog()` call is used.

If `openlog()` has not been called prior to the call to `syslog()`, `openlog()` will be called with no arguments.

Raises an [auditing event](#) `syslog.syslog` with arguments `priority`, `message`.

*Changed in version 3.2:* In previous versions, `openlog()` would not be called automatically if it wasn't called prior to the call to `syslog()`, deferring to the syslog implementation to call `openlog()`.

`syslog.openlog([ident[, logoption[, facility]]])`

Logging options of subsequent `syslog()` calls can be set by calling `openlog()`. `syslog()` will call `openlog()` with no arguments if the log is not currently open.

The optional *ident* keyword argument is a string which is prepended to every message, and defaults to `sys.argv[0]` with leading path components stripped. The optional *logoption* keyword argument (default is 0) is a bit field – see below for possible values to combine. The optional *facility* keyword argument (default is `LOG_USER`) sets the default facility for messages which do not have a facility explicitly encoded.

Raises an [auditing event](#) `syslog.openlog` with arguments *ident*, *logoption*, *facility*.

*Changed in version 3.2:* In previous versions, keyword arguments were not allowed, and *ident* was required.

`syslog.closelog()`

Reset the syslog module values and call the system library `closelog()`.

This causes the module to behave as it does when initially imported. For example, `openlog()` will be called on the first `syslog()` call (if `openlog()` hasn't already been called), and *ident* and other `openlog()` parameters are reset to defaults.

Raises an [auditing event](#) `syslog.closelog` with no arguments.

`syslog.setlogmask(maskpri)`

Set the priority mask to *maskpri* and return the previous mask

value. Calls to `syslog()` with a priority level not set in *maskpri* are ignored. The default is to log all priorities. The function `LOG_MASK(pri)` calculates the mask for the individual priority *pri*. The function `LOG_UPTO(pri)` calculates the mask for all priorities up to and including *pri*.

Raises an [auditing event](#) `syslog.setlogmask` with argument `maskpri`.

The module defines the following constants:

Priority levels (high to low):

`LOG_EMERG`, `LOG_ALERT`, `LOG_CRIT`, `LOG_ERR`,  
`LOG_WARNING`, `LOG_NOTICE`, `LOG_INFO`, `LOG_DEBUG`.

Facilities:

`LOG_KERN`, `LOG_USER`, `LOG_MAIL`, `LOG_DAEMON`,  
`LOG_AUTH`, `LOG_LPR`, `LOG_NEWS`, `LOG_UUCP`, `LOG_CRON`,  
`LOG_SYSLOG`, `LOG_LOCAL0` to `LOG_LOCAL7`, and, if  
defined in `<syslog.h>`, `LOG_AUTHPRIV`.

Log options:

`LOG_PID`, `LOG_CONS`, `LOG_NDELAY`, and, if defined in  
`<syslog.h>`, `LOG_ODELAY`, `LOG_NOWAIT`, and  
`LOG_PERROR`.

## Examples

### Simple example

A simple set of examples:

```
import syslog

syslog.syslog('Processing started')
if error:
    syslog.syslog(syslog.LOG_ERR, 'Processing started')
```

An example of setting some log options, these would include the process ID in logged messages, and write the messages to the

destination facility used for mail logging:

```
syslog.openlog(logoption=syslog.LOG_PID, facility=syslog.LOG_MAIL)
syslog.syslog('E-mail processing initiated...')
```

# Superseded Modules

The modules described in this chapter are deprecated and only kept for backwards compatibility. They have been superseded by other modules.

- **aifc** — Read and write AIFF and AIFC files
- **asynchat** — Asynchronous socket command/response handler
  - [asynchat Example](#)
- **asyncore** — Asynchronous socket handler
  - [asyncore Example basic HTTP client](#)
  - [asyncore Example basic echo server](#)
- **audioop** — Manipulate raw audio data
- **cgi** — Common Gateway Interface support
  - [Introduction](#)
  - [Using the cgi module](#)

- PureProxy Objects
- SMTPChannel Objects

- **sndhdr** — Determine type of sound file

- **spwd** — The shadow password database

- **sunau** — Read and write Sun AU files

- AU\_read Objects
- AU\_write Objects

- **telnetlib** — Telnet client

- Telnet Objects
- Telnet Example

- **uu** — Encode and decode uuencode files

- **xdrlib** — Encode and decode XDR data

- Packer Objects
- Unpacker Objects
- Exceptions

# aifc — Read and write AIFF and AIFC files

**Source code:** [Lib/aifc.py](https://github.com/python/cpython/tree/3.11/Lib/aifc.py) [https://github.com/python/cpython/tree/3.11/Lib/aifc.py]

*Deprecated since version 3.11, will be removed in version 3.13:* The **aifc** module is deprecated (see [PEP 594](https://peps.python.org/pep-0594/#aifc) [https://peps.python.org/pep-0594/#aifc] for details).

---

This module provides support for reading and writing AIFF and AIFF-C files. AIFF is Audio Interchange File Format, a format for storing digital audio samples in a file. AIFF-C is a newer version of the format that includes the ability to compress the audio data.

Audio files have a number of parameters that describe the audio data. The sampling rate or frame rate is the number of times per second the sound is sampled. The number of channels indicate if the audio is mono, stereo, or quadro. Each frame consists of one sample per channel. The sample size is the size in bytes of each sample. Thus a frame consists of `nchannels * samplesize` bytes, and a second's worth of audio consists of `nchannels * samplesize * framerate` bytes.

For example, CD quality audio has a sample size of two bytes (16 bits), uses two channels (stereo) and has a frame rate of 44,100 frames/second. This gives a frame size of 4 bytes (2\*2), and a second's worth occupies 2\*2\*44100 bytes (176,400 bytes).

Module **aifc** defines the following function:

`aifc.open(file, mode=None)`

Open an AIFF or AIFF-C file and return an object instance with methods that are described below. The argument *file* is either a string naming a file or a [file object](#). *mode* must be

'r' or 'rb' when the file must be opened for reading, or 'w' or 'wb' when the file must be opened for writing. If omitted, `file.mode` is used if it exists, otherwise 'rb' is used. When used for writing, the file object should be seekable, unless you know ahead of time how many samples you are going to write in total and use `writeframesraw()` and `setnframes()`. The `open()` function may be used in a `with` statement. When the `with` block completes, the `close()` method is called.

*Changed in version 3.4:* Support for the `with` statement was added.

Objects returned by `open()` when a file is opened for reading have the following methods:

`aifc.getnchannels()`

Return the number of audio channels (1 for mono, 2 for stereo).

`aifc.getsampwidth()`

Return the size in bytes of individual samples.

`aifc.getframerate()`

Return the sampling rate (number of audio frames per second).

`aifc.getnframes()`

Return the number of audio frames in the file.

`aifc.getcomptype()`

Return a bytes array of length 4 describing the type of compression used in the audio file. For AIFF files, the returned value is `b'NONE'`.

`aifc.getcompname()`

Return a bytes array convertible to a human-readable

description of the type of compression used in the audio file. For AIFF files, the returned value is `b'not compressed'`.

`aifc.getparams()`

Returns a `namedtuple()` (`nchannels`, `sampwidth`, `framerate`, `nframes`, `comptype`, `compname`), equivalent to output of the `get*()` methods.

`aifc.getmarkers()`

Return a list of markers in the audio file. A marker consists of a tuple of three elements. The first is the mark ID (an integer), the second is the mark position in frames from the beginning of the data (an integer), the third is the name of the mark (a string).

`aifc.getmark(id)`

Return the tuple as described in `getmarkers()` for the mark with the given *id*.

`aifc.readframes(nframes)`

Read and return the next *nframes* frames from the audio file. The returned data is a string containing for each frame the uncompressed samples of all channels.

`aifc.rewind()`

Rewind the read pointer. The next `readframes()` will start from the beginning.

`aifc.setpos(pos)`

Seek to the specified frame number.

`aifc.tell()`

Return the current frame number.

`aifc.close()`

Close the AIFF file. After calling this method, the object can no longer be used.

Objects returned by `open()` when a file is opened for writing have all the above methods, except for `readframes()` and `setpos()`. In addition the following methods exist. The `get*()` methods can only be called after the corresponding `set*()` methods have been called. Before the first `writeframes()` or `writeframesraw()`, all parameters except for the number of frames must be filled in.

`aifc.aiff()`

Create an AIFF file. The default is that an AIFF-C file is created, unless the name of the file ends in `'.aiff'` in which case the default is an AIFF file.

`aifc.aifc()`

Create an AIFF-C file. The default is that an AIFF-C file is created, unless the name of the file ends in `'.aiff'` in which case the default is an AIFF file.

`aifc.setnchannels(nchannels)`

Specify the number of channels in the audio file.

`aifc.setsampwidth(width)`

Specify the size in bytes of audio samples.

`aifc.setframerate(rate)`

Specify the sampling frequency in frames per second.

`aifc.setnframes(nframes)`

Specify the number of frames that are to be written to the audio file. If this parameter is not set, or not set correctly, the file needs to support seeking.

`aifc.setcomptype(type, name)`

Specify the compression type. If not specified, the audio data

will not be compressed. In AIFF files, compression is not possible. The name parameter should be a human-readable description of the compression type as a bytes array, the type parameter should be a bytes array of length 4. Currently the following compression types are supported: `b'NONE'`, `b'ULAW'`, `b'ALAW'`, `b'G722'`.

`aifc.setparams(nchannels, sampwidth, framerate, comptype, compname)`

Set all the above parameters at once. The argument is a tuple consisting of the various parameters. This means that it is possible to use the result of a `getparams()` call as argument to `setparams()`.

`aifc.setmark(id, pos, name)`

Add a mark with the given id (larger than 0), and the given name at the given position. This method can be called at any time before `close()`.

`aifc.tell()`

Return the current write position in the output file. Useful in combination with `setmark()`.

`aifc.writeframes(data)`

Write data to the output file. This method can only be called after the audio file parameters have been set.

*Changed in version 3.4:* Any [bytes-like object](#) is now accepted.

`aifc.writeframesraw(data)`

Like `writeframes()`, except that the header of the audio file is not updated.

*Changed in version 3.4:* Any [bytes-like object](#) is now accepted.

`aifc.close()`

Close the AIFF file. The header of the file is updated to reflect

the actual size of the audio data. After calling this method, the object can no longer be used.

# asynchat — Asynchronous socket command/response handler

**Source code:** [Lib/asynchat.py](https://github.com/python/cpython/tree/3.11/Lib/asynchat.py) [https://github.com/python/cpython/tree/3.11/Lib/asynchat.py]

*Deprecated since version 3.6, will be removed in version 3.12:* The **asynchat** module is deprecated (see [PEP 594](https://peps.python.org/pep-0594/#asynchat) [https://peps.python.org/pep-0594/#asynchat] for details). Please use **asyncio** instead.

---

## Note

This module exists for backwards compatibility only. For new code we recommend using **asyncio**.

This module builds on the **asyncore** infrastructure, simplifying asynchronous clients and servers and making it easier to handle protocols whose elements are terminated by arbitrary strings, or are of variable length. **asynchat** defines the abstract class **async\_chat** that you subclass, providing implementations of the **collect\_incoming\_data()** and **found\_terminator()** methods. It uses the same asynchronous loop as **asyncore**, and the two types of channel, **asyncore.dispatcher** and **asynchat.async\_chat**, can freely be mixed in the channel map. Typically an **asyncore.dispatcher** server channel generates new **asynchat.async\_chat** channel objects as it receives incoming connection requests.

**Availability:** not Emscripten, not WASI.

This module does not work or is not available on WebAssembly platforms `wasm32-emscrip`ten and `wasm32-wasi`. See

[WebAssembly platforms](#) for more information.

*class* `asyncchat.async_chat`

This class is an abstract subclass of `asyncore.dispatcher`. To make practical use of the code you must subclass `async_chat`, providing meaningful `collect_incoming_data()` and `found_terminator()` methods. The `asyncore.dispatcher` methods can be used, although not all make sense in a message/response context.

Like `asyncore.dispatcher`, `async_chat` defines a set of events that are generated by an analysis of socket conditions after a `select()` call. Once the polling loop has been started the `async_chat` object's methods are called by the event-processing framework with no action on the part of the programmer.

Two class attributes can be modified, to improve performance, or possibly even to conserve memory.

`ac_in_buffer_size`

The asynchronous input buffer size (default 4096).

`ac_out_buffer_size`

The asynchronous output buffer size (default 4096).

Unlike `asyncore.dispatcher`, `async_chat` allows you to define a FIFO queue of *producers*. A producer need have only one method, `more()`, which should return data to be transmitted on the channel. The producer indicates exhaustion (*i.e.* that it contains no more data) by having its `more()` method return the empty bytes object. At this point the `async_chat` object removes the producer from the queue and starts using the next producer, if any. When the producer queue is empty the `handle_write()` method does nothing. You use the channel object's `set_terminator()` method to describe how to recognize the end of, or an important breakpoint in, an incoming transmission from the remote endpoint.

To build a functioning `async_chat` subclass your input methods `collect_incoming_data()` and `found_terminator()` must handle the data that the channel receives asynchronously. The methods are described below.

`async_chat.close_when_done()`

Pushes a `None` on to the producer queue. When this producer is popped off the queue it causes the channel to be closed.

`async_chat.collect_incoming_data(data)`

Called with *data* holding an arbitrary amount of received data. The default method, which must be overridden, raises a `NotImplementedError` exception.

`async_chat.discard_buffers()`

In emergencies this method will discard any data held in the input and/or output buffers and the producer queue.

`async_chat.found_terminator()`

Called when the incoming data stream matches the termination condition set by `set_terminator()`. The default method, which must be overridden, raises a `NotImplementedError` exception. The buffered input data should be available via an instance attribute.

`async_chat.get_terminator()`

Returns the current terminator for the channel.

`async_chat.push(data)`

Pushes data on to the channel's queue to ensure its transmission. This is all you need to do to have the channel write the data out to the network, although it is possible to use your own producers in more complex schemes to implement encryption and chunking, for example.

`async_chat.push_with_producer(producer)`

Takes a producer object and adds it to the producer queue associated with the channel. When all currently pushed producers have been exhausted the channel will consume this producer's data by calling its `more()` method and send the data to the remote endpoint.

`async_chat.set_terminator(term)`

Sets the terminating condition to be recognized on the channel. `term` may be any of three types of value, corresponding to three different ways to handle incoming protocol data.

#### Description

---

Will call `found_terminator()` when the string is found in the input stream

---

Will call `found_terminator()` when the indicated number of characters have been received

---

The channel continues to collect data forever

---

Note that any data following the terminator will be available for reading by the channel after `found_terminator()` is called.

## asynchat Example

The following partial example shows how HTTP requests can be read with `async_chat`. A web server might create an `http_request_handler` object for each incoming client connection. Notice that initially the channel terminator is set to match the blank line at the end of the HTTP headers, and a flag indicates that the headers are being read.

Once the headers have been read, if the request is of type POST (indicating that further data are present in the input stream) then the `Content-Length:` header is used to set a numeric terminator to read the right amount of data from the channel.

The `handle_request()` method is called once all relevant input

has been marshalled, after setting the channel terminator to `None` to ensure that any extraneous data sent by the web client are ignored.

```
import asynchat
```

```
class http_request_handler(asynchat.async_chat):
```

```
    def __init__(self, sock, addr, sessions, log):
        asynchat.async_chat.__init__(self, sock=sock)
        self.addr = addr
        self.sessions = sessions
        self.ibuffer = []
        self.obuffer = b""
        self.set_terminator(b"\r\n\r\n")
        self.reading_headers = True
        self.handling = False
        self.cgi_data = None
        self.log = log
```

```
    def collect_incoming_data(self, data):
        """Buffer the data"""
        self.ibuffer.append(data)
```

```
    def found_terminator(self):
        if self.reading_headers:
            self.reading_headers = False
            self.parse_headers(b"".join(self.ibuffer))
            self.ibuffer = []
            if self.op.upper() == b"POST":
                clen = self.headers.getheader("content-length")
                self.set_terminator(int(clen))
            else:
                self.handling = True
                self.set_terminator(None)
                self.handle_request()
        elif not self.handling:
            self.set_terminator(None) # browsers sometimes
            self.cgi_data = parse(self.headers, b"".join
```

```
self.handling = True
self.ibuffer = []
self.handle_request()
```

# asyncore — Asynchronous socket handler

**Source code:** [Lib/asyncore.py](https://github.com/python/cpython/tree/3.11/Lib/asyncore.py) [https://github.com/python/cpython/tree/3.11/Lib/asyncore.py]

*Deprecated since version 3.6, will be removed in version 3.12:* The **asyncore** module is deprecated (see [PEP 594](https://peps.python.org/pep-0594/#asyncore) [https://peps.python.org/pep-0594/#asyncore] for details). Please use **asyncio** instead.

---

## Note

This module exists for backwards compatibility only. For new code we recommend using **asyncio**.

This module provides the basic infrastructure for writing asynchronous socket service clients and servers.

**Availability:** not Emscripten, not WASI.

This module does not work or is not available on WebAssembly platforms `wasm32-emscripten` and `wasm32-wasi`. See [WebAssembly platforms](#) for more information.

There are only two ways to have a program on a single processor do “more than one thing at a time.” Multi-threaded programming is the simplest and most popular way to do it, but there is another very different technique, that lets you have nearly all the advantages of multi-threading, without actually using multiple threads. It’s really only practical if your program is largely I/O bound. If your program is processor bound, then pre-emptive scheduled threads are probably what you really need. Network servers are rarely processor bound, however.

If your operating system supports the `select()` system call in its I/O library (and nearly all do), then you can use it to juggle multiple communication channels at once; doing other work while your I/O is taking place in the “background.” Although this strategy can seem strange and complex, especially at first, it is in many ways easier to understand and control than multi-threaded programming. The `asyncore` module solves many of the difficult problems for you, making the task of building sophisticated high-performance network servers and clients a snap. For “conversational” applications and protocols the companion `asynchat` module is invaluable.

The basic idea behind both modules is to create one or more network *channels*, instances of class `asyncore.dispatcher` and `asynchat.async_chat`. Creating the channels adds them to a global map, used by the `loop()` function if you do not provide it with your own *map*.

Once the initial channel(s) is(are) created, calling the `loop()` function activates channel service, which continues until the last channel (including any that have been added to the map during asynchronous service) is closed.

```
asyncore.loop([timeout[, use_poll[, map[, count]]]])
```

Enter a polling loop that terminates after *count* passes or all open channels have been closed. All arguments are optional. The *count* parameter defaults to `None`, resulting in the loop terminating only when all channels have been closed. The *timeout* argument sets the timeout parameter for the appropriate `select()` or `poll()` call, measured in seconds; the default is 30 seconds. The *use\_poll* parameter, if true, indicates that `poll()` should be used in preference to `select()` (the default is `False`).

The *map* parameter is a dictionary whose items are the channels to watch. As channels are closed they are deleted from their map. If *map* is omitted, a global map is used. Channels (instances of `asyncore.dispatcher`, `asynchat.async_chat` and subclasses thereof) can freely be mixed in the map.

*class* `asyncore.dispatcher`

The `dispatcher` class is a thin wrapper around a low-level socket object. To make it more useful, it has a few methods for event-handling which are called from the asynchronous loop. Otherwise, it can be treated as a normal non-blocking socket object.

The firing of low-level events at certain times or in certain connection states tells the asynchronous loop that certain higher-level events have taken place. For example, if we have asked for a socket to connect to another host, we know that the connection has been made when the socket becomes writable for the first time (at this point you know that you may write to it with the expectation of success). The implied higher-level events are:

Description
Implied by the first (read or write event
Implied by a <code>read</code> event with no data available
Implied by a <code>read</code> event on a listening socket

During asynchronous processing, each mapped channel's `readable()` and `writable()` methods are used to determine whether the channel's socket should be added to the list of channels `select()`ed or `poll()`ed for read and write events.

Thus, the set of channel events is larger than the basic socket events. The full set of methods that can be overridden in your subclass follows:

`handle_read()`

Called when the asynchronous loop detects that a `read()` call on the channel's socket will succeed.

`handle_write()`

Called when the asynchronous loop detects that a writable socket can be written. Often this method will implement the necessary buffering for performance. For example:

```
def handle_write(self):  
    sent = self.send(self.buffer)  
    self.buffer = self.buffer[sent:]
```

### `handle_expt()`

Called when there is out of band (OOB) data for a socket connection. This will almost never happen, as OOB is tenuously supported and rarely used.

### `handle_connect()`

Called when the active opener's socket actually makes a connection. Might send a “welcome” banner, or initiate a protocol negotiation with the remote endpoint, for example.

### `handle_close()`

Called when the socket is closed.

### `handle_error()`

Called when an exception is raised and not otherwise handled. The default version prints a condensed traceback.

### `handle_accept()`

Called on listening channels (passive openers) when a connection can be established with a new remote endpoint that has issued a `connect()` call for the local endpoint. Deprecated in version 3.2; use `handle_accepted()` instead.

*Deprecated since version 3.2.*

### `handle_accepted(sock, addr)`

Called on listening channels (passive openers) when a connection has been established with a new remote endpoint that has issued a `connect()` call for the local endpoint. `sock` is a *new* socket object usable to

send and receive data on the connection, and *addr* is the address bound to the socket on the other end of the connection.

*New in version 3.2.*

`readable()`

Called each time around the asynchronous loop to determine whether a channel's socket should be added to the list on which read events can occur. The default method simply returns `True`, indicating that by default, all channels will be interested in read events.

`writable()`

Called each time around the asynchronous loop to determine whether a channel's socket should be added to the list on which write events can occur. The default method simply returns `True`, indicating that by default, all channels will be interested in write events.

In addition, each channel delegates or extends many of the socket methods. Most of these are nearly identical to their socket partners.

`create_socket(family=socket.AF_INET,  
type=socket.SOCK_STREAM)`

This is identical to the creation of a normal socket, and will use the same options for creation. Refer to the [socket](#) documentation for information on creating sockets.

*Changed in version 3.3:* *family* and *type* arguments can be omitted.

`connect(address)`

As with the normal socket object, *address* is a tuple with the first element the host to connect to, and the second the port number.

`send(data)`

Send *data* to the remote end-point of the socket.

`recv(buffer_size)`

Read at most *buffer\_size* bytes from the socket's remote end-point. An empty bytes object implies that the channel has been closed from the other end.

Note that `recv()` may raise `BlockingIOError`, even though `select.select()` or `select.poll()` has reported the socket ready for reading.

`listen(backlog)`

Listen for connections made to the socket. The *backlog* argument specifies the maximum number of queued connections and should be at least 1; the maximum value is system-dependent (usually 5).

`bind(address)`

Bind the socket to *address*. The socket must not already be bound. (The format of *address* depends on the address family — refer to the `socket` documentation for more information.) To mark the socket as re-usable (setting the `SO_REUSEADDR` option), call the `dispatcher` object's `set_reuse_addr()` method.

`accept()`

Accept a connection. The socket must be bound to an address and listening for connections. The return value can be either `None` or a pair `(conn, address)` where *conn* is a *new* socket object usable to send and receive data on the connection, and *address* is the address bound to the socket on the other end of the connection. When `None` is returned it means the connection didn't take place, in which case the server should just ignore this event and keep listening for further incoming connections.

`close()`

Close the socket. All future operations on the socket object will fail. The remote end-point will receive no more data (after queued data is flushed). Sockets are automatically closed when they are garbage-collected.

*class* `asyncore.dispatcher_with_send`

A `dispatcher` subclass which adds simple buffered output capability, useful for simple clients. For more sophisticated usage use `asynchat.async_chat`.

*class* `asyncore.file_dispatcher`

A `file_dispatcher` takes a file descriptor or `file object` along with an optional `map` argument and wraps it for use with the `poll()` or `loop()` functions. If provided a file object or anything with a `fileno()` method, that method will be called and passed to the `file_wrapper` constructor.

*Availability:* Unix.

*class* `asyncore.file_wrapper`

A `file_wrapper` takes an integer file descriptor and calls `os.dup()` to duplicate the handle so that the original handle may be closed independently of the `file_wrapper`. This class implements sufficient methods to emulate a socket for use by the `file_dispatcher` class.

*Availability:* Unix.

## asyncore Example basic HTTP client

Here is a very basic HTTP client that uses the `dispatcher` class to implement its socket handling:

```
import asyncore
```

```
class HTTPClient(asyncore.dispatcher):
```

```

def __init__(self, host, path):
    asyncore.dispatcher.__init__(self)
    self.create_socket()
    self.connect( (host, 80) )
    self.buffer = bytes('GET %s HTTP/1.0\r\nHost: %s\r\n' %
                        (path, host), 'ascii')

def handle_connect(self):
    pass

def handle_close(self):
    self.close()

def handle_read(self):
    print(self.recv(8192))

def writable(self):
    return (len(self.buffer) > 0)

def handle_write(self):
    sent = self.send(self.buffer)
    self.buffer = self.buffer[sent:]

```

```

client = HTTPClient('www.python.org', '/')
asyncore.loop()

```

## asyncore Example basic echo server

Here is a basic echo server that uses the [dispatcher](#) class to accept connections and dispatches the incoming connections to a handler:

```

import asyncore

class EchoHandler(asyncore.dispatcher_with_send):

    def handle_read(self):

```

```
        data = self.recv(8192)
        if data:
            self.send(data)

class EchoServer(asyncore.dispatcher):

    def __init__(self, host, port):
        asyncore.dispatcher.__init__(self)
        self.create_socket()
        self.set_reuse_addr()
        self.bind((host, port))
        self.listen(5)

    def handle_accepted(self, sock, addr):
        print('Incoming connection from %s' % repr(addr))
        handler = EchoHandler(sock)

server = EchoServer('localhost', 8080)
asyncore.loop()
```

# audioop — Manipulate raw audio data

*Deprecated since version 3.11, will be removed in version 3.13:* The **audioop** module is deprecated (see [PEP 594](https://peps.python.org/pep-0594/#audioop) [https://peps.python.org/pep-0594/#audioop] for details).

---

The **audioop** module contains some useful operations on sound fragments. It operates on sound fragments consisting of signed integer samples 8, 16, 24 or 32 bits wide, stored in **bytes-like objects**. All scalar items are integers, unless specified otherwise.

*Changed in version 3.4:* Support for 24-bit samples was added. All functions now accept any **bytes-like object**. String input now results in an immediate error.

This module provides support for a-LAW, u-LAW and Intel/DVI ADPCM encodings.

A few of the more complicated operations only take 16-bit samples, otherwise the sample size (in bytes) is always a parameter of the operation.

The module defines the following variables and functions:

*exception* `audioop.error`

This exception is raised on all errors, such as unknown number of bytes per sample, etc.

`audioop.add(fragment1, fragment2, width)`

Return a fragment which is the addition of the two samples passed as parameters. *width* is the sample width in bytes, either 1, 2, 3 or 4. Both fragments should have the same length. Samples are truncated in case of overflow.

`audioop.adpcm2lin(adpcmfragment, width, state)`

Decode an Intel/DVI ADPCM coded fragment to a linear fragment. See the description of `lin2adpcm()` for details on ADPCM coding. Return a tuple (*sample*, *newstate*) where the sample has the width specified in *width*.

`audioop.alaw2lin(fragment, width)`

Convert sound fragments in a-LAW encoding to linearly encoded sound fragments. a-LAW encoding always uses 8 bits samples, so *width* refers only to the sample width of the output fragment here.

`audioop.avg(fragment, width)`

Return the average over all samples in the fragment.

`audioop.avgpp(fragment, width)`

Return the average peak-peak value over all samples in the fragment. No filtering is done, so the usefulness of this routine is questionable.

`audioop.bias(fragment, width, bias)`

Return a fragment that is the original fragment with a bias added to each sample. Samples wrap around in case of overflow.

`audioop.byteswap(fragment, width)`

“Byteswap” all samples in a fragment and returns the modified fragment. Converts big-endian samples to little-endian and vice versa.

*New in version 3.4.*

`audioop.cross(fragment, width)`

Return the number of zero crossings in the fragment passed as an argument.

`audioop.findfactor(fragment, reference)`

Return a factor  $F$  such that `rms(add(fragment, mul(reference, -F)))` is minimal, i.e., return the factor with which you should multiply *reference* to make it match as well as possible to *fragment*. The fragments should both contain 2-byte samples.

The time taken by this routine is proportional to `len(fragment)`.

`audioop.findfit(fragment, reference)`

Try to match *reference* as well as possible to a portion of *fragment* (which should be the longer fragment). This is (conceptually) done by taking slices out of *fragment*, using `findfactor()` to compute the best match, and minimizing the result. The fragments should both contain 2-byte samples. Return a tuple (*offset*, *factor*) where *offset* is the (integer) offset into *fragment* where the optimal match started and *factor* is the (floating-point) factor as per `findfactor()`.

`audioop.findmax(fragment, length)`

Search *fragment* for a slice of length *length* samples (not bytes!) with maximum energy, i.e., return  $i$  for which `rms(fragment[i*2:(i+length)*2])` is maximal. The fragments should both contain 2-byte samples.

The routine takes time proportional to `len(fragment)`.

`audioop.getsample(fragment, width, index)`

Return the value of sample *index* from the fragment.

`audioop.lin2adpcm(fragment, width, state)`

Convert samples to 4 bit Intel/DVI ADPCM encoding. ADPCM coding is an adaptive coding scheme, whereby each 4 bit number is the difference between one sample and the next, divided by a (varying) step. The Intel/DVI ADPCM algorithm has been selected for use by the IMA, so it may well become a

standard.

*state* is a tuple containing the state of the coder. The coder returns a tuple (*adpcmfrag*, *newstate*), and the *newstate* should be passed to the next call of `lin2adpcm()`. In the initial call, `None` can be passed as the state. *adpcmfrag* is the ADPCM coded fragment packed 2 4-bit values per byte.

`audioop.lin2alaw(fragment, width)`

Convert samples in the audio fragment to a-LAW encoding and return this as a bytes object. a-LAW is an audio encoding format whereby you get a dynamic range of about 13 bits using only 8 bit samples. It is used by the Sun audio hardware, among others.

`audioop.lin2lin(fragment, width, newwidth)`

Convert samples between 1-, 2-, 3- and 4-byte formats.

### Note

In some audio formats, such as .WAV files, 16, 24 and 32 bit samples are signed, but 8 bit samples are unsigned. So when converting to 8 bit wide samples for these formats, you need to also add 128 to the result:

```
new_frames = audioop.lin2lin(frames, old_width, 1)
new_frames = audioop.bias(new_frames, 1, 128)
```

The same, in reverse, has to be applied when converting from 8 to 16, 24 or 32 bit width samples.

`audioop.lin2ulaw(fragment, width)`

Convert samples in the audio fragment to u-LAW encoding and return this as a bytes object. u-LAW is an audio encoding format whereby you get a dynamic range of about 14 bits using only 8 bit samples. It is used by the Sun audio hardware, among others.

`audioop.max(fragment, width)`

Return the maximum of the *absolute value* of all samples in a fragment.

`audioop.maxpp(fragment, width)`

Return the maximum peak-peak value in the sound fragment.

`audioop.minmax(fragment, width)`

Return a tuple consisting of the minimum and maximum values of all samples in the sound fragment.

`audioop.mul(fragment, width, factor)`

Return a fragment that has all samples in the original fragment multiplied by the floating-point value *factor*. Samples are truncated in case of overflow.

`audioop.ratecv(fragment, width, nchannels, inrate, outrate, state[, weightA[, weightB]])`

Convert the frame rate of the input fragment.

*state* is a tuple containing the state of the converter. The converter returns a tuple (*newfragment*, *newstate*), and *newstate* should be passed to the next call of `ratecv()`. The initial call should pass `None` as the state.

The *weightA* and *weightB* arguments are parameters for a simple digital filter and default to 1 and 0 respectively.

`audioop.reverse(fragment, width)`

Reverse the samples in a fragment and returns the modified fragment.

`audioop.rms(fragment, width)`

Return the root-mean-square of the fragment, i.e.  
 $\sqrt{\text{sum}(S_i^2) / n}$ .

This is a measure of the power in an audio signal.

`audioop.tomono(fragment, width, lfactor, rfactor)`

Convert a stereo fragment to a mono fragment. The left channel is multiplied by *lfactor* and the right channel by *rfactor* before adding the two channels to give a mono signal.

`audioop.tostereo(fragment, width, lfactor, rfactor)`

Generate a stereo fragment from a mono fragment. Each pair of samples in the stereo fragment are computed from the mono sample, whereby left channel samples are multiplied by *lfactor* and right channel samples by *rfactor*.

`audioop.ulaw2lin(fragment, width)`

Convert sound fragments in u-LAW encoding to linearly encoded sound fragments. u-LAW encoding always uses 8 bits samples, so *width* refers only to the sample width of the output fragment here.

Note that operations such as `mul()` or `max()` make no distinction between mono and stereo fragments, i.e. all samples are treated equal. If this is a problem the stereo fragment should be split into two mono fragments first and recombined later. Here is an example of how to do that:

```
def mul_stereo(sample, width, lfactor, rfactor):
    lsample = audioop.tomono(sample, width, 1, 0)
    rsample = audioop.tomono(sample, width, 0, 1)
    lsample = audioop.mul(lsample, width, lfactor)
    rsample = audioop.mul(rsample, width, rfactor)
    lsample = audioop.tostereo(lsample, width, 1, 0)
    rsample = audioop.tostereo(rsample, width, 0, 1)
    return audioop.add(lsample, rsample, width)
```

If you use the ADPCM coder to build network packets and you want your protocol to be stateless (i.e. to be able to tolerate packet loss) you should not only transmit the data but also the state. Note that you should send the *initial* state (the one you passed to

`lin2adpcm()`) along to the decoder, not the final state (as returned by the coder). If you want to use `struct.Struct` to store the state in binary you can code the first element (the predicted value) in 16 bits and the second (the delta index) in 8.

The ADPCM coders have never been tried against other ADPCM coders, only against themselves. It could well be that I misinterpreted the standards in which case they will not be interoperable with the respective standards.

The `find*`() routines might look a bit funny at first sight. They are primarily meant to do echo cancellation. A reasonably fast way to do this is to pick the most energetic piece of the output sample, locate that in the input sample and subtract the whole output sample from the input sample:

```
def echocancel(outputdata, inputdata):
    pos = audioop.findmax(outputdata, 800)      # one tenth
    out_test = outputdata[pos*2:]
    in_test = inputdata[pos*2:]
    ipos, factor = audioop.findfit(in_test, out_test)
    # Optional (for better cancellation):
    # factor = audioop.findfactor(in_test[ipos*2:ipos*2+
    #                               out_test)
    prefill = '\0'*(pos+ipos)*2
    postfill = '\0'*(len(inputdata)-len(prefill)-len(out_test))
    outputdata = prefill + audioop.mul(outputdata, 2, -factor*in_test)
    return audioop.add(inputdata, outputdata, 2)
```

# cgi — Common Gateway Interface support

**Source code:** [Lib/cgi.py](https://github.com/python/cpython/tree/3.11/Lib/cgi.py) [https://github.com/python/cpython/tree/3.11/Lib/cgi.py]

*Deprecated since version 3.11, will be removed in version 3.13:* The **cgi** module is deprecated (see [PEP 594](https://peps.python.org/pep-0594/#cgi) [https://peps.python.org/pep-0594/#cgi] for details and alternatives).

The **FieldStorage** class can typically be replaced with [urllib.parse.parse\\_qs\(\)](https://docs.python.org/3/library/urllib.parse.html#urllib.parse.parse_qs) for GET and HEAD requests, and the [email.message](https://docs.python.org/3/library/email.message.html) module or [multipart](https://pypi.org/project/multipart/) [https://pypi.org/project/multipart/] for POST and PUT. Most [utility functions](#) have replacements.

---

Support module for Common Gateway Interface (CGI) scripts.

This module defines a number of utilities for use by CGI scripts written in Python.

The global variable `maxlen` can be set to an integer indicating the maximum size of a POST request. POST requests larger than this size will result in a [ValueError](#) being raised during parsing. The default value of this variable is `0`, meaning the request size is unlimited.

[Availability](#): not Emscripten, not WASI.

This module does not work or is not available on WebAssembly platforms `wasm32-emscrip`ten and `wasm32-wasi`. See [WebAssembly platforms](#) for more information.

## Introduction

A CGI script is invoked by an HTTP server, usually to process user input submitted through an HTML `<FORM>` or `<ISINDEX>` element.

Most often, CGI scripts live in the server's special `cgi-bin` directory. The HTTP server places all sorts of information about the request (such as the client's hostname, the requested URL, the query string, and lots of other goodies) in the script's shell environment, executes the script, and sends the script's output back to the client.

The script's input is connected to the client too, and sometimes the form data is read this way; at other times the form data is passed via the "query string" part of the URL. This module is intended to take care of the different cases and provide a simpler interface to the Python script. It also provides a number of utilities that help in debugging scripts, and the latest addition is support for file uploads from a form (if your browser supports it).

The output of a CGI script should consist of two sections, separated by a blank line. The first section contains a number of headers, telling the client what kind of data is following. Python code to generate a minimal header section looks like this:

```
print("Content-Type: text/html")      # HTML is following
print()                               # blank line, end of headers
```

The second section is usually HTML, which allows the client software to display nicely formatted text with header, in-line images, etc. Here's Python code that prints a simple piece of HTML:

```
print("<TITLE>CGI script output</TITLE>")
print("<H1>This is my first CGI script</H1>")
print("Hello, world!")
```

## Using the cgi module

Begin by writing `import cgi`.

When you write a new script, consider adding these lines:

```
import cgitb
cgitb.enable()
```

This activates a special exception handler that will display detailed reports in the web browser if any errors occur. If you'd rather not show the guts of your program to users of your script, you can have the reports saved to files instead, with code like this:

```
import cgitb
cgitb.enable(display=0, logdir="/path/to/logdir")
```

It's very helpful to use this feature during script development. The reports produced by **cgitb** provide information that can save you a lot of time in tracking down bugs. You can always remove the `cgitb` line later when you have tested your script and are confident that it works correctly.

To get at submitted form data, use the **FieldStorage** class. If the form contains non-ASCII characters, use the *encoding* keyword parameter set to the value of the encoding defined for the document. It is usually contained in the META tag in the HEAD section of the HTML document or by the *Content-Type* header. This reads the form contents from the standard input or the environment (depending on the value of various environment variables set according to the CGI standard). Since it may consume standard input, it should be instantiated only once.

The **FieldStorage** instance can be indexed like a Python dictionary. It allows membership testing with the **in** operator, and also supports the standard dictionary method **keys()** and the built-in function **len()**. Form fields containing empty strings are ignored and do not appear in the dictionary; to keep such values, provide a true value for the optional *keep\_blank\_values* keyword parameter when creating the **FieldStorage** instance.

For instance, the following code (which assumes that the *Content-Type* header and blank line have already been printed) checks that the fields `name` and `addr` are both set to a non-empty string:

```
form = cgi.FieldStorage()
if "name" not in form or "addr" not in form:
```

```

print("<H1>Error</H1>")
print("Please fill in the name and addr fields.")
return
print("<p>name:", form["name"].value)
print("<p>addr:", form["addr"].value)
...further form processing here...

```

Here the fields, accessed through `form[key]`, are themselves instances of **FieldStorage** (or **MiniFieldStorage**, depending on the form encoding). The **value** attribute of the instance yields the string value of the field. The **getvalue()** method returns this string value directly; it also accepts an optional second argument as a default to return if the requested key is not present.

If the submitted form data contains more than one field with the same name, the object retrieved by `form[key]` is not a **FieldStorage** or **MiniFieldStorage** instance but a list of such instances. Similarly, in this situation, `form.getvalue(key)` would return a list of strings. If you expect this possibility (when your HTML form contains multiple fields with the same name), use the **getlist()** method, which always returns a list of values (so that you do not need to special-case the single item case). For example, this code concatenates any number of username fields, separated by commas:

```

value = form.getlist("username")
usernames = ",".join(value)

```

If a field represents an uploaded file, accessing the value via the **value** attribute or the **getvalue()** method reads the entire file in memory as bytes. This may not be what you want. You can test for an uploaded file by testing either the **filename** attribute or the **file** attribute. You can then read the data from the **file** attribute before it is automatically closed as part of the garbage collection of the **FieldStorage** instance (the **read()** and **readline()** methods will return bytes):

```

fileitem = form["userfile"]
if fileitem.file:
    # It's an uploaded file; count lines

```

```
linecount = 0
while True:
    line = fileitem.file.readline()
    if not line: break
    linecount = linecount + 1
```

**FieldStorage** objects also support being used in a **with** statement, which will automatically close them when done.

If an error is encountered when obtaining the contents of an uploaded file (for example, when the user interrupts the form submission by clicking on a Back or Cancel button) the **done** attribute of the object for the field will be set to the value -1.

The file upload draft standard entertains the possibility of uploading multiple files from one field (using a recursive *multipart/\** encoding). When this occurs, the item will be a dictionary-like **FieldStorage** item. This can be determined by testing its **type** attribute, which should be *multipart/form-data* (or perhaps another MIME type matching *multipart/\**). In this case, it can be iterated over recursively just like the top-level form object.

When a form is submitted in the “old” format (as the query string or as a single data part of type *application/x-www-form-urlencoded*), the items will actually be instances of the class **MiniFieldStorage**. In this case, the **list**, **file**, and **filename** attributes are always **None**.

A form submitted via POST that also has a query string will contain both **FieldStorage** and **MiniFieldStorage** items.

*Changed in version 3.4:* The **file** attribute is automatically closed upon the garbage collection of the creating **FieldStorage** instance.

*Changed in version 3.5:* Added support for the context management protocol to the **FieldStorage** class.

## Higher Level Interface

The previous section explains how to read CGI form data using the **FieldStorage** class. This section describes a higher level interface which was added to this class to allow one to do it in a more readable and intuitive way. The interface doesn't make the techniques described in previous sections obsolete — they are still useful to process file uploads efficiently, for example.

The interface consists of two simple methods. Using the methods you can process form data in a generic way, without the need to worry whether only one or more values were posted under one name.

In the previous section, you learned to write following code anytime you expected a user to post more than one value under one name:

```
item = form.getvalue("item")
if isinstance(item, list):
    # The user is requesting more than one item.
else:
    # The user is requesting only one item.
```

This situation is common for example when a form contains a group of multiple checkboxes with the same name:

```
<input type="checkbox" name="item" value="1" />
<input type="checkbox" name="item" value="2" />
```

In most situations, however, there's only one form control with a particular name in a form and then you expect and need only one value associated with this name. So you write a script containing for example this code:

```
user = form.getvalue("user").upper()
```

The problem with the code is that you should never expect that a client will provide valid input to your scripts. For example, if a curious user appends another `user=foo` pair to the query string, then the script would crash, because in this situation the `getvalue("user")` method call returns a list instead of a string. Calling the `upper()` method on a list is not valid (since lists do

not have a method of this name) and results in an `AttributeError` exception.

Therefore, the appropriate way to read form data values was to always use the code which checks whether the obtained value is a single value or a list of values. That's annoying and leads to less readable scripts.

A more convenient approach is to use the methods `getfirst()` and `getlist()` provided by this higher level interface.

`FieldStorage.getfirst(name, default=None)`

This method always returns only one value associated with form field *name*. The method returns only the first value in case that more values were posted under such name. Please note that the order in which the values are received may vary from browser to browser and should not be counted on. <sup>1</sup> If no such form field or value exists then the method returns the value specified by the optional parameter *default*. This parameter defaults to `None` if not specified.

`FieldStorage.getlist(name)`

This method always returns a list of values associated with form field *name*. The method returns an empty list if no such form field or value exists for *name*. It returns a list consisting of one item if only one such value exists.

Using these methods you can write nice compact code:

```
import cgi
form = cgi.FieldStorage()
user = form.getfirst("user", "").upper()      # This way i
for item in form.getlist("item"):
    do_something(item)
```

## Functions

These are useful if you want more control, or if you want to employ some of the algorithms implemented in this module in other

circumstances.

```
cgi.parse(fp=None, environ=os.environ, keep_blank_values=False,  
strict_parsing=False, separator='&')
```

Parse a query in the environment or from a file (the file defaults to `sys.stdin`). The `keep_blank_values`, `strict_parsing` and `separator` parameters are passed to `urllib.parse.parse_qs()` unchanged.

*Deprecated since version 3.11, will be removed in version 3.13:*  
This function, like the rest of the `cgi` module, is deprecated. It can be replaced by calling `urllib.parse.parse_qs()` directly on the desired query string (except for `multipart/form-data` input, which can be handled as described for `parse_multipart()`).

```
cgi.parse_multipart(fp, pdict, encoding='utf-8', errors='replace',  
separator='&')
```

Parse input of type *multipart/form-data* (for file uploads). Arguments are `fp` for the input file, `pdict` for a dictionary containing other parameters in the *Content-Type* header, and `encoding`, the request encoding.

Returns a dictionary just like `urllib.parse.parse_qs()`: keys are the field names, each value is a list of values for that field. For non-file fields, the value is a list of strings.

This is easy to use but not much good if you are expecting megabytes to be uploaded — in that case, use the **FieldStorage** class instead which is much more flexible.

*Changed in version 3.7:* Added the `encoding` and `errors` parameters. For non-file fields, the value is now a list of strings, not bytes.

*Changed in version 3.10:* Added the `separator` parameter.

*Deprecated since version 3.11, will be removed in version 3.13:*  
This function, like the rest of the `cgi` module, is deprecated. It can be replaced with the functionality in the `email`

package (e.g. `email.message.EmailMessage/`  
`email.message.Message`) which implements the same  
MIME RFCs, or with the `multipart` [[https://pypi.org/project/](https://pypi.org/project/multipart/)  
`multipart/`] PyPI project.

### `cgi.parse_header(string)`

Parse a MIME header (such as *Content-Type*) into a main value  
and a dictionary of parameters.

*Deprecated since version 3.11, will be removed in version 3.13:*  
This function, like the rest of the `cgi` module, is deprecated.  
It can be replaced with the functionality in the `email`  
package, which implements the same MIME RFCs.

For example, with `email.message.EmailMessage`:

```
from email.message import EmailMessage
msg = EmailMessage()
msg['content-type'] = 'application/json; charset="u
main, params = msg.get_content_type(), msg['content
```

### `cgi.test()`

Robust test CGI script, usable as main program. Writes  
minimal HTTP headers and formats all information provided  
to the script in HTML format.

### `cgi.print_enviro()`

Format the shell environment in HTML.

### `cgi.print_form(form)`

Format a form in HTML.

### `cgi.print_directory()`

Format the current directory in HTML.

### `cgi.print_enviro_usage()`

Print a list of useful (used by CGI) environment variables in

HTML.

## Caring about security

There's one important rule: if you invoke an external program (via `os.system()`, `os.popen()` or other functions with similar functionality), make very sure you don't pass arbitrary strings received from the client to the shell. This is a well-known security hole whereby clever hackers anywhere on the web can exploit a gullible CGI script to invoke arbitrary shell commands. Even parts of the URL or field names cannot be trusted, since the request doesn't have to come from your form!

To be on the safe side, if you must pass a string gotten from a form to a shell command, you should make sure the string contains only alphanumeric characters, dashes, underscores, and periods.

## Installing your CGI script on a Unix system

Read the documentation for your HTTP server and check with your local system administrator to find the directory where CGI scripts should be installed; usually this is in a directory `cgi-bin` in the server tree.

Make sure that your script is readable and executable by “others”; the Unix file mode should be `00755` octal (use `chmod 0755 filename`). Make sure that the first line of the script contains `#!/` starting in column 1 followed by the pathname of the Python interpreter, for instance:

```
#!/usr/local/bin/python
```

Make sure the Python interpreter exists and is executable by “others”.

Make sure that any files your script needs to read or write are readable or writable, respectively, by “others” — their mode should be `00644` for readable and `00666` for writable. This is because,

for security reasons, the HTTP server executes your script as user “nobody”, without any special privileges. It can only read (write, execute) files that everybody can read (write, execute). The current directory at execution time is also different (it is usually the server’s cgi-bin directory) and the set of environment variables is also different from what you get when you log in. In particular, don’t count on the shell’s search path for executables (**PATH**) or the Python module search path (**PYTHONPATH**) to be set to anything interesting.

If you need to load modules from a directory which is not on Python’s default module search path, you can change the path in your script, before importing other modules. For example:

```
import sys
sys.path.insert(0, "/usr/home/joe/lib/python")
sys.path.insert(0, "/usr/local/lib/python")
```

(This way, the directory inserted last will be searched first!)

Instructions for non-Unix systems will vary; check your HTTP server’s documentation (it will usually have a section on CGI scripts).

## Testing your CGI script

Unfortunately, a CGI script will generally not run when you try it from the command line, and a script that works perfectly from the command line may fail mysteriously when run from the server. There’s one reason why you should still test your script from the command line: if it contains a syntax error, the Python interpreter won’t execute it at all, and the HTTP server will most likely send a cryptic error to the client.

Assuming your script has no syntax errors, yet it does not work, you have no choice but to read the next section.

## Debugging CGI scripts

First of all, check for trivial installation errors — reading the section

above on installing your CGI script carefully can save you a lot of time. If you wonder whether you have understood the installation procedure correctly, try installing a copy of this module file (`cgi.py`) as a CGI script. When invoked as a script, the file will dump its environment and the contents of the form in HTML format. Give it the right mode etc., and send it a request. If it's installed in the standard `cgi-bin` directory, it should be possible to send it a request by entering a URL into your browser of the form:

```
http://yourhostname/cgi-bin/cgi.py?name=Joe+Blow&addr=At
```

If this gives an error of type 404, the server cannot find the script – perhaps you need to install it in a different directory. If it gives another error, there's an installation problem that you should fix before trying to go any further. If you get a nicely formatted listing of the environment and form content (in this example, the fields should be listed as “addr” with value “At Home” and “name” with value “Joe Blow”), the `cgi.py` script has been installed correctly. If you follow the same procedure for your own script, you should now be able to debug it.

The next step could be to call the `cgi` module's `test()` function from your script: replace its main code with the single statement

```
cgi.test()
```

This should produce the same results as those gotten from installing the `cgi.py` file itself.

When an ordinary Python script raises an unhandled exception (for whatever reason: of a typo in a module name, a file that can't be opened, etc.), the Python interpreter prints a nice traceback and exits. While the Python interpreter will still do this when your CGI script raises an exception, most likely the traceback will end up in one of the HTTP server's log files, or be discarded altogether.

Fortunately, once you have managed to get your script to execute *some* code, you can easily send tracebacks to the web browser using the `cgitb` module. If you haven't done so already, just add the lines:

```
import cgitb
cgitb.enable()
```

to the top of your script. Then try running it again; when a problem occurs, you should see a detailed report that will likely make apparent the cause of the crash.

If you suspect that there may be a problem in importing the `cgitb` module, you can use an even more robust approach (which only uses built-in modules):

```
import sys
sys.stderr = sys.stdout
print("Content-Type: text/plain")
print()
...your code here...
```

This relies on the Python interpreter to print the traceback. The content type of the output is set to plain text, which disables all HTML processing. If your script works, the raw HTML will be displayed by your client. If it raises an exception, most likely after the first two lines have been printed, a traceback will be displayed. Because no HTML interpretation is going on, the traceback will be readable.

## Common problems and solutions

- Most HTTP servers buffer the output from CGI scripts until the script is completed. This means that it is not possible to display a progress report on the client's display while the script is running.
- Check the installation instructions above.
- Check the HTTP server's log files. (`tail -f logfile` in a separate window may be useful!)
- Always check a script for syntax errors first, by doing something like `python script.py`.
- If your script does not have any syntax errors, try adding `import cgitb; cgitb.enable()` to the top of the script.
- When invoking external programs, make sure they can be found. Usually, this means using absolute path names —

**PATH** is usually not set to a very useful value in a CGI script.

- When reading or writing external files, make sure they can be read or written by the userid under which your CGI script will be running: this is typically the userid under which the web server is running, or some explicitly specified userid for a web server's `suidexec` feature.
- Don't try to give a CGI script a set-uid mode. This doesn't work on most systems, and is a security liability as well.

## Footnotes

1

Note that some recent versions of the HTML specification do state what order the field values should be supplied in, but knowing whether a request was received from a conforming browser, or even from a browser at all, is tedious and error-prone.

# **cgitb** — Traceback manager for CGI scripts

**Source code:** [Lib/cgitb.py](https://github.com/python/cpython/tree/3.11/Lib/cgitb.py) [https://github.com/python/cpython/tree/3.11/Lib/cgitb.py]

*Deprecated since version 3.11, will be removed in version 3.13:* The **cgitb** module is deprecated (see [PEP 594](https://peps.python.org/pep-0594/#cgitb) [https://peps.python.org/pep-0594/#cgitb] for details).

---

The **cgitb** module provides a special exception handler for Python scripts. (Its name is a bit misleading. It was originally designed to display extensive traceback information in HTML for CGI scripts. It was later generalized to also display this information in plain text.) After this module is activated, if an uncaught exception occurs, a detailed, formatted report will be displayed. The report includes a traceback showing excerpts of the source code for each level, as well as the values of the arguments and local variables to currently running functions, to help you debug the problem. Optionally, you can save this information to a file instead of sending it to the browser.

To enable this feature, simply add this to the top of your CGI script:

```
import cgitb
cgitb.enable()
```

The options to the **enable()** function control whether the report is displayed in the browser and whether the report is logged to a file for later analysis.

```
cgitb.enable(display=1, logdir=None, context=5, format='html')
```

This function causes the **cgitb** module to take over the interpreter's default handling for exceptions by setting the value of **sys.excepthook**.

The optional argument *display* defaults to 1 and can be set to 0 to suppress sending the traceback to the browser. If the argument *logdir* is present, the traceback reports are written to files. The value of *logdir* should be a directory where these files will be placed. The optional argument *context* is the number of lines of context to display around the current line of source code in the traceback; this defaults to 5. If the optional argument *format* is "html", the output is formatted as HTML. Any other value forces plain text output. The default value is "html".

`cgibtb.text(info, context=5)`

This function handles the exception described by *info* (a 3-tuple containing the result of `sys.exc_info()`), formatting its traceback as text and returning the result as a string. The optional argument *context* is the number of lines of context to display around the current line of source code in the traceback; this defaults to 5.

`cgibtb.html(info, context=5)`

This function handles the exception described by *info* (a 3-tuple containing the result of `sys.exc_info()`), formatting its traceback as HTML and returning the result as a string. The optional argument *context* is the number of lines of context to display around the current line of source code in the traceback; this defaults to 5.

`cgibtb.handler(info=None)`

This function handles an exception using the default settings (that is, show a report in the browser, but don't log to a file). This can be used when you've caught an exception and want to report it using `cgibtb`. The optional *info* argument should be a 3-tuple containing an exception type, exception value, and traceback object, exactly like the tuple returned by `sys.exc_info()`. If the *info* argument is not supplied, the current exception is obtained from `sys.exc_info()`.

# chunk — Read IFF chunked data

**Source code:** [Lib/chunk.py](#) [<https://github.com/python/cpython/tree/3.11/Lib/chunk.py>]

*Deprecated since version 3.11, will be removed in version 3.13:* The **chunk** module is deprecated (see [PEP 594](#) [<https://peps.python.org/pep-0594/#chunk>] for details).

---

This module provides an interface for reading files that use EA IFF 85 chunks. [1](#) This format is used in at least the Audio Interchange File Format (AIFF/AIFF-C) and the Real Media File Format (RMFF). The WAVE audio file format is closely related and can also be read using this module.

A chunk has the following structure:

Offsets	
Chunk ID	
Size of chunk in big-endian byte order, not including the header	
Data bytes, where $n$ is the size given in the preceding field	
Pad byte needed if $n$ is odd and chunk alignment is used	

The ID is a 4-byte string which identifies the type of chunk.

The size field (a 32-bit value, encoded using big-endian byte order) gives the size of the chunk data, not including the 8-byte header.

Usually an IFF-type file consists of one or more chunks. The proposed usage of the **Chunk** class defined here is to instantiate an instance at the start of each chunk and read from the instance until it reaches the end, after which a new instance can be instantiated. At the end of the file, creating a new instance will fail with an **EOFError** exception.

```
class chunk.Chunk(file, align = True, bigendian = True,
incheader = False)
```

Class which represents a chunk. The *file* argument is expected to be a file-like object. An instance of this class is specifically allowed. The only method that is needed is `read()`. If the methods `seek()` and `tell()` are present and don't raise an exception, they are also used. If these methods are present and raise an exception, they are expected to not have altered the object. If the optional argument *align* is true, chunks are assumed to be aligned on 2-byte boundaries. If *align* is false, no alignment is assumed. The default value is true. If the optional argument *bigendian* is false, the chunk size is assumed to be in little-endian order. This is needed for WAVE audio files. The default value is true. If the optional argument *incheader* is true, the size given in the chunk header includes the size of the header. The default value is false.

A **Chunk** object supports the following methods:

`getname()`

Returns the name (ID) of the chunk. This is the first 4 bytes of the chunk.

`getsize()`

Returns the size of the chunk.

`close()`

Close and skip to the end of the chunk. This does not close the underlying file.

The remaining methods will raise **OSError** if called after the `close()` method has been called. Before Python 3.3, they used to raise **IOError**, now an alias of **OSError**.

`isatty()`

Returns `False`.

`seek(pos, whence = 0)`

Set the chunk's current position. The *whence* argument is optional and defaults to 0 (absolute file positioning); other values are 1 (seek relative to the current position) and 2 (seek relative to the file's end). There is no return value. If the underlying file does not allow seek, only forward seeks are allowed.

`tell()`

Return the current position into the chunk.

`read(size = - 1)`

Read at most *size* bytes from the chunk (less if the read hits the end of the chunk before obtaining *size* bytes). If the *size* argument is negative or omitted, read all data until the end of the chunk. An empty bytes object is returned when the end of the chunk is encountered immediately.

`skip()`

Skip to the end of the chunk. All further calls to `read()` for the chunk will return `b''`. If you are not interested in the contents of the chunk, this method should be called so that the file points to the start of the next chunk.

# crypt — Function to check Unix passwords

**Source code:** [Lib/crypt.py](https://github.com/python/cpython/tree/3.11/Lib/crypt.py) [https://github.com/python/cpython/tree/3.11/Lib/crypt.py]

*Deprecated since version 3.11, will be removed in version 3.13:* The **crypt** module is deprecated (see [PEP 594](https://peps.python.org/pep-0594/#crypt) [https://peps.python.org/pep-0594/#crypt] for details and alternatives). The **hashlib** module is a potential replacement for certain use cases.

---

This module implements an interface to the **crypt(3)** routine, which is a one-way hash function based upon a modified DES algorithm; see the Unix man page for further details. Possible uses include storing hashed passwords so you can check passwords without storing the actual password, or attempting to crack Unix passwords with a dictionary.

Notice that the behavior of this module depends on the actual implementation of the **crypt(3)** routine in the running system. Therefore, any extensions available on the current implementation will also be available on this module.

**Availability:** Unix, not VxWorks.

**Availability:** not Emscripten, not WASI.

This module does not work or is not available on WebAssembly platforms `wasm32-emscripten` and `wasm32-wasi`. See [WebAssembly platforms](#) for more information.

## Hashing Methods

*New in version 3.3.*

The **crypt** module defines the list of hashing methods (not all methods are available on all platforms):

`crypt.METHOD_SHA512`

A Modular Crypt Format method with 16 character salt and 86 character hash based on the SHA-512 hash function. This is the strongest method.

`crypt.METHOD_SHA256`

Another Modular Crypt Format method with 16 character salt and 43 character hash based on the SHA-256 hash function.

`crypt.METHOD_BLOWFISH`

Another Modular Crypt Format method with 22 character salt and 31 character hash based on the Blowfish cipher.

*New in version 3.7.*

`crypt.METHOD_MD5`

Another Modular Crypt Format method with 8 character salt and 22 character hash based on the MD5 hash function.

`crypt.METHOD_CRYPT`

The traditional method with a 2 character salt and 13 characters of hash. This is the weakest method.

## Module Attributes

*New in version 3.3.*

`crypt.methods`

A list of available password hashing algorithms, as `crypt.METHOD_*` objects. This list is sorted from strongest to weakest.

## Module Functions

The `crypt` module defines the following functions:

`crypt.crypt(word, salt=None)`

`word` will usually be a user's password as typed at a prompt or in a graphical interface. The optional `salt` is either a string as returned from `mksalt()`, one of the `crypt.METHOD_*` values (though not all may be available on all platforms), or a full encrypted password including salt, as returned by this function. If `salt` is not provided, the strongest method available in `methods` will be used.

Checking a password is usually done by passing the plain-text password as `word` and the full results of a previous `crypt()` call, which should be the same as the results of this call.

`salt` (either a random 2 or 16 character string, possibly prefixed with `$digit$` to indicate the method) which will be used to perturb the encryption algorithm. The characters in `salt` must be in the set `[./a-zA-Z0-9]`, with the exception of Modular Crypt Format which prefixes a `$digit$`.

Returns the hashed password as a string, which will be composed of characters from the same alphabet as the salt.

Since a few `crypt(3)` extensions allow different values, with different sizes in the `salt`, it is recommended to use the full crypt password as salt when checking for a password.

*Changed in version 3.3:* Accept `crypt.METHOD_*` values in addition to strings for `salt`.

`crypt.mksalt(method=None, *, rounds=None)`

Return a randomly generated salt of the specified method. If no `method` is given, the strongest method available in `methods` is used.

The return value is a string suitable for passing as the `salt` argument to `crypt()`.

*rounds* specifies the number of rounds for `METHOD_SHA256`, `METHOD_SHA512` and `METHOD_BLOWFISH`. For `METHOD_SHA256` and `METHOD_SHA512` it must be an integer between 1000 and 999\_999\_999, the default is 5000. For `METHOD_BLOWFISH` it must be a power of two between 16 ( $2^4$ ) and 2\_147\_483\_648 ( $2^{31}$ ), the default is 4096 ( $2^{12}$ ).

*New in version 3.3.*

*Changed in version 3.7:* Added the *rounds* parameter.

## Examples

A simple example illustrating typical use (a constant-time comparison operation is needed to limit exposure to timing attacks. `hmac.compare_digest()` is suitable for this purpose):

```
import pwd
import crypt
import getpass
from hmac import compare_digest as compare_hash

def login():
    username = input('Python login: ')
    cryptpasswd = pwd.getpwnam(username)[1]
    if cryptpasswd:
        if cryptpasswd == 'x' or cryptpasswd == '*':
            raise ValueError('no support for shadow pass')
        cleartext = getpass.getpass()
        return compare_hash(crypt.crypt(cleartext, cryptpasswd))
    else:
        return True
```

To generate a hash of a password using the strongest available method and check it against the original:

```
import crypt
from hmac import compare_digest as compare_hash
```

```
hashed = crypt.crypt(plaintext)
if not compare_hash(hashed, crypt.crypt(plaintext, hashed)):
    raise ValueError("hashed version doesn't validate against original")
```

# imghdr — Determine the type of an image

**Source code:** [Lib/imghdr.py](https://github.com/python/cpython/tree/3.11/Lib/imghdr.py) [https://github.com/python/cpython/tree/3.11/Lib/imghdr.py]

*Deprecated since version 3.11, will be removed in version 3.13:* The [imghdr](https://peps.python.org/pep-0594/#imghdr) module is deprecated (see [PEP 594](https://peps.python.org/pep-0594/#imghdr) [https://peps.python.org/pep-0594/#imghdr] for details and alternatives).

---

The [imghdr](#) module determines the type of image contained in a file or byte stream.

The [imghdr](#) module defines the following function:

`imghdr.what(file, h=None)`

Tests the image data contained in the file named by *file*, and returns a string describing the image type. If optional *h* is provided, the *file* argument is ignored and *h* is assumed to contain the byte stream to test.

*Changed in version 3.6:* Accepts a [path-like object](#).

The following image types are recognized, as listed below with the return value from `what()`:

## Image format

SGI ImageLib Files
CGI 87a and 89a Files
Portable Bitmap Files
Portable Graymap Files
Portable Pixmap Files
TIFF Files
Sun Raster Files
X-Bitmap Files

JPEG data in JFIF or Exif formats

BMP files

Portable Network Graphics

Webp files

OpenEXR Files

*New in version 3.5:* The *exr* and *webp* formats were added.

You can extend the list of file types `imghdr` can recognize by appending to this variable:

`imghdr.tests`

A list of functions performing the individual tests. Each function takes two arguments: the byte-stream and an open file-like object. When `what()` is called with a byte-stream, the file-like object will be `None`.

The test function should return a string describing the image type if the test succeeded, or `None` if it failed.

Example:

```
>>> import imghdr
>>> imghdr.what('bass.gif')
'gif'
```

# imp — Access the import internals

**Source code:** [Lib/imp.py](https://github.com/python/cpython/tree/3.11/Lib/imp.py) [<https://github.com/python/cpython/tree/3.11/Lib/imp.py>]

*Deprecated since version 3.4, will be removed in version 3.12:* The `imp` module is deprecated in favor of `importlib`.

---

This module provides an interface to the mechanisms used to implement the `import` statement. It defines the following constants and functions:

`imp.get_magic()`

Return the magic string value used to recognize byte-compiled code files (`.pyc` files). (This value may be different for each Python version.)

*Deprecated since version 3.4:* Use `importlib.util.MAGIC_NUMBER` instead.

`imp.get_suffixes()`

Return a list of 3-element tuples, each describing a particular type of module. Each triple has the form `(suffix, mode, type)`, where `suffix` is a string to be appended to the module name to form the filename to search for, `mode` is the mode string to pass to the built-in `open()` function to open the file (this can be `'r'` for text files or `'rb'` for binary files), and `type` is the file type, which has one of the values `PY_SOURCE`, `PY_COMPILED`, or `C_EXTENSION`, described below.

*Deprecated since version 3.3:* Use the constants defined on `importlib.machinery` instead.

`imp.find_module(name[, path])`

Try to find the module *name*. If *path* is omitted or `None`, the list of directory names given by `sys.path` is searched, but first a few special places are searched: the function tries to find a built-in module with the given name (`C_BUILTIN`), then a frozen module (`PY_FROZEN`), and on some systems some other places are looked in as well (on Windows, it looks in the registry which may point to a specific file).

Otherwise, *path* must be a list of directory names; each directory is searched for files with any of the suffixes returned by `get_suffixes()` above. Invalid names in the list are silently ignored (but all list items must be strings).

If search is successful, the return value is a 3-element tuple (*file*, *pathname*, *description*):

*file* is an open [file object](#) positioned at the beginning, *pathname* is the pathname of the file found, and *description* is a 3-element tuple as contained in the list returned by `get_suffixes()` describing the kind of module found.

If the module is built-in or frozen then *file* and *pathname* are both `None` and the *description* tuple contains empty strings for its suffix and mode; the module type is indicated as given in parentheses above. If the search is unsuccessful, `ImportError` is raised. Other exceptions indicate problems with the arguments or environment.

If the module is a package, *file* is `None`, *pathname* is the package path and the last item in the *description* tuple is `PKG_DIRECTORY`.

This function does not handle hierarchical module names (names containing dots). In order to find *P.M*, that is, submodule *M* of package *P*, use `find_module()` and `load_module()` to find and load package *P*, and then use `find_module()` with the *path* argument set to `P.__path__`. When *P* itself has a dotted name, apply this recipe recursively.

*Deprecated since version 3.3:* Use

`importlib.util.find_spec()` instead unless Python 3.3 compatibility is required, in which case use `importlib.find_loader()`. For example usage of the former case, see the [Examples](#) section of the `importlib` documentation.

`imp.load_module(name, file, pathname, description)`

Load a module that was previously found by `find_module()` (or by an otherwise conducted search yielding compatible results). This function does more than importing the module: if the module was already imported, it will reload the module! The *name* argument indicates the full module name (including the package name, if this is a submodule of a package). The *file* argument is an open file, and *pathname* is the corresponding file name; these can be `None` and `' '`, respectively, when the module is a package or not being loaded from a file. The *description* argument is a tuple, as would be returned by `get_suffixes()`, describing what kind of module must be loaded.

If the load is successful, the return value is the module object; otherwise, an exception (usually `ImportError`) is raised.

**Important:** the caller is responsible for closing the *file* argument, if it was not `None`, even when an exception is raised. This is best done using a `try ... finally` statement.

*Deprecated since version 3.3:* If previously used in conjunction with `imp.find_module()` then consider using `importlib.import_module()`, otherwise use the loader returned by the replacement you chose for `imp.find_module()`. If you called `imp.load_module()` and related functions directly with file path arguments then use a combination of `importlib.util.spec_from_file_location()` and `importlib.util.module_from_spec()`. See the [Examples](#) section of the `importlib` documentation for details of the various approaches.

`imp.new_module(name)`

Return a new empty module object called *name*. This object is *not* inserted in `sys.modules`.

*Deprecated since version 3.4:* Use

`importlib.util.module_from_spec()` instead.

`imp.reload(module)`

Reload a previously imported *module*. The argument must be a module object, so it must have been successfully imported before. This is useful if you have edited the module source file using an external editor and want to try out the new version without leaving the Python interpreter. The return value is the module object (the same as the *module* argument).

When `reload(module)` is executed:

- Python modules' code is recompiled and the module-level code reexecuted, defining a new set of objects which are bound to names in the module's dictionary. The `init` function of extension modules is not called a second time.
- As with all other objects in Python the old objects are only reclaimed after their reference counts drop to zero.
- The names in the module namespace are updated to point to any new or changed objects.
- Other references to the old objects (such as names external to the module) are not rebound to refer to the new objects and must be updated in each namespace where they occur if that is desired.

There are a number of other caveats:

When a module is reloaded, its dictionary (containing the module's global variables) is retained. Redefinitions of names will override the old definitions, so this is generally not a problem. If the new version of a module does not define a name that was defined by the old version, the old definition remains. This feature can be used to the module's advantage

if it maintains a global table or cache of objects — with a **try** statement it can test for the table's presence and skip its initialization if desired:

```
try:
    cache
except NameError:
    cache = {}
```

It is legal though generally not very useful to reload built-in or dynamically loaded modules, except for **sys**, **\_\_main\_\_** and **builtins**. In many cases, however, extension modules are not designed to be initialized more than once, and may fail in arbitrary ways when reloaded.

If a module imports objects from another module using **from ... import ...**, calling **reload()** for the other module does not redefine the objects imported from it — one way around this is to re-execute the **from** statement, another is to use **import** and qualified names (*module.\*name\**) instead.

If a module instantiates instances of a class, reloading the module that defines the class does not affect the method definitions of the instances — they continue to use the old class definition. The same is true for derived classes.

*Changed in version 3.3:* Relies on both **\_\_name\_\_** and **\_\_loader\_\_** being defined on the module being reloaded instead of just **\_\_name\_\_**.

*Deprecated since version 3.4:* Use **importlib.reload()** instead.

The following functions are conveniences for handling **PEP 3147** [<https://peps.python.org/pep-3147/>] byte-compiled file paths.

*New in version 3.2.*

**imp.cache\_from\_source(path, debug\_override=None)**

Return the **PEP 3147** [<https://peps.python.org/pep-3147/>] path to the byte-compiled file associated with the source *path*. For

example, if *path* is `/foo/bar/baz.py` the return value would be `/foo/bar/__pycache__/baz.cpython-32.pyc` for Python 3.2. The `cpython-32` string comes from the current magic tag (see `get_tag()`; if `sys.implementation.cache_tag` is not defined then `NotImplementedError` will be raised). By passing in `True` or `False` for *debug\_override* you can override the system's value for `__debug__`, leading to optimized bytecode.

*path* need not exist.

*Changed in version 3.3:* If

`sys.implementation.cache_tag` is `None`, then `NotImplementedError` is raised.

*Deprecated since version 3.4:* Use

`importlib.util.cache_from_source()` instead.

*Changed in version 3.5:* The *debug\_override* parameter no longer creates a `.pyo` file.

`imp.source_from_cache(path)`

Given the *path* to a [PEP 3147](https://peps.python.org/pep-3147/) file name, return the associated source code file path. For example, if *path* is `/foo/bar/__pycache__/baz.cpython-32.pyc` the returned path would be `/foo/bar/baz.py`. *path* need not exist, however if it does not conform to [PEP 3147](https://peps.python.org/pep-3147/) format, a `ValueError` is raised. If `sys.implementation.cache_tag` is not defined, `NotImplementedError` is raised.

*Changed in version 3.3:* Raise `NotImplementedError` when `sys.implementation.cache_tag` is not defined.

*Deprecated since version 3.4:* Use

`importlib.util.source_from_cache()` instead.

`imp.get_tag()`

Return the [PEP 3147](https://peps.python.org/pep-3147/) magic tag

string matching this version of Python's magic number, as returned by `get_magic()`.

*Deprecated since version 3.4:* Use

**`sys.implementation.cache_tag`** directly starting in Python 3.3.

The following functions help interact with the import system's internal locking mechanism. Locking semantics of imports are an implementation detail which may vary from release to release. However, Python ensures that circular imports work without any deadlocks.

### `imp.lock_held()`

Return `True` if the global import lock is currently held, else `False`. On platforms without threads, always return `False`.

On platforms with threads, a thread executing an import first holds a global import lock, then sets up a per-module lock for the rest of the import. This blocks other threads from importing the same module until the original import completes, preventing other threads from seeing incomplete module objects constructed by the original thread. An exception is made for circular imports, which by construction have to expose an incomplete module object at some point.

*Changed in version 3.3:* The locking scheme has changed to per-module locks for the most part. A global import lock is kept for some critical tasks, such as initializing the per-module locks.

*Deprecated since version 3.4.*

### `imp.acquire_lock()`

Acquire the interpreter's global import lock for the current thread. This lock should be used by import hooks to ensure thread-safety when importing modules.

Once a thread has acquired the import lock, the same thread may acquire it again without blocking; the thread must

release it once for each time it has acquired it.

On platforms without threads, this function does nothing.

*Changed in version 3.3:* The locking scheme has changed to per-module locks for the most part. A global import lock is kept for some critical tasks, such as initializing the per-module locks.

*Deprecated since version 3.4.*

`imp.release_lock()`

Release the interpreter's global import lock. On platforms without threads, this function does nothing.

*Changed in version 3.3:* The locking scheme has changed to per-module locks for the most part. A global import lock is kept for some critical tasks, such as initializing the per-module locks.

*Deprecated since version 3.4.*

The following constants with integer values, defined in this module, are used to indicate the search result of `find_module()`.

`imp.PY_SOURCE`

The module was found as a source file.

*Deprecated since version 3.3.*

`imp.PY_COMPILED`

The module was found as a compiled code object file.

*Deprecated since version 3.3.*

`imp.C_EXTENSION`

The module was found as dynamically loadable shared library.

*Deprecated since version 3.3.*

`imp.PKG_DIRECTORY`

The module was found as a package directory.

*Deprecated since version 3.3.*

`imp.C_BUILTIN`

The module was found as a built-in module.

*Deprecated since version 3.3.*

`imp.PY_FROZEN`

The module was found as a frozen module.

*Deprecated since version 3.3.*

`class imp.NullImporter(path_string)`

The `NullImporter` type is a [PEP 302](https://peps.python.org/pep-0302/) [https://peps.python.org/pep-0302/] import hook that handles non-directory path strings by failing to find any modules. Calling this type with an existing directory or empty string raises `ImportError`. Otherwise, a `NullImporter` instance is returned.

Instances have only one method:

`find_module(fullname[, path])`

This method always returns `None`, indicating that the requested module could not be found.

*Changed in version 3.3:* `None` is inserted into `sys.path_importer_cache` instead of an instance of `NullImporter`.

*Deprecated since version 3.4:* Insert `None` into `sys.path_importer_cache` instead.

## Examples

The following function emulates what was the standard import

statement up to Python 1.4 (no hierarchical module names). (This *implementation* wouldn't work in that version, since `find_module()` has been extended and `load_module()` has been added in 1.4.)

```
import imp
import sys
```

```
def __import__(name, globals=None, locals=None, fromlist=
    # Fast path: see if the module has already been imported
    try:
        return sys.modules[name]
    except KeyError:
        pass

    # If any of the following calls raises an exception,
    # there's a problem we can't handle -- let the caller
    # know.

    fp, pathname, description = imp.find_module(name)

    try:
        return imp.load_module(name, fp, pathname, description)
    finally:
        # Since we may exit via an exception, close fp if open
        if fp:
            fp.close()
```

# mailcap — Mailcap file handling

**Source code:** [Lib/mailcap.py](https://github.com/python/cpython/tree/3.11/Lib/mailcap.py) [https://github.com/python/cpython/tree/3.11/Lib/mailcap.py]

*Deprecated since version 3.11, will be removed in version 3.13:* The **mailcap** module is deprecated (see [PEP 594](https://peps.python.org/pep-0594/#mailcap) [https://peps.python.org/pep-0594/#mailcap] for details). The **mimetypes** module provides an alternative.

---

Mailcap files are used to configure how MIME-aware applications such as mail readers and web browsers react to files with different MIME types. (The name “mailcap” is derived from the phrase “mail capability”.) For example, a mailcap file might contain a line like `video/mpeg; xmpeg %s`. Then, if the user encounters an email message or web document with the MIME type `video/mpeg`, `%s` will be replaced by a filename (usually one belonging to a temporary file) and the **xmpeg** program can be automatically started to view the file.

The mailcap format is documented in [RFC 1524](https://datatracker.ietf.org/doc/html/rfc1524.html) [https://datatracker.ietf.org/doc/html/rfc1524.html], “A User Agent Configuration Mechanism For Multimedia Mail Format Information”, but is not an internet standard. However, mailcap files are supported on most Unix systems.

```
mailcap.findmatch(caps, MIMEtype, key='view', filename='/dev/null', plist=[])
```

Return a 2-tuple; the first element is a string containing the command line to be executed (which can be passed to `os.system()`), and the second element is the mailcap entry for a given MIME type. If no matching MIME type can be found, `(None, None)` is returned.

*key* is the name of the field desired, which represents the type of activity to be performed; the default value is 'view', since in the most common case you simply want to view the body of the MIME-typed data. Other possible values might be 'compose' and 'edit', if you wanted to create a new body of the given MIME type or alter the existing body data. See [RFC 1524](https://datatracker.ietf.org/doc/html/rfc1524.html) [https://datatracker.ietf.org/doc/html/rfc1524.html] for a complete list of these fields.

*filename* is the filename to be substituted for %s in the command line; the default value is '/dev/null' which is almost certainly not what you want, so usually you'll override it by specifying a filename.

*plist* can be a list containing named parameters; the default value is simply an empty list. Each entry in the list must be a string containing the parameter name, an equals sign ('='), and the parameter's value. Mailcap entries can contain named parameters like %{foo}, which will be replaced by the value of the parameter named 'foo'. For example, if the command line `showpartial %{id} %{number} %{total}` was in a mailcap file, and *plist* was set to `['id=1', 'number=2', 'total=3']`, the resulting command line would be `'showpartial 1 2 3'`.

In a mailcap file, the "test" field can optionally be specified to test some external condition (such as the machine architecture, or the window system in use) to determine whether or not the mailcap line applies. `findmatch()` will automatically check such conditions and skip the entry if the check fails.

*Changed in version 3.11:* To prevent security issues with shell metacharacters (symbols that have special effects in a shell command line), `findmatch` will refuse to inject ASCII characters other than alphanumerics and `@+=:./-_` into the returned command line.

If a disallowed character appears in *filename*, `findmatch` will always return `(None, None)` as if no entry was found. If such a character appears elsewhere (a value in *plist* or in

*MIMEtype*), `findmatch` will ignore all mailcap entries which use that value. A **warning** will be raised in either case.

### `mailcap.getcaps()`

Returns a dictionary mapping MIME types to a list of mailcap file entries. This dictionary must be passed to the `findmatch()` function. An entry is stored as a list of dictionaries, but it shouldn't be necessary to know the details of this representation.

The information is derived from all of the mailcap files found on the system. Settings in the user's mailcap file `$HOME/.mailcap` will override settings in the system mailcap files `/etc/mailcap`, `/usr/etc/mailcap`, and `/usr/local/etc/mailcap`.

### An example usage:

```
>>> import mailcap
>>> d = mailcap.getcaps()
>>> mailcap.findmatch(d, 'video/mpeg', filename='tmp1223',
('xmpeg tmp1223', {'view': 'xmpeg %s'}))
```

# msilib — Read and write Microsoft Installer files

**Source code:** [Lib/msilib/\\_init\\_.py](https://github.com/python/cpython/tree/3.11/Lib/msilib/_init_.py) [https://github.com/python/cpython/tree/3.11/Lib/msilib/\_init\_.py]

*Deprecated since version 3.11, will be removed in version 3.13:* The **msilib** module is deprecated (see [PEP 594](https://peps.python.org/pep-0594/#msilib) [https://peps.python.org/pep-0594/#msilib] for details).

---

The **msilib** supports the creation of Microsoft Installer (`.msi`) files. Because these files often contain an embedded “cabinet” file (`.cab`), it also exposes an API to create CAB files. Support for reading `.cab` files is currently not implemented; read support for the `.msi` database is possible.

This package aims to provide complete access to all tables in an `.msi` file, therefore, it is a fairly low-level API. One primary application of this package is the creation of Python installer package itself (although that currently uses a different version of `msilib`).

The package contents can be roughly split into four parts: low-level CAB routines, low-level MSI routines, higher-level MSI routines, and standard table structures.

`msilib.FCICreate(cabname, files)`

Create a new CAB file named *cabname*. *files* must be a list of tuples, each containing the name of the file on disk, and the name of the file inside the CAB file.

The files are added to the CAB file in the order they appear in the list. All files are added into a single CAB file, using the MSZIP compression algorithm.

Callbacks to Python for the various steps of MSI creation are currently not exposed.

`msilib.UuidCreate()`

Return the string representation of a new unique identifier. This wraps the Windows API functions **UuidCreate()** and **UuidToString()**.

`msilib.OpenDatabase(path, persist)`

Return a new database object by calling `MsiOpenDatabase`. *path* is the file name of the MSI file; *persist* can be one of the constants `MSIDBOPEN_CREATEDIRECT`, `MSIDBOPEN_CREATE`, `MSIDBOPEN_DIRECT`, `MSIDBOPEN_READONLY`, or `MSIDBOPEN_TRANSACT`, and may include the flag `MSIDBOPEN_PATCHFILE`. See the Microsoft documentation for the meaning of these flags; depending on the flags, an existing database is opened, or a new one created.

`msilib.CreateRecord(count)`

Return a new record object by calling **MSICreateRecord()**. *count* is the number of fields of the record.

`msilib.init_database(name, schema, ProductName, ProductCode, ProductVersion, Manufacturer)`

Create and return a new database *name*, initialize it with *schema*, and set the properties *ProductName*, *ProductCode*, *ProductVersion*, and *Manufacturer*.

*schema* must be a module object containing `tables` and `_Validation_records` attributes; typically, **`msilib.schema`** should be used.

The database will contain just the schema and the validation records when this function returns.

`msilib.add_data(database, table, records)`

Add all *records* to the table named *table* in *database*.

The *table* argument must be one of the predefined tables in the MSI schema, e.g. 'Feature', 'File', 'Component', 'Dialog', 'Control', etc.

*records* should be a list of tuples, each one containing all fields of a record according to the schema of the table. For optional fields, `None` can be passed.

Field values can be ints, strings, or instances of the Binary class.

`class msilib.Binary(filename)`

Represents entries in the Binary table; inserting such an object using `add_data()` reads the file named *filename* into the table.

`msilib.add_tables(database, module)`

Add all table content from *module* to *database*. *module* must contain an attribute *tables* listing all tables for which content should be added, and one attribute per table that has the actual content.

This is typically used to install the sequence tables.

`msilib.add_stream(database, name, path)`

Add the file *path* into the `_Stream` table of *database*, with the stream name *name*.

`msilib.gen_uuid()`

Return a new UUID, in the format that MSI typically requires (i.e. in curly braces, and with all hexdigits in uppercase).

## Database Objects

### Database.OpenView(*sql*)

Return a view object, by calling **MSIDatabaseOpenView()**.  
*sql* is the SQL statement to execute.

### Database.Commit()

Commit the changes pending in the current transaction, by calling **MSIDatabaseCommit()**.

### Database.GetSummaryInformation(*count*)

Return a new summary information object, by calling **MsiGetSummaryInformation()**. *count* is the maximum number of updated values.

### Database.Close()

Close the database object, through **MsiCloseHandle()**.

*New in version 3.7.*

### See also

[MSIDatabaseOpenView](https://msdn.microsoft.com/en-us/library/windows/desktop/aa370082.aspx) [https://msdn.microsoft.com/en-us/library/windows/desktop/aa370082.aspx] [MSIDatabaseCommit](https://msdn.microsoft.com/en-us/library/windows/desktop/aa370075.aspx) [https://msdn.microsoft.com/en-us/library/windows/desktop/aa370075.aspx]  
[MSIGetSummaryInformation](https://msdn.microsoft.com/en-us/library/windows/desktop/aa370301.aspx) [https://msdn.microsoft.com/en-us/library/windows/desktop/aa370301.aspx] [MsiCloseHandle](https://msdn.microsoft.com/en-us/library/windows/desktop/aa370067.aspx) [https://msdn.microsoft.com/en-us/library/windows/desktop/aa370067.aspx]

## View Objects

## View.Execute(*params*)

Execute the SQL query of the view, through **MSIViewExecute()**. If *params* is not `None`, it is a record describing actual values of the parameter tokens in the query.

## View.GetColumnInfo(*kind*)

Return a record describing the columns of the view, through calling **MsiViewGetColumnInfo()**. *kind* can be either `MSICOLINFO_NAMES` or `MSICOLINFO_TYPES`.

## View.Fetch()

Return a result record of the query, through calling **MsiViewFetch()**.

## View.Modify(*kind*, *data*)

Modify the view, by calling **MsiViewModify()**. *kind* can be one of `MSIMODIFY_SEEK`, `MSIMODIFY_REFRESH`, `MSIMODIFY_INSERT`, `MSIMODIFY_UPDATE`, `MSIMODIFY_ASSIGN`, `MSIMODIFY_REPLACE`, `MSIMODIFY_MERGE`, `MSIMODIFY_DELETE`, `MSIMODIFY_INSERT_TEMPORARY`, `MSIMODIFY_VALIDATE`, `MSIMODIFY_VALIDATE_NEW`, `MSIMODIFY_VALIDATE_FIELD`, or `MSIMODIFY_VALIDATE_DELETE`.

*data* must be a record describing the new data.

## View.Close()

Close the view, through **MsiViewClose()**.

## Summary Information Objects

### SummaryInformation.GetProperty(*field*)

Return a property of the summary, through **MsiSummaryInfoGetProperty()**. *field* is the name of the property, and can be one of the constants `PID_CODEPAGE`, `PID_TITLE`, `PID_SUBJECT`, `PID_AUTHOR`, `PID_KEYWORDS`, `PID_COMMENTS`, `PID_TEMPLATE`, `PID_LASTAUTHOR`, `PID_REVNUMBER`, `PID_LASTPRINTED`, `PID_CREATE_DTM`, `PID_LASTSAVE_DTM`, `PID_PAGECOUNT`, `PID_WORDCOUNT`, `PID_CHARCOUNT`, `PID_APPNAME`, or `PID_SECURITY`.

### SummaryInformation.GetPropertyCount()

Return the number of summary properties, through **MsiSummaryInfoGetPropertyCount()**.

### SummaryInformation.SetProperty(*field*, *value*)

Set a property through **MsiSummaryInfoSetProperty()**. *field* can have the same values as in [GetProperty\(\)](#), *value* is the new value of the property. Possible value types are integer and string.

### SummaryInformation.Persist()

Write the modified properties to the summary information stream, using **MsiSummaryInfoPersist()**.

### See also

[MsiSummaryInfoGetProperty](https://msdn.microsoft.com/en-us/library/windows/desktop/aa370409.aspx) [https://msdn.microsoft.com/en-us/library/windows/desktop/aa370409.aspx] [MsiSummaryInfoGetPropertyCount](https://msdn.microsoft.com/en-us/library/windows/desktop/aa370488.aspx) [https://msdn.microsoft.com/en-us/library/windows/desktop/aa370488.aspx] [MsiSummaryInfoSetProperty](https://msdn.microsoft.com/en-us/library/windows/desktop/aa370488.aspx) [https://msdn.microsoft.com/en-us/library/windows/desktop/aa370488.aspx]

## Record Objects

`Record.GetFieldCount()`

Return the number of fields of the record, through **`MsiRecordGetFieldCount()`**.

`Record.GetInteger(field)`

Return the value of *field* as an integer where possible. *field* must be an integer.

`Record.GetString(field)`

Return the value of *field* as a string where possible. *field* must be an integer.

`Record.SetString(field, value)`

Set *field* to *value* through **`MsiRecordSetString()`**. *field* must be an integer; *value* a string.

`Record.SetStream(field, value)`

Set *field* to the contents of the file named *value*, through **`MsiRecordSetStream()`**. *field* must be an integer; *value* a string.

`Record.SetInteger(field, value)`

Set *field* to *value* through **`MsiRecordSetInteger()`**. Both *field* and *value* must be an integer.

`Record.ClearData()`

Set all fields of the record to 0, through **`MsiRecordClearData()`**.

**See also**

[MsiRecordGetFieldCount](https://msdn.microsoft.com/en-us/library/windows/desktop/aa370366.aspx) [https://msdn.microsoft.com/en-us/library/windows/desktop/aa370366.aspx] [MsiRecordSetString](https://msdn.microsoft.com/en-us/library/windows/desktop/aa370373.aspx) [https://msdn.microsoft.com/en-us/library/windows/desktop/aa370373.aspx] [MsiRecordSetStream](https://msdn.microsoft.com/en-us/library/windows/desktop/aa370372.aspx) [https://msdn.microsoft.com/en-us/library/windows/desktop/aa370372.aspx] [MsiRecordSetInteger](https://msdn.microsoft.com/en-us/library/windows/desktop/aa370371.aspx) [https://msdn.microsoft.com/en-us/library/windows/desktop/aa370371.aspx] [MsiRecordClearData](https://msdn.microsoft.com/en-us/library/windows/desktop/aa370364.aspx) [https://msdn.microsoft.com/en-us/library/windows/desktop/aa370364.aspx]

## Errors

All wrappers around MSI functions raise **MSIError**; the string inside the exception will contain more detail.

## CAB Objects

*class* msilib.CAB(*name*)

The class **CAB** represents a CAB file. During MSI construction, files will be added simultaneously to the `Files` table, and to a CAB file. Then, when all files have been added, the CAB file can be written, then added to the MSI file.

*name* is the name of the CAB file in the MSI file.

*append(full, file, logical)*

Add the file with the pathname *full* to the CAB file, under the name *logical*. If there is already a file named *logical*, a new file name is created.

Return the index of the file in the CAB file, and the new name of the file inside the CAB file.

*commit(database)*

Generate a CAB file, add it as a stream to the MSI file, put it into the `Media` table, and remove the generated file from the disk.

# Directory Objects

*class msilib.Directory(database, cab, basedir, physical, logical, default[, componentflags])*

Create a new directory in the Directory table. There is a current component at each point in time for the directory, which is either explicitly created through **start\_component()**, or implicitly when files are added for the first time. Files are added into the current component, and into the cab file. To create a directory, a base directory object needs to be specified (can be `None`), the path to the physical directory, and a logical directory name. *default* specifies the DefaultDir slot in the directory table. *componentflags* specifies the default flags that new components get.

*start\_component(component = None, feature = None, flags = None, keyfile = None, uuid = None)*

Add an entry to the Component table, and make this component the current component for this directory. If no component name is given, the directory name is used. If no *feature* is given, the current feature is used. If no *flags* are given, the directory's default flags are used. If no *keyfile* is given, the KeyPath is left null in the Component table.

*add\_file(file, src = None, version = None, language = None)*

Add a file to the current component of the directory, starting a new one if there is no current component. By default, the file name in the source and the file table will be identical. If the *src* file is specified, it is interpreted relative to the current directory. Optionally, a *version* and a *language* can be specified for the entry in the File table.

*glob(pattern, exclude = None)*

Add a list of files to the current component as specified

in the glob pattern. Individual files can be excluded in the *exclude* list.

`remove_pyc()`

Remove `.pyc` files on uninstall.

## See also

[Directory Table](https://msdn.microsoft.com/en-us/library/windows/desktop/aa368295.aspx) [https://msdn.microsoft.com/en-us/library/windows/desktop/aa368295.aspx] [File Table](https://msdn.microsoft.com/en-us/library/windows/desktop/aa368596.aspx) [https://msdn.microsoft.com/en-us/library/windows/desktop/aa368596.aspx] [Component Table](https://msdn.microsoft.com/en-us/library/windows/desktop/aa368007.aspx) [https://msdn.microsoft.com/en-us/library/windows/desktop/aa368007.aspx] [FeatureComponents Table](https://msdn.microsoft.com/en-us/library/windows/desktop/aa368579.aspx) [https://msdn.microsoft.com/en-us/library/windows/desktop/aa368579.aspx]

## Features

*class* `msilib.Feature(db, id, title, desc, display, level = 1, parent = None, directory = None, attributes = 0)`

Add a new record to the `Feature` table, using the values *id*, *parent.id*, *title*, *desc*, *display*, *level*, *directory*, and *attributes*. The resulting feature object can be passed to the **`start_component()`** method of [Directory](#).

`set_current()`

Make this feature the current feature of [msilib](#). New components are automatically added to the default feature, unless a feature is explicitly specified.

## See also

[Feature Table](https://msdn.microsoft.com/en-us/library/windows/desktop/aa368585.aspx) [https://msdn.microsoft.com/en-us/library/windows/desktop/aa368585.aspx]

## GUI classes

**msilib** provides several classes that wrap the GUI tables in an MSI database. However, no standard user interface is provided.

*class* msilib.Control(*dlg*, *name*)

Base class of the dialog controls. *dlg* is the dialog object the control belongs to, and *name* is the control's name.

event(*event*, *argument*, *condition* = 1, *ordering* = None)

Make an entry into the `ControlEvent` table for this control.

mapping(*event*, *attribute*)

Make an entry into the `EventMapping` table for this control.

condition(*action*, *condition*)

Make an entry into the `ControlCondition` table for this control.

*class* msilib.RadioButtonGroup(*dlg*, *name*, *property*)

Create a radio button control named *name*. *property* is the installer property that gets set when a radio button is selected.

add(*name*, *x*, *y*, *width*, *height*, *text*, *value* = None)

Add a radio button named *name* to the group, at the coordinates *x*, *y*, *width*, *height*, and with the label *text*. If *value* is `None`, it defaults to *name*.

*class* msilib.Dialog(*db*, *name*, *x*, *y*, *w*, *h*, *attr*, *title*, *first*, *default*, *cancel*)

Return a new **Dialog** object. An entry in the `Dialog` table is made, with the specified coordinates, dialog attributes, title, name of the first, default, and cancel controls.

control(*name*, *type*, *x*, *y*, *width*, *height*, *attributes*, *property*, *text*,

*control\_next, help)*

Return a new **Control** object. An entry in the `Control` table is made with the specified parameters.

This is a generic method; for specific types, specialized methods are provided.

*text(name, x, y, width, height, attributes, text)*

Add and return a `Text` control.

*bitmap(name, x, y, width, height, text)*

Add and return a `Bitmap` control.

*line(name, x, y, width, height)*

Add and return a `Line` control.

*pushbutton(name, x, y, width, height, attributes, text, next\_control)*

Add and return a `PushButton` control.

*radiogroup(name, x, y, width, height, attributes, property, text, next\_control)*

Add and return a `RadioButtonGroup` control.

*checkbox(name, x, y, width, height, attributes, property, text, next\_control)*

Add and return a `CheckBox` control.

## Precomputed tables

**msilib** provides a few subpackages that contain only schema and table definitions. Currently, these definitions are based on MSI version 2.0.

### msilib.schema

This is the standard MSI schema for MSI 2.0, with the *tables* variable providing a list of table definitions, and *\_Validation\_records* providing the data for MSI validation.

### msilib.sequence

This module contains table contents for the standard sequence tables: *AdminExecuteSequence*, *AdminUISequence*, *AdvtExecuteSequence*, *InstallExecuteSequence*, and *InstallUISequence*.

### msilib.text

This module contains definitions for the UIText and ActionText tables, for the standard installer actions.

# **nis** — Interface to Sun's NIS (Yellow Pages)

*Deprecated since version 3.11, will be removed in version 3.13:* The **nis** module is deprecated (see [PEP 594](https://peps.python.org/pep-0594/#nis) [https://peps.python.org/pep-0594/#nis] for details).

---

The **nis** module gives a thin wrapper around the NIS library, useful for central administration of several hosts.

Because NIS exists only on Unix systems, this module is only available for Unix.

**Availability:** not Emscripten, not WASI.

This module does not work or is not available on WebAssembly platforms `wasm32-emscripten` and `wasm32-wasi`. See [WebAssembly platforms](#) for more information.

The **nis** module defines the following functions:

`nis.match(key, mapname, domain = default_domain)`

Return the match for *key* in map *mapname*, or raise an error (**nis.error**) if there is none. Both should be strings, *key* is 8-bit clean. Return value is an arbitrary array of bytes (may contain `NULL` and other joys).

Note that *mapname* is first checked if it is an alias to another name.

The *domain* argument allows overriding the NIS domain used for the lookup. If unspecified, lookup is in the default NIS domain.

`nis.cat(mapname, domain = default_domain)`

Return a dictionary mapping *key* to *value* such that `match(key, mapname) == value`. Note that both keys and values of the dictionary are arbitrary arrays of bytes.

Note that *mapname* is first checked if it is an alias to another name.

The *domain* argument allows overriding the NIS domain used for the lookup. If unspecified, lookup is in the default NIS domain.

`nis.maps(domain = default_domain)`

Return a list of all valid maps.

The *domain* argument allows overriding the NIS domain used for the lookup. If unspecified, lookup is in the default NIS domain.

`nis.get_default_domain()`

Return the system default NIS domain.

The **nis** module defines the following exception:

*exception* `nis.error`

An error raised when a NIS function returns an error code.

# nntplib — NNTP protocol client

**Source code:** [Lib/nntplib.py](https://github.com/python/cpython/tree/3.11/Lib/nntplib.py) [https://github.com/python/cpython/tree/3.11/Lib/nntplib.py]

*Deprecated since version 3.11:* The **nntplib** module is deprecated (see [PEP 594](https://peps.python.org/pep-0594/) [https://peps.python.org/pep-0594/] for details).

---

This module defines the class **NNTP** which implements the client side of the Network News Transfer Protocol. It can be used to implement a news reader or poster, or automated news processors. It is compatible with [RFC 3977](https://datatracker.ietf.org/doc/html/rfc3977.html) [https://datatracker.ietf.org/doc/html/rfc3977.html] as well as the older [RFC 977](https://datatracker.ietf.org/doc/html/rfc977.html) [https://datatracker.ietf.org/doc/html/rfc977.html] and [RFC 2980](https://datatracker.ietf.org/doc/html/rfc2980.html) [https://datatracker.ietf.org/doc/html/rfc2980.html].

**Availability:** not Emscripten, not WASI.

This module does not work or is not available on WebAssembly platforms `wasm32-emscripten` and `wasm32-wasi`. See [WebAssembly platforms](#) for more information.

Here are two small examples of how it can be used. To list some statistics about a newsgroup and print the subjects of the last 10 articles:

```
>>> s = nntplib.NNTP('news.gmane.io')
>>> resp, count, first, last, name = s.group('gmane.comp.python')
>>> print('Group', name, 'has', count, 'articles, range', first, last)
Group gmane.comp.python.committers has 1096 articles, range 1-1096
>>> resp, overviews = s.over((last - 9, last))
>>> for id, over in overviews:
...     print(id, nntplib.decode_header(over['subject']))
... 
```

```
1087 Re: Commit privileges for Łukasz Langa
1088 Re: 3.2 alpha 2 freeze
1089 Re: 3.2 alpha 2 freeze
1090 Re: Commit privileges for Łukasz Langa
1091 Re: Commit privileges for Łukasz Langa
1092 Updated ssh key
1093 Re: Updated ssh key
1094 Re: Updated ssh key
1095 Hello fellow committers!
1096 Re: Hello fellow committers!
>>> s.quit()
'205 Bye!'
```

To post an article from a binary file (this assumes that the article has valid headers, and that you have right to post on the particular newsgroup):

```
>>> s = nntplib.NNTP('news.gmane.io')
>>> f = open('article.txt', 'rb')
>>> s.post(f)
'240 Article posted successfully.'
>>> s.quit()
'205 Bye!'
```

The module itself defines the following classes:

```
class nntplib.NNTP(host, port=119, user=None, password=None,
readermode=None, usenetrc=False[, timeout])
```

Return a new **NNTP** object, representing a connection to the NNTP server running on host *host*, listening at port *port*. An optional *timeout* can be specified for the socket connection. If the optional *user* and *password* are provided, or if suitable credentials are present in `/.netrc` and the optional flag *usenetrc* is true, the `AUTHINFO USER` and `AUTHINFO PASS` commands are used to identify and authenticate the user to the server. If the optional flag *readermode* is true, then a mode `reader` command is sent before authentication is performed. Reader mode is sometimes necessary if you are connecting to an NNTP server on the local machine and

intend to call reader-specific commands, such as `group`. If you get unexpected [NNTPPermanentErrors](#), you might need to set `readermode`. The [NNTP](#) class supports the `with` statement to unconditionally consume [OSError](#) exceptions and to close the NNTP connection when done, e.g.:

```
>>> from nntplib import NNTP
>>> with NNTP('news.gmane.io') as n:
...     n.group('gmane.comp.python.committers')
...
('211 1755 1 1755 gmane.comp.python.committers', 17
>>>
```

Raises an [auditing event](#) `nntplib.connect` with arguments `self`, `host`, `port`.

All commands will raise an [auditing event](#) `nntplib.putline` with arguments `self` and `line`, where `line` is the bytes about to be sent to the remote host.

*Changed in version 3.2:* `usenetr` is now `False` by default.

*Changed in version 3.3:* Support for the `with` statement was added.

*Changed in version 3.9:* If the `timeout` parameter is set to be zero, it will raise a [ValueError](#) to prevent the creation of a non-blocking socket.

```
class nntplib.NNTP_SSL(host, port=563, user=None,
password=None, ssl_context=None, readermode=None,
usenetr=False[, timeout])
```

Return a new [NNTP\\_SSL](#) object, representing an encrypted connection to the NNTP server running on host `host`, listening at port `port`. [NNTP\\_SSL](#) objects have the same methods as [NNTP](#) objects. If `port` is omitted, port 563 (NNTPS) is used. `ssl_context` is also optional, and is a [SSLContext](#) object. Please read [Security considerations](#) for best practices. All other parameters behave the same as for [NNTP](#).

Note that SSL-on-563 is discouraged per [RFC 4642](https://datatracker.ietf.org/doc/html/rfc4642.html) [https://datatracker.ietf.org/doc/html/rfc4642.html], in favor of STARTTLS as described below. However, some servers only support the former.

Raises an [auditing event](#) `nntplib.connect` with arguments `self`, `host`, `port`.

All commands will raise an [auditing event](#) `nntplib.putline` with arguments `self` and `line`, where `line` is the bytes about to be sent to the remote host.

*New in version 3.2.*

*Changed in version 3.4:* The class now supports hostname check with `ssl.SSLContext.check_hostname` and *Server Name Indication* (see `ssl.HAS_SNI`).

*Changed in version 3.9:* If the `timeout` parameter is set to be zero, it will raise a [ValueError](#) to prevent the creation of a non-blocking socket.

*exception* `nntplib.NNTPError`

Derived from the standard exception [Exception](#), this is the base class for all exceptions raised by the `nntplib` module. Instances of this class have the following attribute:

`response`

The response of the server if available, as a [str](#) object.

*exception* `nntplib.NNTPReplyError`

Exception raised when an unexpected reply is received from the server.

*exception* `nntplib.NNTPTemporaryError`

Exception raised when a response code in the range 400–499 is received.

*exception* `nntplib.NNTPPermanentError`

Exception raised when a response code in the range 500–599 is received.

*exception* `nntplib.NNTPProtocolError`

Exception raised when a reply is received from the server that does not begin with a digit in the range 1–5.

*exception* `nntplib.NNTPDataError`

Exception raised when there is some error in the response data.

## NNTP Objects

When connected, `NNTP` and `NNTP_SSL` objects support the following methods and attributes.

### Attributes

`NNTP.nntp_version`

An integer representing the version of the NNTP protocol supported by the server. In practice, this should be `2` for servers advertising [RFC 3977](https://datatracker.ietf.org/doc/html/rfc3977) [https://datatracker.ietf.org/doc/html/rfc3977.html] compliance and `1` for others.

*New in version 3.2.*

`NNTP.nntp_implementation`

A string describing the software name and version of the NNTP server, or `None` if not advertised by the server.

*New in version 3.2.*

### Methods

The *response* that is returned as the first item in the return tuple of almost all methods is the server's response: a string beginning with a three-digit code. If the server's response indicates an error, the method raises one of the above exceptions.

Many of the following methods take an optional keyword-only argument *file*. When the *file* argument is supplied, it must be either a [file object](#) opened for binary writing, or the name of an on-disk file to be written to. The method will then write any data returned by the server (except for the response line and the terminating dot) to the file; any list of lines, tuples or objects that the method normally returns will be empty.

*Changed in version 3.2:* Many of the following methods have been reworked and fixed, which makes them incompatible with their 3.1 counterparts.

### NNTP.quit()

Send a `QUIT` command and close the connection. Once this method has been called, no other methods of the `NNTP` object should be called.

### NNTP.getwelcome()

Return the welcome message sent by the server in reply to the initial connection. (This message sometimes contains disclaimers or help information that may be relevant to the user.)

### NNTP.getcapabilities()

Return the [RFC 3977](#) [<https://datatracker.ietf.org/doc/html/rfc3977.html>] capabilities advertised by the server, as a [dict](#) instance mapping capability names to (possibly empty) lists of values. On legacy servers which don't understand the `CAPABILITIES` command, an empty dictionary is returned instead.

```
>>> s = NNTP('news.gmane.io')
>>> 'POST' in s.getcapabilities()
True
```

*New in version 3.2.*

`NNTP.login(user=None, password=None, usenetrc=True)`

Send `AUTHINFO` commands with the user name and password. If *user* and *password* are `None` and *usenetcrc* is true, credentials from `~/.netrc` will be used if possible.

Unless intentionally delayed, login is normally performed during the `NNTP` object initialization and separately calling this function is unnecessary. To force authentication to be delayed, you must not set *user* or *password* when creating the object, and must set *usenetcrc* to `False`.

*New in version 3.2.*

`NNTP.starttls(context=None)`

Send a `STARTTLS` command. This will enable encryption on the `NNTP` connection. The *context* argument is optional and should be a `ssl.SSLContext` object. Please read [Security considerations](#) for best practices.

Note that this may not be done after authentication information has been transmitted, and authentication occurs by default if possible during a `NNTP` object initialization. See `NNTP.login()` for information on suppressing this behavior.

*New in version 3.2.*

*Changed in version 3.4:* The method now supports hostname check with `ssl.SSLContext.check_hostname` and *Server Name Indication* (see `ssl.HAS_SNI`).

`NNTP.newgroups(date, *, file=None)`

Send a `NEWGROUPS` command. The *date* argument should be a `datetime.date` or `datetime.datetime` object. Return a pair (*response*, *groups*) where *groups* is a list representing the groups that are new since the given *date*. If *file* is supplied, though, then *groups* will be empty.

```
>>> from datetime import date, timedelta
>>> resp, groups = s.newgroups(date.today() - timed
>>> len(groups)
```

```
>>> groups[0]  
GroupInfo(group='gmane.network.tor.devel', last='4'
```

`NNTP.newnews(group, date, *, file=None)`

Send a `NEWNEWS` command. Here, *group* is a group name or '\*', and *date* has the same meaning as for `newgroups()`. Return a pair (*response*, *articles*) where *articles* is a list of message ids.

This command is frequently disabled by NNTP server administrators.

`NNTP.list(group_pattern=None, *, file=None)`

Send a `LIST` or `LIST ACTIVE` command. Return a pair (*response*, *list*) where *list* is a list of tuples representing all the groups available from this NNTP server, optionally matching the pattern string *group\_pattern*. Each tuple has the form (*group*, *last*, *first*, *flag*), where *group* is a group name, *last* and *first* are the last and first article numbers, and *flag* usually takes one of these values:

- *y*: Local postings and articles from peers are allowed.
- *m*: The group is moderated and all postings must be approved.
- *n*: No local postings are allowed, only articles from peers.
- *j*: Articles from peers are filed in the junk group instead.
- *x*: No local postings, and articles from peers are ignored.
- *=foo.bar*: Articles are filed in the `foo.bar` group instead.

If *flag* has another value, then the status of the newsgroup should be considered unknown.

This command can return very large results, especially if *group\_pattern* is not specified. It is best to cache the results offline unless you really need to refresh them.

*Changed in version 3.2: `group_pattern` was added.*

### NNTP.descriptions(*grouppattern*)

Send a `LIST NEWSGROUPS` command, where *grouppattern* is a wildmat string as specified in [RFC 3977](https://datatracker.ietf.org/doc/html/rfc3977) [https://datatracker.ietf.org/doc/html/rfc3977.html] (it's essentially the same as DOS or UNIX shell wildcard strings). Return a pair (*response*, *descriptions*), where *descriptions* is a dictionary mapping group names to textual descriptions.

```
>>> resp, descs = s.descriptions('gmane.comp.python')
>>> len(descs)
295
>>> descs.popitem()
('gmane.comp.python.bio.general', 'BioPython discuss')
```

### NNTP.description(*group*)

Get a description for a single group *group*. If more than one group matches (if 'group' is a real wildmat string), return the first match. If no group matches, return an empty string.

This elides the response code from the server. If the response code is needed, use [descriptions\(\)](#).

### NNTP.group(*name*)

Send a `GROUP` command, where *name* is the group name. The group is selected as the current group, if it exists. Return a tuple (*response*, *count*, *first*, *last*, *name*) where *count* is the (estimated) number of articles in the group, *first* is the first article number in the group, *last* is the last article number in the group, and *name* is the group name.

### NNTP.over(*message\_spec*, \*, *file* = None)

Send an `OVER` command, or an `XOVER` command on legacy servers. *message\_spec* can be either a string representing a message id, or a (*first*, *last*) tuple of numbers indicating a range of articles in the current group, or a (*first*, None) tuple indicating a range of articles starting

from *first* to the last article in the current group, or **None** to select the current article in the current group.

Return a pair (response, overviews). *overviews* is a list of (article\_number, overview) tuples, one for each article selected by *message\_spec*. Each *overview* is a dictionary with the same number of items, but this number depends on the server. These items are either message headers (the key is then the lower-cased header name) or metadata items (the key is then the metadata name prepended with ": "). The following items are guaranteed to be present by the NNTP specification:

- the subject, from, date, message-id and references headers
- the :bytes metadata: the number of bytes in the entire raw article (including headers and body)
- the :lines metadata: the number of lines in the article body

The value of each item is either a string, or **None** if not present.

It is advisable to use the **decode\_header()** function on header values when they may contain non-ASCII characters:

```
>>> _, _, first, last, _ = s.group('gmane.comp.pyth
>>> resp, overviews = s.over((last, last))
>>> art_num, over = overviews[0]
>>> art_num
117216
>>> list(over.keys())
['xref', 'from', ':lines', ':bytes', 'references',
>>> over['from']
'=?UTF-8?B?Ik1hcnRpbIB2LiBMw7Z3aXMi?= <martin@v.lo
>>> nntplib.decode_header(over['from'])
'"Martin v. Löwis" <martin@v.loewis.de>'
```

*New in version 3.2.*

`NNTP.help(*, file=None)`

Send a `HELP` command. Return a pair `(response, list)` where *list* is a list of help strings.

`NNTP.stat(message_spec=None)`

Send a `STAT` command, where *message\_spec* is either a message id (enclosed in `'<'` and `'>'`) or an article number in the current group. If *message\_spec* is omitted or `None`, the current article in the current group is considered. Return a triple `(response, number, id)` where *number* is the article number and *id* is the message id.

```
>>> _, _, first, last, _ = s.group('gmane.comp.pyth
>>> resp, number, message_id = s.stat(first)
>>> number, message_id
(9099, '<20030112190404.GE29873@epoch.metaslash.com
```

`NNTP.next()`

Send a `NEXT` command. Return as for `stat()`.

`NNTP.last()`

Send a `LAST` command. Return as for `stat()`.

`NNTP.article(message_spec=None, *, file=None)`

Send an `ARTICLE` command, where *message\_spec* has the same meaning as for `stat()`. Return a tuple `(response, info)` where *info* is a `namedtuple` with three attributes *number*, *message\_id* and *lines* (in that order). *number* is the article number in the group (or 0 if the information is not available), *message\_id* the message id as a string, and *lines* a list of lines (without terminating newlines) comprising the raw message including headers and body.

```
>>> resp, info = s.article('<20030112190404.GE29873
>>> info.number
0
>>> info.message_id
```

```
'<20030112190404.GE29873@epoch.metaslash.com>'
>>> len(info.lines)
65
>>> info.lines[0]
b'Path: main.gmane.org!not-for-mail'
>>> info.lines[1]
b'From: Neal Norwitz <neal@metaslash.com>'
>>> info.lines[-3:]
[b'There is a patch for 2.3 as well as 2.2.', b'', b'']
```

**NNTP.head(*message\_spec*=None, \*, *file*=None)**

Same as **article()**, but sends a HEAD command. The *lines* returned (or written to *file*) will only contain the message headers, not the body.

**NNTP.body(*message\_spec*=None, \*, *file*=None)**

Same as **article()**, but sends a BODY command. The *lines* returned (or written to *file*) will only contain the message body, not the headers.

**NNTP.post(*data*)**

Post an article using the POST command. The *data* argument is either a **file object** opened for binary reading, or any iterable of bytes objects (representing raw lines of the article to be posted). It should represent a well-formed news article, including the required headers. The **post()** method automatically escapes lines beginning with . and appends the termination line.

If the method succeeds, the server's response is returned. If the server refuses posting, a **NNTPReplyError** is raised.

**NNTP.ihave(*message\_id*, *data*)**

Send an IHAVE command. *message\_id* is the id of the message to send to the server (enclosed in '<' and '>'). The *data* parameter and the return value are the same as for **post()**.

NNTP.date()

Return a pair (response, date). *date* is a [datetime](#) object containing the current date and time of the server.

NNTP.slave()

Send a SLAVE command. Return the server's *response*.

NNTP.set\_debuglevel(*level*)

Set the instance's debugging level. This controls the amount of debugging output printed. The default, 0, produces no debugging output. A value of 1 produces a moderate amount of debugging output, generally a single line per request or response. A value of 2 or higher produces the maximum amount of debugging output, logging each line sent and received on the connection (including message text).

The following are optional NNTP extensions defined in [RFC 2980](#) [<https://datatracker.ietf.org/doc/html/rfc2980.html>]. Some of them have been superseded by newer commands in [RFC 3977](#) [<https://datatracker.ietf.org/doc/html/rfc3977.html>].

NNTP.xhdr(*hdr*, *str*, \*, *file*=None)

Send an XHDR command. The *hdr* argument is a header keyword, e.g. 'subject'. The *str* argument should have the form 'first-last' where *first* and *last* are the first and last article numbers to search. Return a pair (response, list), where *list* is a list of pairs (id, text), where *id* is an article number (as a string) and *text* is the text of the requested header for that article. If the *file* parameter is supplied, then the output of the XHDR command is stored in a file. If *file* is a string, then the method will open a file with that name, write to it then close it. If *file* is a [file object](#), then it will start calling **write()** on it to store the lines of the command output. If *file* is supplied, then the returned *list* is an empty list.

NNTP.xover(*start*, *end*, \*, *file*=None)

Send an `XOVER` command. *start* and *end* are article numbers delimiting the range of articles to select. The return value is the same of for `over()`. It is recommended to use `over()` instead, since it will automatically use the newer `OVER` command if available.

## Utility functions

The module also defines the following utility function:

`nntplib.decode_header(header_str)`

Decode a header value, un-escaping any escaped non-ASCII characters. *header\_str* must be a `str` object. The unescaped value is returned. Using this function is recommended to display some headers in a human readable form:

```
>>> decode_header("Some subject")
'Some subject'
>>> decode_header("=?ISO-8859-15?Q?D=E9buter_en_Pyt
'Débuter en Python'
>>> decode_header("Re: =?UTF-8?B?cHJvYmzDqG1lIGRlIG
'Re: problème de matrice')
```

# optparse — Parser for command line options

**Source code:** [Lib/optparse.py](https://github.com/python/cpython/tree/3.11/Lib/optparse.py) [https://github.com/python/cpython/tree/3.11/Lib/optparse.py]

*Deprecated since version 3.2:* The **optparse** module is deprecated and will not be developed further; development will continue with the **argparse** module.

---

**optparse** is a more convenient, flexible, and powerful library for parsing command-line options than the old **getopt** module. **optparse** uses a more declarative style of command-line parsing: you create an instance of **OptionParser**, populate it with options, and parse the command line. **optparse** allows users to specify options in the conventional GNU/POSIX syntax, and additionally generates usage and help messages for you.

Here's an example of using **optparse** in a simple script:

```
from optparse import OptionParser
...
parser = OptionParser()
parser.add_option("-f", "--file", dest="filename",
                  help="write report to FILE", metavar="FILE",)
parser.add_option("-q", "--quiet",
                  action="store_false", dest="verbose",
                  help="don't print status messages to s

(options, args) = parser.parse_args()
```

With these few lines of code, users of your script can now do the “usual thing” on the command-line, for example:

```
<yourscript> --file=outfile -q
```

As it parses the command line, `optparse` sets attributes of the options object returned by `parse_args()` based on user-supplied command-line values. When `parse_args()` returns from parsing this command line, `options.filename` will be "outfile" and `options.verbose` will be `False`. `optparse` supports both long and short options, allows short options to be merged together, and allows options to be associated with their arguments in a variety of ways. Thus, the following command lines are all equivalent to the above example:

```
<yourscript> -f outfile --quiet
<yourscript> --quiet --file outfile
<yourscript> -q -foutfile
<yourscript> -qfoutfile
```

Additionally, users can run one of the following

```
<yourscript> -h
<yourscript> --help
```

and `optparse` will print out a brief summary of your script's options:

Usage: `<yourscript> [options]`

Options:

<code>-h, --help</code>	show this help message and exit
<code>-f FILE, --file=FILE</code>	write report to FILE
<code>-q, --quiet</code>	don't print status messages to s

where the value of *yourscript* is determined at runtime (normally from `sys.argv[0]`).

## Background

`optparse` was explicitly designed to encourage the creation of programs with straightforward, conventional command-line interfaces. To that end, it supports only the most common command-line syntax and semantics conventionally used under Unix. If you are unfamiliar with these conventions, read this section

to acquaint yourself with them.

## Terminology

### argument

a string entered on the command-line, and passed by the shell to `exec1()` or `execv()`. In Python, arguments are elements of `sys.argv[1:]` (`sys.argv[0]` is the name of the program being executed). Unix shells also use the term “word”.

It is occasionally desirable to substitute an argument list other than `sys.argv[1:]`, so you should read “argument” as “an element of `sys.argv[1:]`, or of some other list provided as a substitute for `sys.argv[1:]`”.

### option

an argument used to supply extra information to guide or customize the execution of a program. There are many different syntaxes for options; the traditional Unix syntax is a hyphen (“-”) followed by a single letter, e.g. `-x` or `-F`. Also, traditional Unix syntax allows multiple options to be merged into a single argument, e.g. `-x -F` is equivalent to `-xF`. The GNU project introduced `--` followed by a series of hyphen-separated words, e.g. `--file` or `--dry-run`. These are the only two option syntaxes provided by [optparse](#).

Some other option syntaxes that the world has seen include:

- a hyphen followed by a few letters, e.g. `-pf` (this is *not* the same as multiple options merged into a single argument)
- a hyphen followed by a whole word, e.g. `-file` (this is technically equivalent to the previous syntax, but they aren’t usually seen in the same program)
- a plus sign followed by a single letter, or a few letters, or a word, e.g. `+f`, `+rgb`
- a slash followed by a letter, or a few letters, or a word, e.g. `/f`, `/file`

These option syntaxes are not supported by `optparse`, and they never will be. This is deliberate: the first three are non-standard on any environment, and the last only makes sense if you're exclusively targeting Windows or certain legacy platforms (e.g. VMS, MS-DOS).

#### option argument

an argument that follows an option, is closely associated with that option, and is consumed from the argument list when that option is. With `optparse`, option arguments may either be in a separate argument from their option:

```
-f foo
--file foo
```

or included in the same argument:

```
-ffoo
--file=foo
```

Typically, a given option either takes an argument or it doesn't. Lots of people want an "optional option arguments" feature, meaning that some options will take an argument if they see it, and won't if they don't. This is somewhat controversial, because it makes parsing ambiguous: if `-a` takes an optional argument and `-b` is another option entirely, how do we interpret `-ab`? Because of this ambiguity, `optparse` does not support this feature.

#### positional argument

something leftover in the argument list after options have been parsed, i.e. after options and their arguments have been parsed and removed from the argument list.

#### required option

an option that must be supplied on the command-line; note that the phrase "required option" is self-contradictory in English. `optparse` doesn't prevent you from implementing required options, but doesn't give you much help at it either.

For example, consider this hypothetical command-line:

```
prog -v --report report.txt foo bar
```

`-v` and `--report` are both options. Assuming that `--report` takes one argument, `report.txt` is an option argument. `foo` and `bar` are positional arguments.

## What are options for?

Options are used to provide extra information to tune or customize the execution of a program. In case it wasn't clear, options are usually *optional*. A program should be able to run just fine with no options whatsoever. (Pick a random program from the Unix or GNU toolsets. Can it run without any options at all and still make sense? The main exceptions are `find`, `tar`, and `dd`—all of which are mutant oddballs that have been rightly criticized for their non-standard syntax and confusing interfaces.)

Lots of people want their programs to have “required options”. Think about it. If it's required, then it's *not optional*! If there is a piece of information that your program absolutely requires in order to run successfully, that's what positional arguments are for.

As an example of good command-line interface design, consider the humble `cp` utility, for copying files. It doesn't make much sense to try to copy files without supplying a destination and at least one source. Hence, `cp` fails if you run it with no arguments. However, it has a flexible, useful syntax that does not require any options at all:

```
cp SOURCE DEST
cp SOURCE ... DEST-DIR
```

You can get pretty far with just that. Most `cp` implementations provide a bunch of options to tweak exactly how the files are copied: you can preserve mode and modification time, avoid following symlinks, ask before clobbering existing files, etc. But none of this distracts from the core mission of `cp`, which is to copy either one file to another, or several files to another directory.

## What are positional arguments for?

Positional arguments are for those pieces of information that your program absolutely, positively requires to run.

A good user interface should have as few absolute requirements as possible. If your program requires 17 distinct pieces of information in order to run successfully, it doesn't much matter *how* you get that information from the user—most people will give up and walk away before they successfully run the program. This applies whether the user interface is a command-line, a configuration file, or a GUI: if you make that many demands on your users, most of them will simply give up.

In short, try to minimize the amount of information that users are absolutely required to supply—use sensible defaults whenever possible. Of course, you also want to make your programs reasonably flexible. That's what options are for. Again, it doesn't matter if they are entries in a config file, widgets in the “Preferences” dialog of a GUI, or command-line options—the more options you implement, the more flexible your program is, and the more complicated its implementation becomes. Too much flexibility has drawbacks as well, of course; too many options can overwhelm users and make your code much harder to maintain.

## Tutorial

While `optparse` is quite flexible and powerful, it's also straightforward to use in most cases. This section covers the code patterns that are common to any `optparse`-based program.

First, you need to import the `OptionParser` class; then, early in the main program, create an `OptionParser` instance:

```
from optparse import OptionParser
...
parser = OptionParser()
```

Then you can start defining options. The basic syntax is:

```
parser.add_option(opt_str, ...,
                  attr=value, ...)
```

Each option has one or more option strings, such as `-f` or `--file`, and several option attributes that tell `optparse` what to expect and what to do when it encounters that option on the command line.

Typically, each option will have one short option string and one long option string, e.g.:

```
parser.add_option("-f", "--file", ...)
```

You're free to define as many short option strings and as many long option strings as you like (including zero), as long as there is at least one option string overall.

The option strings passed to `OptionParser.add_option()` are effectively labels for the option defined by that call. For brevity, we will frequently refer to *encountering an option* on the command line; in reality, `optparse` encounters *option strings* and looks up options from them.

Once all of your options are defined, instruct `optparse` to parse your program's command line:

```
(options, args) = parser.parse_args()
```

(If you like, you can pass a custom argument list to `parse_args()`, but that's rarely necessary: by default it uses `sys.argv[1:]`.)

`parse_args()` returns two values:

- `options`, an object containing values for all of your options —e.g. if `--file` takes a single string argument, then `options.file` will be the filename supplied by the user, or `None` if the user did not supply that option
- `args`, the list of positional arguments leftover after parsing options

This tutorial section only covers the four most important option

attributes: **action**, **type**, **dest** (destination), and **help**. Of these, **action** is the most fundamental.

## Understanding option actions

Actions tell **optparse** what to do when it encounters an option on the command line. There is a fixed set of actions hard-coded into **optparse**; adding new actions is an advanced topic covered in section **Extending optparse**. Most actions tell **optparse** to store a value in some variable—for example, take a string from the command line and store it in an attribute of `options`.

If you don't specify an option action, **optparse** defaults to `store`.

### The store action

The most common option action is `store`, which tells **optparse** to take the next argument (or the remainder of the current argument), ensure that it is of the correct type, and store it to your chosen destination.

For example:

```
parser.add_option("-f", "--file",
                  action="store", type="string", dest="f")
```

Now let's make up a fake command line and ask **optparse** to parse it:

```
args = ["-f", "foo.txt"]
(options, args) = parser.parse_args(args)
```

When **optparse** sees the option string `-f`, it consumes the next argument, `foo.txt`, and stores it in `options.filename`. So, after this call to **parse\_args()**, `options.filename` is `"foo.txt"`.

Some other option types supported by **optparse** are `int` and `float`. Here's an option that expects an integer argument:

```
parser.add_option("-n", type="int", dest="num")
```

Note that this option has no long option string, which is perfectly acceptable. Also, there's no explicit action, since the default is `store`.

Let's parse another fake command-line. This time, we'll jam the option argument right up against the option: since `-n42` (one argument) is equivalent to `-n 42` (two arguments), the code

```
(options, args) = parser.parse_args(["-n42"])
print(options.num)
```

will print `42`.

If you don't specify a type, **optparse** assumes `string`. Combined with the fact that the default action is `store`, that means our first example can be a lot shorter:

```
parser.add_option("-f", "--file", dest="filename")
```

If you don't supply a destination, **optparse** figures out a sensible default from the option strings: if the first long option string is `--foo-bar`, then the default destination is `foo_bar`. If there are no long option strings, **optparse** looks at the first short option string: the default destination for `-f` is `f`.

**optparse** also includes the built-in `complex` type. Adding types is covered in section [Extending optparse](#).

## Handling boolean (flag) options

Flag options—set a variable to true or false when a particular option is seen—are quite common. **optparse** supports them with two separate actions, `store_true` and `store_false`. For example, you might have a `verbose` flag that is turned on with `-v` and off with `-q`:

```
parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose")
```

Here we have two different options with the same destination, which is perfectly OK. (It just means you have to be a bit careful when setting default values—see below.)

When `optparse` encounters `-v` on the command line, it sets `options.verbose` to `True`; when it encounters `-q`, `options.verbose` is set to `False`.

## Other actions

Some other actions supported by `optparse` are:

`"store_const"`  
store a constant value, pre-set via `Option.const`

`"append"`  
append this option's argument to a list

`"count"`  
increment a counter by one

`"callback"`  
call a specified function

These are covered in section [Reference Guide](#), and section [Option Callbacks](#).

## Default values

All of the above examples involve setting some variable (the “destination”) when certain command-line options are seen. What happens if those options are never seen? Since we didn't supply any defaults, they are all set to `None`. This is usually fine, but sometimes you want more control. `optparse` lets you supply a default value for each destination, which is assigned before the command line is parsed.

First, consider the verbose/quiet example. If we want `optparse` to set `verbose` to `True` unless `-q` is seen, then we can do this:

```
parser.add_option("-v", action="store_true", dest="verbose")
```

```
parser.add_option("-q", action="store_false", dest="verbose")
```

Since default values apply to the *destination* rather than to any particular option, and these two options happen to have the same destination, this is exactly equivalent:

```
parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose")
```

Consider this:

```
parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose")
```

Again, the default value for `verbose` will be `True`: the last default value supplied for any particular destination is the one that counts.

A clearer way to specify default values is the `set_defaults()` method of `OptionParser`, which you can call at any time before calling `parse_args()`:

```
parser.set_defaults(verbose=True)
parser.add_option(...)
(options, args) = parser.parse_args()
```

As before, the last value specified for a given option destination is the one that counts. For clarity, try to use one method or the other of setting default values, not both.

## Generating help

`optparse`'s ability to generate help and usage text automatically is useful for creating user-friendly command-line interfaces. All you have to do is supply a `help` value for each option, and optionally a short usage message for your whole program. Here's an `OptionParser` populated with user-friendly (documented) options:

```
usage = "usage: %prog [options] arg1 arg2"
parser = OptionParser(usage=usage)
parser.add_option("-v", "--verbose",
```

```

        action="store_true", dest="verbose",
        help="make lots of noise [default]")
parser.add_option("-q", "--quiet",
        action="store_false", dest="verbose",
        help="be vewwy quiet (I'm hunting wabb")
parser.add_option("-f", "--filename",
        metavar="FILE", help="write output to")
parser.add_option("-m", "--mode",
        default="intermediate",
        help="interaction mode: novice, intern
        "or expert [default: %default]")

```

If **optparse** encounters either `-h` or `--help` on the command-line, or if you just call **`parser.print_help()`**, it prints the following to standard output:

Usage: <yourscript> [options] arg1 arg2

Options:

```

-h, --help            show this help message and exit
-v, --verbose         make lots of noise [default]
-q, --quiet           be vewwy quiet (I'm hunting wabb
-f FILE, --filename=FILE
                        write output to FILE
-m MODE, --mode=MODE  interaction mode: novice, intern
                        expert [default: intermediate]

```

(If the help output is triggered by a help option, **optparse** exits after printing the help text.)

There's a lot going on here to help **optparse** generate the best possible help message:

- the script defines its own usage message:

```
usage = "usage: %prog [options] arg1 arg2"
```

**optparse** expands `%prog` in the usage string to the name of the current program, i.e.

`os.path.basename(sys.argv[0])`. The expanded string

is then printed before the detailed option help.

If you don't supply a usage string, `optparse` uses a bland but sensible default: `"Usage: %prog [options]"`, which is fine if your script doesn't take any positional arguments.

- every option defines a help string, and doesn't worry about line-wrapping—`optparse` takes care of wrapping lines and making the help output look good.
- options that take a value indicate this fact in their automatically generated help message, e.g. for the “mode” option:

```
-m MODE, --mode=MODE
```

Here, “MODE” is called the meta-variable: it stands for the argument that the user is expected to supply to `-m/--mode`. By default, `optparse` converts the destination variable name to uppercase and uses that for the meta-variable. Sometimes, that's not what you want—for example, the `--filename` option explicitly sets `metavar="FILE"`, resulting in this automatically generated option description:

```
-f FILE, --filename=FILE
```

This is important for more than just saving space, though: the manually written help text uses the meta-variable `FILE` to clue the user in that there's a connection between the semi-formal syntax `-f FILE` and the informal semantic description “write output to `FILE`”. This is a simple but effective way to make your help text a lot clearer and more useful for end users.

- options that have a default value can include `%default` in the help string—`optparse` will replace it with `str()` of the option's default value. If an option has no default value (or the default value is `None`), `%default` expands to `none`.

## Grouping Options

When dealing with many options, it is convenient to group these options for better help output. An `OptionParser` can contain several option groups, each of which can contain several options.

An option group is obtained using the class `OptionGroup`:

```
class optparse.OptionGroup(parser, title, description=None)
    where
```

- `parser` is the `OptionParser` instance the group will be inserted in to
- `title` is the group title
- `description`, optional, is a long description of the group

`OptionGroup` inherits from `OptionContainer` (like `OptionParser`) and so the `add_option()` method can be used to add an option to the group.

Once all the options are declared, using the `OptionParser` method `add_option_group()` the group is added to the previously defined parser.

Continuing with the parser defined in the previous section, adding an `OptionGroup` to a parser is easy:

```
group = OptionGroup(parser, "Dangerous Options",
                    "Caution: use these options at your own risk",
                    "It is believed that some of them bite")
group.add_option("-g", action="store_true", help="Group options")
parser.add_option_group(group)
```

This would result in the following help output:

```
Usage: <yourscript> [options] arg1 arg2
```

```
Options:
```

```
-h, --help            show this help message and exit
-v, --verbose          make lots of noise [default]
-q, --quiet            be vewwy quiet (I'm hunting wabb
-f FILE, --filename=FILE
```

```
                                write output to FILE
-m MODE, --mode=MODE          interaction mode: novice, intern
                                expert [default: intermediate]
```

#### Dangerous Options:

Caution: use these options at your own risk. It is of them bite.

```
-g                                Group option.
```

**A bit more complete example might involve using more than one group: still extending the previous example:**

```
group = OptionGroup(parser, "Dangerous Options",
                    "Caution: use these options at your
                    "It is believed that some of them bi
group.add_option("-g", action="store_true", help="Group
parser.add_option_group(group)
```

```
group = OptionGroup(parser, "Debug Options")
group.add_option("-d", "--debug", action="store_true",
                help="Print debug information")
group.add_option("-s", "--sql", action="store_true",
                help="Print all SQL statements executed
group.add_option("-e", action="store_true", help="Print
parser.add_option_group(group)
```

**that results in the following output:**

Usage: <yourscript> [options] arg1 arg2

#### Options:

```
-h, --help                show this help message and exit
-v, --verbose             make lots of noise [default]
-q, --quiet              be vewwy quiet (I'm hunting wabb
-f FILE, --filename=FILE
                        write output to FILE
-m MODE, --mode=MODE     interaction mode: novice, intern
                        [default: intermediate]
```

### Dangerous Options:

Caution: use these options at your own risk. It is of them bite.

`-g`                      Group option.

### Debug Options:

<code>-d, --debug</code>	Print debug information
<code>-s, --sql</code>	Print all SQL statements executed
<code>-e</code>	Print every action done

Another interesting method, in particular when working programmatically with option groups is:

### `OptionParser.get_option_group(opt_str)`

Return the `OptionGroup` to which the short or long option string `opt_str` (e.g. `'-o'` or `'--option'`) belongs. If there's no such `OptionGroup`, return `None`.

## Printing a version string

Similar to the brief usage string, `optparse` can also print a version string for your program. You have to supply the string as the version argument to `OptionParser`:

```
parser = OptionParser(usage="%prog [-f] [-q]", version="")
```

`%prog` is expanded just like it is in `usage`. Apart from that, `version` can contain anything you like. When you supply it, `optparse` automatically adds a `--version` option to your parser. If it encounters this option on the command line, it expands your version string (by replacing `%prog`), prints it to `stdout`, and exits.

For example, if your script is called `/usr/bin/foo`:

```
$ /usr/bin/foo --version
foo 1.0
```

The following two methods can be used to print and get the

version string:

`OptionParser.print_version(file=None)`

Print the version message for the current program (`self.version`) to *file* (default `stdout`). As with `print_usage()`, any occurrence of `%prog` in `self.version` is replaced with the name of the current program. Does nothing if `self.version` is empty or undefined.

`OptionParser.get_version()`

Same as `print_version()` but returns the version string instead of printing it.

## How `optparse` handles errors

There are two broad classes of errors that `optparse` has to worry about: programmer errors and user errors. Programmer errors are usually erroneous calls to `OptionParser.add_option()`, e.g. invalid option strings, unknown option attributes, missing option attributes, etc. These are dealt with in the usual way: raise an exception (either `optparse.OptionError` or `TypeError`) and let the program crash.

Handling user errors is much more important, since they are guaranteed to happen no matter how stable your code is. `optparse` can automatically detect some user errors, such as bad option arguments (passing `-n 4x` where `-n` takes an integer argument), missing arguments (`-n` at the end of the command line, where `-n` takes an argument of any type). Also, you can call `OptionParser.error()` to signal an application-defined error condition:

```
(options, args) = parser.parse_args()
...
if options.a and options.b:
    parser.error("options -a and -b are mutually exclusi
```

In either case, `optparse` handles the error the same way: it prints

the program's usage message and an error message to standard error and exits with error status 2.

Consider the first example above, where the user passes `4x` to an option that takes an integer:

```
$ /usr/bin/foo -n 4x
Usage: foo [options]
```

```
foo: error: option -n: invalid integer value: '4x'
```

Or, where the user fails to pass a value at all:

```
$ /usr/bin/foo -n
Usage: foo [options]
```

```
foo: error: -n option requires an argument
```

**optparse**-generated error messages take care always to mention the option involved in the error; be sure to do the same when calling **OptionParser.error()** from your application code.

If **optparse**'s default error-handling behaviour does not suit your needs, you'll need to subclass **OptionParser** and override its **exit()** and/or **error()** methods.

## Putting it all together

Here's what **optparse**-based scripts usually look like:

```
from optparse import OptionParser
...
def main():
    usage = "usage: %prog [options] arg"
    parser = OptionParser(usage)
    parser.add_option("-f", "--file", dest="filename",
                      help="read data from FILENAME")
    parser.add_option("-v", "--verbose",
                      action="store_true", dest="verbose")
    parser.add_option("-q", "--quiet",
```

```

        action="store_false", dest="verbose")
    ...
    (options, args) = parser.parse_args()
    if len(args) != 1:
        parser.error("incorrect number of arguments")
    if options.verbose:
        print("reading %s..." % options.filename)
    ...

if __name__ == "__main__":
    main()

```

## Reference Guide

### Creating the parser

The first step in using **optparse** is to create an `OptionParser` instance.

```
class optparse.OptionParser(...)
```

The `OptionParser` constructor has no required arguments, but a number of optional keyword arguments. You should always pass them as keyword arguments, i.e. do not rely on the order in which the arguments are declared.

```
usage (default: "%prog [options]")
```

The usage summary to print when your program is run incorrectly or with a help option. When **optparse** prints the usage string, it expands `%prog` to `os.path.basename(sys.argv[0])` (or to `prog` if you passed that keyword argument). To suppress a usage message, pass the special value **`optparse.SUPPRESS_USAGE`**.

```
option_list (default: [])
```

A list of `Option` objects to populate the parser with. The options in `option_list` are added after any options in `standard_option_list` (a class attribute that may be set by `OptionParser` subclasses), but before any

version or help options. Deprecated; use `add_option()` after creating the parser instead.

`option_class` (default: `optparse.Option`)  
Class to use when adding options to the parser in `add_option()`.

`version` (default: `None`)  
A version string to print when the user supplies a version option. If you supply a true value for `version`, `optparse` automatically adds a version option with the single option string `--version`. The substring `%prog` is expanded the same as for `usage`.

`conflict_handler` (default: `"error"`)  
Specifies what to do when options with conflicting option strings are added to the parser; see section [Conflicts between options](#).

`description` (default: `None`)  
A paragraph of text giving a brief overview of your program. `optparse` reformats this paragraph to fit the current terminal width and prints it when the user requests help (after `usage`, but before the list of options).

`formatter` (default: a new `IndentedHelpFormatter`)  
An instance of `optparse.HelpFormatter` that will be used for printing help text. `optparse` provides two concrete classes for this purpose: `IndentedHelpFormatter` and `TitledHelpFormatter`.

`add_help_option` (default: `True`)  
If true, `optparse` will add a help option (with option strings `-h` and `--help`) to the parser.

`prog`  
The string to use when expanding `%prog` in `usage` and `version` instead of `os.path.basename(sys.argv[0])`.

epilog (default: None)

A paragraph of help text to print after the option help.

## Populating the parser

There are several ways to populate the parser with options. The preferred way is by using `OptionParser.add_option()`, as shown in section [Tutorial](#). `add_option()` can be called in one of two ways:

- pass it an `Option` instance (as returned by `make_option()`)
- pass it any combination of positional and keyword arguments that are acceptable to `make_option()` (i.e., to the `Option` constructor), and it will create the `Option` instance for you

The other alternative is to pass a list of pre-constructed `Option` instances to the `OptionParser` constructor, as in:

```
option_list = [  
    make_option("-f", "--filename",  
                action="store", type="string", dest="fil  
    make_option("-q", "--quiet",  
                action="store_false", dest="verbose"),  
]  
parser = OptionParser(option_list=option_list)
```

(`make_option()` is a factory function for creating `Option` instances; currently it is an alias for the `Option` constructor. A future version of `optparse` may split `Option` into several classes, and `make_option()` will pick the right class to instantiate. Do not instantiate `Option` directly.)

## Defining options

Each `Option` instance represents a set of synonymous command-line option strings, e.g. `-f` and `--file`. You can specify any number of short or long option strings, but you must specify at least one overall option string.

The canonical way to create an `Option` instance is with the

`add_option()` method of `OptionParser`.

`OptionParser.add_option(option)`

`OptionParser.add_option(*opt_str, attr=value, ...)`

To define an option with only a short option string:

```
parser.add_option("-f", attr=value, ...)
```

And to define an option with only a long option string:

```
parser.add_option("--foo", attr=value, ...)
```

The keyword arguments define attributes of the new `Option` object. The most important option attribute is `action`, and it largely determines which other attributes are relevant or required. If you pass irrelevant option attributes, or fail to pass required ones, `optparse` raises an `OptionError` exception explaining your mistake.

An option's *action* determines what `optparse` does when it encounters this option on the command-line. The standard option actions hard-coded into `optparse` are:

`"store"`

store this option's argument (default)

`"store_const"`

store a constant value, pre-set via `Option.const`

`"store_true"`

store `True`

`"store_false"`

store `False`

`"append"`

append this option's argument to a list

`"append_const"`

append a constant value to a list, pre-set via  
`Option.const`

"count"  
    increment a counter by one

"callback"  
    call a specified function

"help"  
    print a usage message including all options and the  
    documentation for them

(If you don't supply an action, the default is "store". For this action, you may also supply **type** and **dest** option attributes; see [Standard option actions](#).)

As you can see, most actions involve storing or updating a value somewhere. **optparse** always creates a special object for this, conventionally called `options`, which is an instance of **`optparse.Values`**.

*class optparse.Values*

An object holding parsed argument names and values as attributes. Normally created by calling `when calling OptionParser.parse_args()`, and can be overridden by a custom subclass passed to the *values* argument of **`OptionParser.parse_args()`** (as described in [Parsing arguments](#)).

Option arguments (and various other values) are stored as attributes of this object, according to the **dest** (destination) option attribute.

For example, when you call

```
parser.parse_args()
```

one of the first things **optparse** does is create the `options` object:

```
options = Values()
```

If one of the options in this parser is defined with

```
parser.add_option("-f", "--file", action="store", type="
```

and the command-line being parsed includes any of the following:

```
-ffoo  
-f foo  
--file=foo  
--file foo
```

then `optparse`, on seeing this option, will do the equivalent of

```
options.filename = "foo"
```

The `type` and `dest` option attributes are almost as important as `action`, but `action` is the only one that makes sense for *all* options.

## Option attributes

*class* `optparse.Option`

A single command line argument, with various attributes passed by keyword to the constructor. Normally created with `OptionParser.add_option()` rather than directly, and can be overridden by a custom class via the *option\_class* argument to `OptionParser`.

The following option attributes may be passed as keyword arguments to `OptionParser.add_option()`. If you pass an option attribute that is not relevant to a particular option, or fail to pass a required option attribute, `optparse` raises `OptionError`.

`Option.action`

(default: "store")

Determines `optparse`'s behaviour when this option is seen on the command line; the available options are documented [here](#).

`Option.type`

(default: "string")

The argument type expected by this option (e.g., "string" or "int"); the available option types are documented [here](#).

#### Option.dest

(default: derived from option strings)

If the option's action implies writing or modifying a value somewhere, this tells `optparse` where to write it: `dest` names an attribute of the `options` object that `optparse` builds as it parses the command line.

#### Option.default

The value to use for this option's destination if the option is not seen on the command line. See also `OptionParser.set_defaults()`.

#### Option.nargs

(default: 1)

How many arguments of type `type` should be consumed when this option is seen. If  $> 1$ , `optparse` will store a tuple of values to `dest`.

#### Option.const

For actions that store a constant value, the constant value to store.

#### Option.choices

For options of type "choice", the list of strings the user may choose from.

#### Option.callback

For options with action "callback", the callable to call when this option is seen. See section [Option Callbacks](#) for detail on the arguments passed to the callable.

#### Option.callback\_args

#### Option.callback\_kwargs

Additional positional and keyword arguments to pass to `callback` after the four standard callback arguments.

### Option.help

Help text to print for this option when listing all available options after the user supplies a `help` option (such as `--help`). If no help text is supplied, the option will be listed without help text. To hide this option, use the special value `optparse.SUPPRESS_HELP`.

### Option.metavar

(default: derived from option strings)

Stand-in for the option argument(s) to use when printing help text. See section [Tutorial](#) for an example.

## Standard option actions

The various option actions all have slightly different requirements and effects. Most actions have several relevant option attributes which you may specify to guide `optparse`'s behaviour; a few have required attributes, which you must specify for any option using that action.

- "store" [relevant: `type`, `dest`, `nargs`, `choices`]

The option must be followed by an argument, which is converted to a value according to `type` and stored in `dest`. If `nargs > 1`, multiple arguments will be consumed from the command line; all will be converted according to `type` and stored to `dest` as a tuple. See the [Standard option types](#) section.

If `choices` is supplied (a list or tuple of strings), the type defaults to "choice".

If `type` is not supplied, it defaults to "string".

If `dest` is not supplied, `optparse` derives a destination from the first long option string (e.g., `--foo-bar` implies

foo\_bar). If there are no long option strings, **optparse** derives a destination from the first short option string (e.g., -f implies f).

Example:

```
parser.add_option("-f")
parser.add_option("-p", type="float", nargs=3, dest="point")
```

As it parses the command line

```
-f foo.txt -p 1 -3.5 4 -fbar.txt
```

**optparse** will set

```
options.f = "foo.txt"
options.point = (1.0, -3.5, 4.0)
options.f = "bar.txt"
```

- "store\_const" [required: **const**; relevant: **dest**]

The value **const** is stored in **dest**.

Example:

```
parser.add_option("-q", "--quiet",
                  action="store_const", const=0, dest="quiet")
parser.add_option("-v", "--verbose",
                  action="store_const", const=1, dest="verbose")
parser.add_option("--noisy",
                  action="store_const", const=2, dest="noisy")
```

If --noisy is seen, **optparse** will set

```
options.verbose = 2
```

- "store\_true" [relevant: **dest**]

A special case of "store\_const" that stores True to **dest**.

- "store\_false" [relevant: **dest**]

Like "store\_true", but stores False.

Example:

```
parser.add_option("--clobber", action="store_true",
parser.add_option("--no-clobber", action="store_false",
```

- "append" [relevant: **type**, **dest**, **nargs**, **choices**]

The option must be followed by an argument, which is appended to the list in **dest**. If no default value for **dest** is supplied, an empty list is automatically created when **optparse** first encounters this option on the command-line. If **nargs** > 1, multiple arguments are consumed, and a tuple of length **nargs** is appended to **dest**.

The defaults for **type** and **dest** are the same as for the "store" action.

Example:

```
parser.add_option("-t", "--tracks", action="append"
```

If `-t3` is seen on the command-line, **optparse** does the equivalent of:

```
options.tracks = []
options.tracks.append(int("3"))
```

If, a little later on, `--tracks=4` is seen, it does:

```
options.tracks.append(int("4"))
```

The `append` action calls the `append` method on the current value of the option. This means that any default value specified must have an `append` method. It also means that if the default value is non-empty, the default elements will be present in the parsed value for the option, with any values from the command line appended after those default values:

```
>>> parser.add_option("--files", action="append", d
>>> opts, args = parser.parse_args(['--files', 'ove
```

```
>>> opts.files
['~/mypkg/defaults', 'overrides.mypkg']
```

- "append\_const" [required: `const`; relevant: `dest`]

Like "store\_const", but the value `const` is appended to `dest`; as with "append", `dest` defaults to `None`, and an empty list is automatically created the first time the option is encountered.

- "count" [relevant: `dest`]

Increment the integer stored at `dest`. If no default value is supplied, `dest` is set to zero before being incremented the first time.

Example:

```
parser.add_option("-v", action="count", dest="verbosity")
```

The first time `-v` is seen on the command line, `optparse` does the equivalent of:

```
options.verbosity = 0
options.verbosity += 1
```

Every subsequent occurrence of `-v` results in

```
options.verbosity += 1
```

- "callback" [required: `callback`; relevant: `type`, `nargs`, `callback_args`, `callback_kwargs`]

Call the function specified by `callback`, which is called as

```
func(option, opt_str, value, parser, *args, **kwargs)
```

See section [Option Callbacks](#) for more detail.

- "help"

Prints a complete help message for all the options in the

current option parser. The help message is constructed from the `usage` string passed to `OptionParser`'s constructor and the `help` string passed to every option.

If no `help` string is supplied for an option, it will still be listed in the help message. To omit an option entirely, use the special value `optparse.SUPPRESS_HELP`.

`optparse` automatically adds a `help` option to all `OptionParsers`, so you do not normally need to create one.

Example:

```
from optparse import OptionParser, SUPPRESS_HELP

# usually, a help option is added automatically, but
# be suppressed using the add_help_option argument
parser = OptionParser(add_help_option=False)

parser.add_option("-h", "--help", action="help")
parser.add_option("-v", action="store_true", dest="verbose",
                  help="Be moderately verbose")
parser.add_option("--file", dest="filename",
                  help="Input file to read data from")
parser.add_option("--secret", help=SUPPRESS_HELP)
```

If `optparse` sees either `-h` or `--help` on the command line, it will print something like the following help message to `stdout` (assuming `sys.argv[0]` is `"foo.py"`):

```
Usage: foo.py [options]
```

Options:

<code>-h, --help</code>	Show this help message and exit
<code>-v</code>	Be moderately verbose
<code>--file=FILENAME</code>	Input file to read data from

After printing the help message, `optparse` terminates your process with `sys.exit(0)`.

- `"version"`

Prints the version number supplied to the `OptionParser` to `stdout` and exits. The version number is actually formatted and printed by the `print_version()` method of `OptionParser`. Generally only relevant if the `version` argument is supplied to the `OptionParser` constructor. As with [help](#) options, you will rarely create `version` options, since [optparse](#) automatically adds them when needed.

## Standard option types

[optparse](#) has five built-in option types: `"string"`, `"int"`, `"choice"`, `"float"` and `"complex"`. If you need to add new option types, see section [Extending optparse](#).

Arguments to string options are not checked or converted in any way: the text on the command line is stored in the destination (or passed to the callback) as-is.

Integer arguments (type `"int"`) are parsed as follows:

- if the number starts with `0x`, it is parsed as a hexadecimal number
- if the number starts with `0`, it is parsed as an octal number
- if the number starts with `0b`, it is parsed as a binary number
- otherwise, the number is parsed as a decimal number

The conversion is done by calling [int\(\)](#) with the appropriate base (2, 8, 10, or 16). If this fails, so will [optparse](#), although with a more useful error message.

`"float"` and `"complex"` option arguments are converted directly with [float\(\)](#) and [complex\(\)](#), with similar error-handling.

`"choice"` options are a subtype of `"string"` options. The [choices](#) option attribute (a sequence of strings) defines the set of allowed option arguments. [optparse.check\\_choice\(\)](#) compares user-supplied option arguments against this master list and raises [OptionValueError](#) if an invalid string is given.

## Parsing arguments

The whole point of creating and populating an `OptionParser` is to call its `parse_args()` method.

`OptionParser.parse_args(args=None, values=None)`

Parse the command-line options found in *args*.

The input parameters are

*args*

the list of arguments to process (default:  
`sys.argv[1:]`)

*values*

an **Values** object to store option arguments in  
(default: a new instance of **Values**) – if you give an  
existing object, the option defaults will not be  
initialized on it

and the return value is a pair (*options*, *args*) where

*options*

the same object that was passed in as *values*, or the  
`optparse.Values` instance created by `optparse`

*args*

the leftover positional arguments after all options have  
been processed

The most common usage is to supply neither keyword argument. If you supply *values*, it will be modified with repeated `setattr()` calls (roughly one for every option argument stored to an option destination) and returned by `parse_args()`.

If `parse_args()` encounters any errors in the argument list, it calls the `OptionParser`'s `error()` method with an appropriate end-user error message. This ultimately terminates your process with an exit status of 2 (the traditional Unix exit status for command-line errors).

## Querying and manipulating your option parser

The default behavior of the option parser can be customized slightly, and you can also poke around your option parser and see what's there. `OptionParser` provides several methods to help you out:

#### `OptionParser.disable_interspersed_args()`

Set parsing to stop on the first non-option. For example, if `-a` and `-b` are both simple options that take no arguments, **optparse** normally accepts this syntax:

```
prog -a arg1 -b arg2
```

and treats it as equivalent to

```
prog -a -b arg1 arg2
```

To disable this feature, call **disable\_interspersed\_args()**. This restores traditional Unix syntax, where option parsing stops with the first non-option argument.

Use this if you have a command processor which runs another command which has options of its own and you want to make sure these options don't get confused. For example, each command might have a different set of options.

#### `OptionParser.enable_interspersed_args()`

Set parsing to not stop on the first non-option, allowing interspersing switches with command arguments. This is the default behavior.

#### `OptionParser.get_option(opt_str)`

Returns the `Option` instance with the option string `opt_str`, or `None` if no options have that option string.

#### `OptionParser.has_option(opt_str)`

Return `True` if the `OptionParser` has an option with option string `opt_str` (e.g., `-q` or `--verbose`).

`OptionParser.remove_option(opt_str)`

If the `OptionParser` has an option corresponding to *opt\_str*, that option is removed. If that option provided any other option strings, all of those option strings become invalid. If *opt\_str* does not occur in any option belonging to this `OptionParser`, raises `ValueError`.

## Conflicts between options

If you're not careful, it's easy to define options with conflicting option strings:

```
parser.add_option("-n", "--dry-run", ...)
...
parser.add_option("-n", "--noisy", ...)
```

(This is particularly true if you've defined your own `OptionParser` subclass with some standard options.)

Every time you add an option, `optparse` checks for conflicts with existing options. If it finds any, it invokes the current conflict-handling mechanism. You can set the conflict-handling mechanism either in the constructor:

```
parser = OptionParser(..., conflict_handler=handler)
```

or with a separate call:

```
parser.set_conflict_handler(handler)
```

The available conflict handlers are:

- "error" (default)  
assume option conflicts are a programming error and raise `OptionConflictError`
- "resolve"  
resolve option conflicts intelligently (see below)

As an example, let's define an `OptionParser` that resolves conflicts intelligently and add conflicting options to it:

```
parser = OptionParser(conflict_handler="resolve")
parser.add_option("-n", "--dry-run", ..., help="do no harm")
parser.add_option("-n", "--noisy", ..., help="be noisy")
```

At this point, `optparse` detects that a previously added option is already using the `-n` option string. Since `conflict_handler` is `"resolve"`, it resolves the situation by removing `-n` from the earlier option's list of option strings. Now `--dry-run` is the only way for the user to activate that option. If the user asks for help, the help message will reflect that:

```
Options:
  --dry-run      do no harm
  ...
  -n, --noisy    be noisy
```

It's possible to whittle away the option strings for a previously added option until there are none left, and the user has no way of invoking that option from the command-line. In that case, `optparse` removes that option completely, so it doesn't show up in help text or anywhere else. Carrying on with our existing `OptionParser`:

```
parser.add_option("--dry-run", ..., help="new dry-run option")
```

At this point, the original `-n/--dry-run` option is no longer accessible, so `optparse` removes it, leaving this help text:

```
Options:
  ...
  -n, --noisy    be noisy
  --dry-run      new dry-run option
```

## Cleanup

`OptionParser` instances have several cyclic references. This should not be a problem for Python's garbage collector, but you may wish to break the cyclic references explicitly by calling `destroy()` on

your `OptionParser` once you are done with it. This is particularly useful in long-running applications where large object graphs are reachable from your `OptionParser`.

## Other methods

`OptionParser` supports several other public methods:

`OptionParser.set_usage(usage)`

Set the usage string according to the rules described above for the `usage` constructor keyword argument. Passing `None` sets the default usage string; use **`optparse.SUPPRESS_USAGE`** to suppress a usage message.

`OptionParser.print_usage(file = None)`

Print the usage message for the current program (`self.usage`) to *file* (default `stdout`). Any occurrence of the string `%prog` in `self.usage` is replaced with the name of the current program. Does nothing if `self.usage` is empty or not defined.

`OptionParser.get_usage()`

Same as **`print_usage()`** but returns the usage string instead of printing it.

`OptionParser.set_defaults(dest = value, ...)`

Set default values for several option destinations at once. Using **`set_defaults()`** is the preferred way to set default values for options, since multiple options can share the same destination. For example, if several “mode” options all set the same destination, any one of them can set the default, and the last one wins:

```
parser.add_option("--advanced", action="store_const",
                  dest="mode", const="advanced",
                  default="novice")      # overridden
parser.add_option("--novice", action="store_const",
                  dest="mode", const="novice",
```

```
default="advanced") # overrides
```

To avoid this confusion, use `set_defaults()`:

```
parser.set_defaults(mode="advanced")
parser.add_option("--advanced", action="store_const",
                  dest="mode", const="advanced")
parser.add_option("--novice", action="store_const",
                  dest="mode", const="novice")
```

## Option Callbacks

When `optparse`'s built-in actions and types aren't quite enough for your needs, you have two choices: extend `optparse` or define a callback option. Extending `optparse` is more general, but overkill for a lot of simple cases. Quite often a simple callback is all you need.

There are two steps to defining a callback option:

- define the option itself using the "callback" action
- write the callback; this is a function (or method) that takes at least four arguments, as described below

### Defining a callback option

As always, the easiest way to define a callback option is by using the `OptionParser.add_option()` method. Apart from `action`, the only option attribute you must specify is `callback`, the function to call:

```
parser.add_option("-c", action="callback", callback=my_callback)
```

`callback` is a function (or other callable object), so you must have already defined `my_callback()` when you create this callback option. In this simple case, `optparse` doesn't even know if `-c` takes any arguments, which usually means that the option takes no arguments—the mere presence of `-c` on the command-line is all it needs to know. In some circumstances, though, you might want your callback to consume an arbitrary number of command-line

arguments. This is where writing callbacks gets tricky; it's covered later in this section.

`optparse` always passes four particular arguments to your callback, and it will only pass additional arguments if you specify them via `callback_args` and `callback_kwargs`. Thus, the minimal callback function signature is:

```
def my_callback(option, opt, value, parser):
```

The four arguments to a callback are described below.

There are several other option attributes that you can supply when you define a callback option:

#### `type`

has its usual meaning: as with the "store" or "append" actions, it instructs `optparse` to consume one argument and convert it to `type`. Rather than storing the converted value(s) anywhere, though, `optparse` passes it to your callback function.

#### `nargs`

also has its usual meaning: if it is supplied and  $> 1$ , `optparse` will consume `nargs` arguments, each of which must be convertible to `type`. It then passes a tuple of converted values to your callback.

#### `callback_args`

a tuple of extra positional arguments to pass to the callback

#### `callback_kwargs`

a dictionary of extra keyword arguments to pass to the callback

## How callbacks are called

All callbacks are called as follows:

```
func(option, opt_str, value, parser, *args, **kwargs)
```

where

`option`

is the `Option` instance that's calling the callback

`opt_str`

is the option string seen on the command-line that's triggering the callback. (If an abbreviated long option was used, `opt_str` will be the full, canonical option string—e.g. if the user puts `--foo` on the command-line as an abbreviation for `--foobar`, then `opt_str` will be `"--foobar"`.)

`value`

is the argument to this option seen on the command-line. `optparse` will only expect an argument if `type` is set; the type of `value` will be the type implied by the option's type. If `type` for this option is `None` (no argument expected), then `value` will be `None`. If `nargs` > 1, `value` will be a tuple of values of the appropriate type.

`parser`

is the `OptionParser` instance driving the whole thing, mainly useful because you can access some other interesting data through its instance attributes:

`parser.largs`

the current list of leftover arguments, ie. arguments that have been consumed but are neither options nor option arguments. Feel free to modify `parser.largs`, e.g. by adding more arguments to it. (This list will become `args`, the second return value of `parse_args()`.)

`parser.rargs`

the current list of remaining arguments, ie. with `opt_str` and `value` (if applicable) removed, and only the arguments following them still there. Feel free to modify `parser.rargs`, e.g. by consuming more arguments.

`parser.values`

the object where option values are by default stored (an instance of `optparse.OptionValues`). This lets callbacks use the same mechanism as the rest of `optparse` for storing option values; you don't need to mess around with globals or closures. You can also access or modify the value(s) of any options already encountered on the command-line.

`args`

is a tuple of arbitrary positional arguments supplied via the `callback_args` option attribute.

`kwargs`

is a dictionary of arbitrary keyword arguments supplied via `callback_kwargs`.

## Raising errors in a callback

The callback function should raise `OptionValueError` if there are any problems with the option or its argument(s). `optparse` catches this and terminates the program, printing the error message you supply to stderr. Your message should be clear, concise, accurate, and mention the option at fault. Otherwise, the user will have a hard time figuring out what they did wrong.

## Callback example 1: trivial callback

Here's an example of a callback option that takes no arguments, and simply records that the option was seen:

```
def record_foo_seen(option, opt_str, value, parser):
    parser.values.saw_foo = True
```

```
parser.add_option("--foo", action="callback", callback=record_foo_seen)
```

Of course, you could do that with the `"store_true"` action.

## Callback example 2: check option order

Here's a slightly more interesting example: record the fact that `-a` is seen, but blow up if it comes after `-b` in the command-line.

```
def check_order(option, opt_str, value, parser):
    if parser.values.b:
        raise OptionValueError("can't use -a after -b")
    parser.values.a = 1
...
parser.add_option("-a", action="callback", callback=check_order)
parser.add_option("-b", action="store_true", dest="b")
```

### Callback example 3: check option order (generalized)

If you want to re-use this callback for several similar options (set a flag, but blow up if `-b` has already been seen), it needs a bit of work: the error message and the flag that it sets must be generalized.

```
def check_order(option, opt_str, value, parser):
    if parser.values.b:
        raise OptionValueError("can't use %s after -b" % opt_str)
    setattr(parser.values, option.dest, 1)
...
parser.add_option("-a", action="callback", callback=check_order)
parser.add_option("-b", action="store_true", dest="b")
parser.add_option("-c", action="callback", callback=check_order)
```

### Callback example 4: check arbitrary condition

Of course, you could put any condition in there—you're not limited to checking the values of already-defined options. For example, if you have options that should not be called when the moon is full, all you have to do is this:

```
def check_moon(option, opt_str, value, parser):
    if is_moon_full():
        raise OptionValueError("%s option invalid when moon is full"
                                % opt_str)
    setattr(parser.values, option.dest, 1)
```

```
...
parser.add_option("--foo",
                  action="callback", callback=check_moon
```

(The definition of `is_moon_full()` is left as an exercise for the reader.)

## Callback example 5: fixed arguments

Things get slightly more interesting when you define callback options that take a fixed number of arguments. Specifying that a callback option takes arguments is similar to defining a "store" or "append" option: if you define `type`, then the option takes one argument that must be convertible to that type; if you further define `nargs`, then the option takes `nargs` arguments.

Here's an example that just emulates the standard "store" action:

```
def store_value(option, opt_str, value, parser):
    setattr(parser.values, option.dest, value)
...
parser.add_option("--foo",
                  action="callback", callback=store_value,
                  type="int", nargs=3, dest="foo")
```

Note that `optparse` takes care of consuming 3 arguments and converting them to integers for you; all you have to do is store them. (Or whatever; obviously you don't need a callback for this example.)

## Callback example 6: variable arguments

Things get hairy when you want an option to take a variable number of arguments. For this case, you must write a callback, as `optparse` doesn't provide any built-in capabilities for it. And you have to deal with certain intricacies of conventional Unix command-line parsing that `optparse` normally handles for you. In particular, callbacks should implement the conventional rules for bare `--` and `-` arguments:

- either `--` or `-` can be option arguments
- bare `--` (if not the argument to some option): halt command-line processing and discard the `--`
- bare `-` (if not the argument to some option): halt command-line processing but keep the `-` (append it to `parser.largs`)

If you want an option that takes a variable number of arguments, there are several subtle, tricky issues to worry about. The exact implementation you choose will be based on which trade-offs you're willing to make for your application (which is why `optparse` doesn't support this sort of thing directly).

Nevertheless, here's a stab at a callback for an option with variable arguments:

```
def vararg_callback(option, opt_str, value, parser):
    assert value is None
    value = []

    def floatable(str):
        try:
            float(str)
            return True
        except ValueError:
            return False

    for arg in parser.rargs:
        # stop on --foo like options
        if arg[:2] == "--" and len(arg) > 2:
            break
        # stop on -a, but not on -3 or -3.0
        if arg[:1] == "-" and len(arg) > 1 and not floatable(arg):
            break
        value.append(arg)

    del parser.rargs[:len(value)]
    setattr(parser.values, option.dest, value)
```

```
...
parser.add_option("-c", "--callback", dest="vararg_attr",
                  action="callback", callback=vararg_cal
```

## Extending `optparse`

Since the two major controlling factors in how `optparse` interprets command-line options are the action and type of each option, the most likely direction of extension is to add new actions and new types.

### Adding new types

To add new types, you need to define your own subclass of `optparse`'s `Option` class. This class has a couple of attributes that define `optparse`'s types: `TYPES` and `TYPE_CHECKER`.

#### `Option.TYPES`

A tuple of type names; in your subclass, simply define a new tuple `TYPES` that builds on the standard one.

#### `Option.TYPE_CHECKER`

A dictionary mapping type names to type-checking functions. A type-checking function has the following signature:

```
def check_mytype(option, opt, value)
```

where `option` is an `Option` instance, `opt` is an option string (e.g., `-f`), and `value` is the string from the command line that must be checked and converted to your desired type. `check_mytype()` should return an object of the hypothetical type `mytype`. The value returned by a type-checking function will wind up in the `OptionValues` instance returned by `OptionParser.parse_args()`, or be passed to a callback as the `value` parameter.

Your type-checking function should raise `OptionValueError` if it encounters any problems. `OptionValueError` takes a single string argument, which is

passed as-is to `OptionParser`'s `error()` method, which in turn prepends the program name and the string "error:" and prints everything to stderr before terminating the process.

Here's a silly example that demonstrates adding a "complex" option type to parse Python-style complex numbers on the command line. (This is even sillier than it used to be, because `optparse` 1.3 added built-in support for complex numbers, but never mind.)

First, the necessary imports:

```
from copy import copy
from optparse import Option, OptionValueError
```

You need to define your type-checker first, since it's referred to later (in the `TYPE_CHECKER` class attribute of your Option subclass):

```
def check_complex(option, opt, value):
    try:
        return complex(value)
    except ValueError:
        raise OptionValueError(
            "option %s: invalid complex value: %r" % (opt, value))
```

Finally, the Option subclass:

```
class MyOption (Option):
    TYPES = Option.TYPES + ("complex",)
    TYPE_CHECKER = copy(Option.TYPE_CHECKER)
    TYPE_CHECKER["complex"] = check_complex
```

(If we didn't make a `copy()` of `Option.TYPE_CHECKER`, we would end up modifying the `TYPE_CHECKER` attribute of `optparse`'s Option class. This being Python, nothing stops you from doing that except good manners and common sense.)

That's it! Now you can write a script that uses the new option type just like any other `optparse`-based script, except you have to

instruct your `OptionParser` to use `MyOption` instead of `Option`:

```
parser = OptionParser(option_class=MyOption)
parser.add_option("-c", type="complex")
```

Alternately, you can build your own option list and pass it to `OptionParser`; if you don't use `add_option()` in the above way, you don't need to tell `OptionParser` which option class to use:

```
option_list = [MyOption("-c", action="store", type="complex")]
parser = OptionParser(option_list=option_list)
```

## Adding new actions

Adding new actions is a bit trickier, because you have to understand that `optparse` has a couple of classifications for actions:

“store” actions

actions that result in `optparse` storing a value to an attribute of the current `OptionValues` instance; these options require a `dest` attribute to be supplied to the `Option` constructor.

“typed” actions

actions that take a value from the command line and expect it to be of a certain type; or rather, a string that can be converted to a certain type. These options require a `type` attribute to the `Option` constructor.

These are overlapping sets: some default “store” actions are `"store"`, `"store_const"`, `"append"`, and `"count"`, while the default “typed” actions are `"store"`, `"append"`, and `"callback"`.

When you add an action, you need to categorize it by listing it in at least one of the following class attributes of `Option` (all are lists of strings):

`Option.ACTIONS`

All actions must be listed in `ACTIONS`.

## Option.STORE\_ACTIONS

“store” actions are additionally listed here.

## Option.TYPED\_ACTIONS

“typed” actions are additionally listed here.

## Option.ALWAYS\_TYPED\_ACTIONS

Actions that always take a type (i.e. whose options always take a value) are additionally listed here. The only effect of this is that `optparse` assigns the default type, “string”, to options with no explicit type whose action is listed in `ALWAYS_TYPED_ACTIONS`.

In order to actually implement your new action, you must override Option’s `take_action()` method and add a case that recognizes your action.

For example, let’s add an “extend” action. This is similar to the standard “append” action, but instead of taking a single value from the command-line and appending it to an existing list, “extend” will take multiple values in a single comma-delimited string, and extend an existing list with them. That is, if `--names` is an “extend” option of type “string”, the command line

```
--names=foo,bar --names blah --names ding,dong
```

would result in a list

```
["foo", "bar", "blah", "ding", "dong"]
```

Again we define a subclass of Option:

```
class MyOption(Option):
```

```
    ACTIONS = Option.ACTIONS + ("extend",)
```

```
    STORE_ACTIONS = Option.STORE_ACTIONS + ("extend",)
```

```
    TYPED_ACTIONS = Option.TYPED_ACTIONS + ("extend",)
```

```
    ALWAYS_TYPED_ACTIONS = Option.ALWAYS_TYPED_ACTIONS +
```

```

def take_action(self, action, dest, opt, value, values):
    if action == "extend":
        lvalue = value.split(",")
        values.ensure_value(dest, []).extend(lvalue)
    else:
        Option.take_action(
            self, action, dest, opt, value, values,

```

Features of note:

- "extend" both expects a value on the command-line and stores that value somewhere, so it goes in both **STORE\_ACTIONS** and **TYPED\_ACTIONS**.
- to ensure that **optparse** assigns the default type of "string" to "extend" actions, we put the "extend" action in **ALWAYS\_TYPED\_ACTIONS** as well.
- **MyOption.take\_action()** implements just this one new action, and passes control back to **Option.take\_action()** for the standard **optparse** actions.
- **values** is an instance of the **optparse\_parser.Values** class, which provides the very useful **ensure\_value()** method. **ensure\_value()** is essentially **getattr()** with a safety valve; it is called as

```
values.ensure_value(attr, value)
```

If the **attr** attribute of **values** doesn't exist or is **None**, then **ensure\_value()** first sets it to **value**, and then returns 'value. This is very handy for actions like "extend", "append", and "count", all of which accumulate data in a variable and expect that variable to be of a certain type (a list for the first two, an integer for the latter). Using **ensure\_value()** means that scripts using your action don't have to worry about setting a default value for the option destinations in question; they can just leave the default as **None** and **ensure\_value()** will take care of getting it right when it's needed.

# Exceptions

*exception* optparse.OptionError

Raised if an **Option** instance is created with invalid or inconsistent arguments.

*exception* optparse.OptionConflictError

Raised if conflicting options are added to an **OptionParser**.

*exception* optparse.OptionValueError

Raised if an invalid option value is encountered on the command line.

*exception* optparse.BadOptionError

Raised if an invalid option is passed on the command line.

*exception* optparse.AmbiguousOptionError

Raised if an ambiguous option is passed on the command line.

# ossaudiodev — Access to OSS-compatible audio devices

*Deprecated since version 3.11, will be removed in version 3.13:* The **ossaudiodev** module is deprecated (see [PEP 594](https://peps.python.org/pep-0594/#ossaudiodev) [https://peps.python.org/pep-0594/#ossaudiodev] for details).

---

This module allows you to access the OSS (Open Sound System) audio interface. OSS is available for a wide range of open-source and commercial Unices, and is the standard audio interface for Linux and recent versions of FreeBSD.

*Changed in version 3.3:* Operations in this module now raise **OSError** where **IOError** was raised.

## See also

**Open Sound System Programmer's Guide** [<http://www.opensound.com/pguide/oss.pdf>]  
the official documentation for the OSS C API

The module defines a large number of constants supplied by the OSS device driver; see `<sys/soundcard.h>` on either Linux or FreeBSD for a listing.

**ossaudiodev** defines the following variables and functions:

*exception* **ossaudiodev.OSSAudioError**

This exception is raised on certain errors. The argument is a string describing what went wrong.

(If **ossaudiodev** receives an error from a system call such as **open()**, **write()**, or **ioctl()**, it raises **OSError**. Errors detected directly by **ossaudiodev** result in

**OSSAudioError.**)

(For backwards compatibility, the exception class is also available as `ossaudiodev.error`.)

`ossaudiodev.open(mode)`

`ossaudiodev.open(device, mode)`

Open an audio device and return an OSS audio device object. This object supports many file-like methods, such as `read()`, `write()`, and `fileno()` (although there are subtle differences between conventional Unix read/write semantics and those of OSS audio devices). It also supports a number of audio-specific methods; see below for the complete list of methods.

*device* is the audio device filename to use. If it is not specified, this module first looks in the environment variable **AUDIODEV** for a device to use. If not found, it falls back to `/dev/dsp`.

*mode* is one of `'r'` for read-only (record) access, `'w'` for write-only (playback) access and `'rw'` for both. Since many sound cards only allow one process to have the recorder or player open at a time, it is a good idea to open the device only for the activity needed. Further, some sound cards are half-duplex: they can be opened for reading or writing, but not both at once.

Note the unusual calling syntax: the *first* argument is optional, and the second is required. This is a historical artifact for compatibility with the older **linuxaudiodev** module which **ossaudiodev** supersedes.

`ossaudiodev.openmixer([device])`

Open a mixer device and return an OSS mixer device object. *device* is the mixer device filename to use. If it is not specified, this module first looks in the environment variable **MIXERDEV** for a device to use. If not found, it falls back to `/dev/mixer`.

# Audio Device Objects

Before you can write to or read from an audio device, you must call three methods in the correct order:

1. **setfmt()** to set the output format
2. **channels()** to set the number of channels
3. **speed()** to set the sample rate

Alternately, you can use the **setparameters()** method to set all three audio parameters at once. This is more convenient, but may not be as flexible in all cases.

The audio device objects returned by **open()** define the following methods and (read-only) attributes:

`oss_audio_device.close()`

Explicitly close the audio device. When you are done writing to or reading from an audio device, you should explicitly close it. A closed device cannot be used again.

`oss_audio_device.fileno()`

Return the file descriptor associated with the device.

`oss_audio_device.read(size)`

Read *size* bytes from the audio input and return them as a Python string. Unlike most Unix device drivers, OSS audio devices in blocking mode (the default) will block **read()** until the entire requested amount of data is available.

`oss_audio_device.write(data)`

Write a **bytes-like object** *data* to the audio device and return the number of bytes written. If the audio device is in blocking mode (the default), the entire data is always written (again, this is different from usual Unix device semantics). If the device is in non-blocking mode, some data may not be written—see **writeall()**.

*Changed in version 3.5:* Writable [bytes-like object](#) is now accepted.

`oss_audio_device.writeall(data)`

Write a [bytes-like object](#) *data* to the audio device: waits until the audio device is able to accept data, writes as much data as it will accept, and repeats until *data* has been completely written. If the device is in blocking mode (the default), this has the same effect as `write()`; `writeall()` is only useful in non-blocking mode. Has no return value, since the amount of data written is always equal to the amount of data supplied.

*Changed in version 3.5:* Writable [bytes-like object](#) is now accepted.

*Changed in version 3.2:* Audio device objects also support the context management protocol, i.e. they can be used in a `with` statement.

The following methods each map to exactly one `ioctl()` system call. The correspondence is obvious: for example, `setfmt()` corresponds to the `SNDCTL_DSP_SETFMT` `ioctl`, and `sync()` to `SNDCTL_DSP_SYNC` (this can be useful when consulting the OSS documentation). If the underlying `ioctl()` fails, they all raise [OSError](#).

`oss_audio_device.nonblock()`

Put the device into non-blocking mode. Once in non-blocking mode, there is no way to return it to blocking mode.

`oss_audio_device.getfmts()`

Return a bitmask of the audio output formats supported by the soundcard. Some of the formats supported by OSS are:

Description
<code>AFMT_U_16</code> 16-bit unsigned integer encoding (used by Sun .au files and /dev/audio)
<code>AFMT_A_16</code> 16-bit signed integer encoding
<code>AFMT_C_16</code> 16-bit signed integer format defined by the Interactive

Multimedia Association

**AFMT\_U8**, 8-bit audio

**AFMT\_S16\_LE**, 16-bit audio, little-endian byte order (as used by Intel processors)

**AFMT\_S16\_BE**, 16-bit audio, big-endian byte order (as used by 68k, PowerPC, Sparc)

**AFMT\_S8**, 8-bit audio

**AFMT\_U16\_LE**, 16-bit little-endian audio

**AFMT\_U16\_BE**, 16-bit big-endian audio

Consult the OSS documentation for a full list of audio formats, and note that most devices support only a subset of these formats. Some older devices only support **AFMT\_U8**; the most common format used today is **AFMT\_S16\_LE**.

`oss_audio_device.setfmt(format)`

Try to set the current audio format to *format*—see [getfmts\(\)](#) for a list. Returns the audio format that the device was set to, which may not be the requested format. May also be used to return the current audio format—do this by passing an “audio format” of **AFMT\_QUERY**.

`oss_audio_device.channels(nchannels)`

Set the number of output channels to *nchannels*. A value of 1 indicates monophonic sound, 2 stereophonic. Some devices may have more than 2 channels, and some high-end devices may not support mono. Returns the number of channels the device was set to.

`oss_audio_device.speed(samplerate)`

Try to set the audio sampling rate to *samplerate* samples per second. Returns the rate actually set. Most sound devices don’t support arbitrary sampling rates. Common rates are:

Description
8000
11025
22050
44100

### `oss_audio_device.sync()`

Wait until the sound device has played every byte in its buffer. (This happens implicitly when the device is closed.) The OSS documentation recommends closing and re-opening the device rather than using `sync()`.

### `oss_audio_device.reset()`

Immediately stop playing or recording and return the device to a state where it can accept commands. The OSS documentation recommends closing and re-opening the device after calling `reset()`.

### `oss_audio_device.post()`

Tell the driver that there is likely to be a pause in the output, making it possible for the device to handle the pause more intelligently. You might use this after playing a spot sound effect, before waiting for user input, or before doing disk I/O.

The following convenience methods combine several ioctls, or one ioctl and some simple calculations.

### `oss_audio_device.setparameters(format, nchannels, samplerate [, strict=False])`

Set the key audio sampling parameters—sample format, number of channels, and sampling rate—in one method call. *format*, *nchannels*, and *samplerate* should be as specified in the `setfmt()`, `channels()`, and `speed()` methods. If *strict* is true, `setparameters()` checks to see if each parameter was actually set to the requested value, and raises `OSSAudioError` if not. Returns a tuple (*format*, *nchannels*, *samplerate*) indicating the parameter values that were actually set by the device driver (i.e., the same as the return values of `setfmt()`, `channels()`, and `speed()`).

For example,

```
(fmt, channels, rate) = dsp.setparameters(fmt, chan
```

is equivalent to

```
fmt = dsp.setfmt(fmt)
channels = dsp.channels(channels)
rate = dsp.rate(rate)
```

`oss_audio_device.bufsize()`

Returns the size of the hardware buffer, in samples.

`oss_audio_device.obufcount()`

Returns the number of samples that are in the hardware buffer yet to be played.

`oss_audio_device.obuffree()`

Returns the number of samples that could be queued into the hardware buffer to be played without blocking.

Audio device objects also support several read-only attributes:

`oss_audio_device.closed`

Boolean indicating whether the device has been closed.

`oss_audio_device.name`

String containing the name of the device file.

`oss_audio_device.mode`

The I/O mode for the file, either `"r"`, `"rw"`, or `"w"`.

## Mixer Device Objects

The mixer object provides two file-like methods:

`oss_mixer_device.close()`

This method closes the open mixer device file. Any further attempts to use the mixer after this file is closed will raise an

## **OSError.**

`oss_mixer_device.fileno()`

Returns the file handle number of the open mixer device file.

*Changed in version 3.2:* Mixer objects also support the context management protocol.

The remaining methods are specific to audio mixing:

`oss_mixer_device.controls()`

This method returns a bitmask specifying the available mixer controls (“Control” being a specific mixable “channel”, such as **SOUND\_MIXER\_PCM** or **SOUND\_MIXER\_SYNTH**). This bitmask indicates a subset of all available mixer controls—the **SOUND\_MIXER\_\*** constants defined at module level. To determine if, for example, the current mixer object supports a PCM mixer, use the following Python code:

```
mixer=ossaudiodev.openmixer()
if mixer.controls() & (1 << ossaudiodev.SOUND_MIXER_PCM):
    # PCM is supported
    ... code ...
```

For most purposes, the **SOUND\_MIXER\_VOLUME** (master volume) and **SOUND\_MIXER\_PCM** controls should suffice—but code that uses the mixer should be flexible when it comes to choosing mixer controls. On the Gravis Ultrasound, for example, **SOUND\_MIXER\_VOLUME** does not exist.

`oss_mixer_device.stereocontrols()`

Returns a bitmask indicating stereo mixer controls. If a bit is set, the corresponding control is stereo; if it is unset, the control is either monophonic or not supported by the mixer (use in combination with `controls()` to determine which).

See the code example for the `controls()` function for an example of getting data from a bitmask.

`oss_mixer_device.reccontrols()`

Returns a bitmask specifying the mixer controls that may be used to record. See the code example for `controls()` for an example of reading from a bitmask.

`oss_mixer_device.get(control)`

Returns the volume of a given mixer control. The returned volume is a 2-tuple `(left_volume, right_volume)`. Volumes are specified as numbers from 0 (silent) to 100 (full volume). If the control is monophonic, a 2-tuple is still returned, but both volumes are the same.

Raises `OSSAudioError` if an invalid control is specified, or `OSError` if an unsupported control is specified.

`oss_mixer_device.set(control, (left, right))`

Sets the volume for a given mixer control to `(left, right)`. `left` and `right` must be ints and between 0 (silent) and 100 (full volume). On success, the new volume is returned as a 2-tuple. Note that this may not be exactly the same as the volume specified, because of the limited resolution of some soundcard's mixers.

Raises `OSSAudioError` if an invalid mixer control was specified, or if the specified volumes were out-of-range.

`oss_mixer_device.get_recsrc()`

This method returns a bitmask indicating which control(s) are currently being used as a recording source.

`oss_mixer_device.set_recsrc(bitmask)`

Call this function to specify a recording source. Returns a bitmask indicating the new recording source (or sources) if successful; raises `OSError` if an invalid source was specified. To set the current recording source to the microphone input:

```
mixer.set_recsrc (1 << ossaudiodev.SOUND_MIXER_MIC)
```

# `pipes` — Interface to shell pipelines

**Source code:** [Lib/pipes.py](https://github.com/python/cpython/tree/3.11/Lib/pipes.py) [https://github.com/python/cpython/tree/3.11/Lib/pipes.py]

*Deprecated since version 3.11, will be removed in version 3.13:* The `pipes` module is deprecated (see [PEP 594](https://peps.python.org/pep-0594/#pipes) [https://peps.python.org/pep-0594/#pipes] for details). Please use the `subprocess` module instead.

---

The `pipes` module defines a class to abstract the concept of a *pipeline* — a sequence of converters from one file to another.

Because the module uses `/bin/sh` command lines, a POSIX or compatible shell for `os.system()` and `os.popen()` is required.

**Availability:** Unix, not VxWorks.

The `pipes` module defines the following class:

`class pipes.Template`

An abstraction of a pipeline.

Example:

```
>>> import pipes
>>> t = pipes.Template()
>>> t.append('tr a-z A-Z', '--')
>>> f = t.open('pipefile', 'w')
>>> f.write('hello world')
>>> f.close()
>>> open('pipefile').read()
'HELLO WORLD'
```

# Template Objects

Template objects following methods:

`Template.reset()`

Restore a pipeline template to its initial state.

`Template.clone()`

Return a new, equivalent, pipeline template.

`Template.debug(flag)`

If *flag* is true, turn debugging on. Otherwise, turn debugging off. When debugging is on, commands to be executed are printed, and the shell is given `set -x` command to be more verbose.

`Template.append(cmd, kind)`

Append a new action at the end. The *cmd* variable must be a valid bourne shell command. The *kind* variable consists of two letters.

The first letter can be either of `'-'` (which means the command reads its standard input), `'f'` (which means the commands reads a given file on the command line) or `'.'` (which means the commands reads no input, and hence must be first.)

Similarly, the second letter can be either of `'-'` (which means the command writes to standard output), `'f'` (which means the command writes a file on the command line) or `'.'` (which means the command does not write anything, and hence must be last.)

`Template.prepend(cmd, kind)`

Add a new action at the beginning. See [append\(\)](#) for explanations of the arguments.

Template.open(*file*, *mode*)

Return a file-like object, open to *file*, but read from or written to by the pipeline. Note that only one of 'r', 'w' may be given.

Template.copy(*infile*, *outfile*)

Copy *infile* to *outfile* through the pipe.

# smtpd — SMTP Server

**Source code:** [Lib/smtpd.py](#) [<https://github.com/python/cpython/tree/3.11/Lib/smtpd.py>]

---

This module offers several classes to implement SMTP (email) servers.

*Deprecated since version 3.6, will be removed in version 3.12:* The [smtpd](#) module is deprecated (see [PEP 594](#) [<https://peps.python.org/pep-0594/#smtpd>] for details). The [aiosmtpd](#) [<https://aiosmtpd.readthedocs.io/>] package is a recommended replacement for this module. It is based on [asyncio](#) and provides a more straightforward API.

Several server implementations are present; one is a generic do-nothing implementation, which can be overridden, while the other two offer specific mail-sending strategies.

Additionally the SMTPChannel may be extended to implement very specific interaction behaviour with SMTP clients.

The code supports [RFC 5321](#) [<https://datatracker.ietf.org/doc/html/rfc5321.html>], plus the [RFC 1870](#) [<https://datatracker.ietf.org/doc/html/rfc1870.html>] SIZE and [RFC 6531](#) [<https://datatracker.ietf.org/doc/html/rfc6531.html>] SMTPUTF8 extensions.

**Availability:** not Emscripten, not WASI.

This module does not work or is not available on WebAssembly platforms `wasm32-emscripten` and `wasm32-wasi`. See [WebAssembly platforms](#) for more information.

## SMTPServer Objects

```
class smtpd.SMTPServer(localaddr, remoteaddr,  
data_size_limit=33554432, map=None, enable_SMTPUTF8=False,  
decode_data=False)
```

Create a new **SMTPServer** object, which binds to local address *localaddr*. It will treat *remoteaddr* as an upstream SMTP relay. Both *localaddr* and *remoteaddr* should be a (host, port) tuple. The object inherits from **asyncore.dispatcher**, and so will insert itself into **asyncore**'s event loop on instantiation.

*data\_size\_limit* specifies the maximum number of bytes that will be accepted in a DATA command. A value of `None` or `0` means no limit.

*map* is the socket map to use for connections (an initially empty dictionary is a suitable value). If not specified the **asyncore** global socket map is used.

*enable\_SMTPUTF8* determines whether the SMTPUTF8 extension (as defined in **RFC 6531** [<https://datatracker.ietf.org/doc/html/rfc6531.html>]) should be enabled. The default is `False`. When `True`, SMTPUTF8 is accepted as a parameter to the MAIL command and when present is passed to **process\_message()** in the `kwargs['mail_options']` list. *decode\_data* and *enable\_SMTPUTF8* cannot be set to `True` at the same time.

*decode\_data* specifies whether the data portion of the SMTP transaction should be decoded using UTF-8. When *decode\_data* is `False` (the default), the server advertises the 8BITMIME extension (**RFC 6152** [<https://datatracker.ietf.org/doc/html/rfc6152.html>]), accepts the BODY=8BITMIME parameter to the MAIL command, and when present passes it to **process\_message()** in the `kwargs['mail_options']` list. *decode\_data* and *enable\_SMTPUTF8* cannot be set to `True` at the same time.

```
process_message(peer, mailfrom, rcpttos, data, **kwargs)
```

Raise a **NotImplementedError** exception. Override this in subclasses to do something useful with this

message. Whatever was passed in the constructor as *remoteaddr* will be available as the **`_remoteaddr`** attribute. *peer* is the remote host's address, *mailfrom* is the envelope originator, *rcpttos* are the envelope recipients and *data* is a string containing the contents of the e-mail (which should be in [RFC 5321](https://datatracker.ietf.org/doc/html/rfc5321.html) [https://datatracker.ietf.org/doc/html/rfc5321.html] format).

If the *decode\_data* constructor keyword is set to `True`, the *data* argument will be a unicode string. If it is set to `False`, it will be a bytes object.

*kwargs* is a dictionary containing additional information. It is empty if *decode\_data*=`True` was given as an init argument, otherwise it contains the following keys:

*mail\_options*:

a list of all received parameters to the MAIL command (the elements are uppercase strings; example: [ 'BODY=8BITMIME', 'SMTPUTF8' ]).

*rcpt\_options*:

same as *mail\_options* but for the RCPT command. Currently no RCPT TO options are supported, so for now this will always be an empty list.

Implementations of *process\_message* should use the **`**kwargs`** signature to accept arbitrary keyword arguments, since future feature enhancements may add keys to the *kwargs* dictionary.

Return `None` to request a normal 250 Ok response; otherwise return the desired response string in [RFC 5321](https://datatracker.ietf.org/doc/html/rfc5321.html) [https://datatracker.ietf.org/doc/html/rfc5321.html] format.

`channel_class`

Override this in subclasses to use a custom [SMTPChannel](#) for managing SMTP clients.

*New in version 3.4:* The `map` constructor argument.

*Changed in version 3.5:* `localaddr` and `remoteaddr` may now contain IPv6 addresses.

*New in version 3.5:* The `decode_data` and `enable_SMTPUTF8` constructor parameters, and the `kwargs` parameter to [process\\_message\(\)](#) when `decode_data` is `False`.

*Changed in version 3.6:* `decode_data` is now `False` by default.

## DebuggingServer Objects

`class smtpd.DebuggingServer(localaddr, remoteaddr)`

Create a new debugging server. Arguments are as per [SMTPServer](#). Messages will be discarded, and printed on stdout.

## PureProxy Objects

`class smtpd.PureProxy(localaddr, remoteaddr)`

Create a new pure proxy server. Arguments are as per [SMTPServer](#). Everything will be relayed to `remoteaddr`. Note that running this has a good chance to make you into an open relay, so please be careful.

## SMTPChannel Objects

`class smtpd.SMTPChannel(server, conn, addr,  
data_size_limit=33554432, map=None, enable_SMTPUTF8=False,  
decode_data=False)`

Create a new [SMTPChannel](#) object which manages the communication between the server and a single SMTP client.

*conn* and *addr* are as per the instance variables described below.

*data\_size\_limit* specifies the maximum number of bytes that will be accepted in a `DATA` command. A value of `None` or `0` means no limit.

*enable\_SMTPUTF8* determines whether the `SMTPUTF8` extension (as defined in [RFC 6531](https://datatracker.ietf.org/doc/html/rfc6531.html) [https://datatracker.ietf.org/doc/html/rfc6531.html]) should be enabled. The default is `False`. *decode\_data* and *enable\_SMTPUTF8* cannot be set to `True` at the same time.

A dictionary can be specified in *map* to avoid using a global socket map.

*decode\_data* specifies whether the data portion of the SMTP transaction should be decoded using UTF-8. The default is `False`. *decode\_data* and *enable\_SMTPUTF8* cannot be set to `True` at the same time.

To use a custom SMTPChannel implementation you need to override the `SMTPServer.channel_class` of your `SMTPServer`.

*Changed in version 3.5:* The *decode\_data* and *enable\_SMTPUTF8* parameters were added.

*Changed in version 3.6:* *decode\_data* is now `False` by default.

The `SMTPChannel` has the following instance variables:

*smtp\_server*

Holds the `SMTPServer` that spawned this channel.

*conn*

Holds the socket object connecting to the client.

*addr*

Holds the address of the client, the second value returned by `socket.accept`

received\_lines

Holds a list of the line strings (decoded using UTF-8) received from the client. The lines have their `"\r\n"` line ending translated to `"\n"`.

smtp\_state

Holds the current state of the channel. This will be either **COMMAND** initially and then **DATA** after the client sends a "DATA" line.

seen\_greeting

Holds a string containing the greeting sent by the client in its "HELO".

mailfrom

Holds a string containing the address identified in the "MAIL FROM:" line from the client.

rcpttos

Holds a list of strings containing the addresses identified in the "RCPT TO:" lines from the client.

received\_data

Holds a string containing all of the data sent by the client during the DATA state, up to but not including the terminating `"\r\n.\r\n"`.

fqdn

Holds the fully qualified domain name of the server as returned by `socket.getfqdn()`.

peer

Holds the name of the client peer as returned by `conn.getpeername()` where `conn` is `conn`.

The **SMTPChannel** operates by invoking methods named `smtp_<command>` upon reception of a command line from

the client. Built into the base `SMTPChannel` class are methods for handling the following commands (and responding to them appropriately):

### Action taken

---

**HELO** Accepts the greeting from the client and stores it in `seen_greeting`. Sets server to base command mode.

---

**EHLO** Accepts the greeting from the client and stores it in `seen_greeting`. Sets server to extended command mode.

---

**NOOP** No action.

---

**QUIT** Closes the connection cleanly.

---

**MAIL** Accepts the “MAIL FROM:” syntax and stores the supplied address as `mailfrom`. In extended command mode, accepts the **RFC 1870** SIZE attribute and responds appropriately based on the value of `data_size_limit`.

---

**RCPT** Accepts the “RCPT TO:” syntax and stores the supplied addresses in the `rcpttos` list.

---

**SEND** Resets the `mailfrom`, `rcpttos`, and `received_data`, but not the greeting.

---

**DATA** Sets the internal state to **DATA** and stores remaining lines from the client in `received_data` until the terminator “\r\n.\r\n” is received.

---

**HELP** Prints minimal information on command syntax

---

**RETRY** Prints code 252 (the server doesn’t know if the address is valid)

---

**UNKNOWN** Prints that the command is not implemented.

---

# sndhdr — Determine type of sound file

**Source code:** [Lib/sndhdr.py](#) [<https://github.com/python/cpython/tree/3.11/Lib/sndhdr.py>]

*Deprecated since version 3.11, will be removed in version 3.13:* The **sndhdr** module is deprecated (see [PEP 594](#) [<https://peps.python.org/pep-0594/#sndhdr>] for details and alternatives).

---

The **sndhdr** provides utility functions which attempt to determine the type of sound data which is in a file. When these functions are able to determine what type of sound data is stored in a file, they return a **namedtuple()**, containing five attributes: (*filetype*, *framerate*, *nchannels*, *nframes*, *sampwidth*). The value for *type* indicates the data type and will be one of the strings 'aifc', 'aiff', 'au', 'hcom', 'sndr', 'sndt', 'voc', 'wav', '8svx', 'sb', 'ub', or 'ul'. The *sampling\_rate* will be either the actual value or 0 if unknown or difficult to decode. Similarly, *channels* will be either the number of channels or 0 if it cannot be determined or if the value is difficult to decode. The value for *frames* will be either the number of frames or -1. The last item in the tuple, *bits\_per\_sample*, will either be the sample size in bits or 'A' for A-LAW or 'U' for u-LAW.

**sndhdr.what(filename)**

Determines the type of sound data stored in the file *filename* using **whathdr()**. If it succeeds, returns a namedtuple as described above, otherwise `None` is returned.

*Changed in version 3.5:* Result changed from a tuple to a namedtuple.

**sndhdr.whathdr(filename)**

Determines the type of sound data stored in a file based on the file header. The name of the file is given by *filename*. This function returns a namedtuple as described above on success, or `None`.

*Changed in version 3.5:* Result changed from a tuple to a namedtuple.

The following sound header types are recognized, as listed below with the return value from `whathdr()`: and `what()`:

### Sound header format

---

Compressed Audio Interchange Files

---

Audio Interchange Files

---

Aiff Files

---

HC-OM Files

---

Sndtool Sound Files

---

Creative Labs Audio Files

---

Waveform Audio File Format Files

---

8-Bit Sampled Voice Files

---

Signed Byte Audio Data Files

---

U-Buffer Files

---

uLAW Audio Files

---

### sndhdr.tests

A list of functions performing the individual tests. Each function takes two arguments: the byte-stream and an open file-like object. When `what()` is called with a byte-stream, the file-like object will be `None`.

The test function should return a string describing the image type if the test succeeded, or `None` if it failed.

Example:

```
>>> import sndhdr
>>> imghdr.what('bass.wav')
'wav'
>>> imghdr.whathdr('bass.wav')
'wav'
```

# spwd — The shadow password database

*Deprecated since version 3.11, will be removed in version 3.13:* The **spwd** module is deprecated (see [PEP 594](https://peps.python.org/pep-0594/#spwd) [https://peps.python.org/pep-0594/#spwd] for details and alternatives).

---

This module provides access to the Unix shadow password database. It is available on various Unix versions.

**Availability:** not Emscripten, not WASI.

This module does not work or is not available on WebAssembly platforms `wasm32-emscripten` and `wasm32-wasi`. See [WebAssembly platforms](#) for more information.

You must have enough privileges to access the shadow password database (this usually means you have to be root).

Shadow password database entries are reported as a tuple-like object, whose attributes correspond to the members of the `spwd` structure (Attribute field below, see `<shadow.h>`):

Member
<code>sp_namp</code>
<code>sp_pwdp</code>
<code>sp_lstchg</code>
<code>sp_min</code>
<code>sp_max</code>
<code>sp_warn</code>
<code>sp_inact</code>
<code>sp_expire</code>
<code>sp_reserved</code>

The `sp_namp` and `sp_pwdp` items are strings, all others are integers.

**KeyError** is raised if the entry asked for cannot be found.

The following functions are defined:

`spwd.getspnam(name)`

Return the shadow password database entry for the given user name.

*Changed in version 3.6:* Raises a **PermissionError** instead of **KeyError** if the user doesn't have privileges.

`spwd.getspall()`

Return a list of all available shadow password database entries, in arbitrary order.

**See also**

**Module** **grp**

An interface to the group database, similar to this.

**Module** **pwd**

An interface to the normal password database, similar to this.

# sunau — Read and write Sun AU files

**Source code:** [Lib/sunau.py](https://github.com/python/cpython/tree/3.11/Lib/sunau.py) [https://github.com/python/cpython/tree/3.11/Lib/sunau.py]

*Deprecated since version 3.11, will be removed in version 3.13:* The **sunau** module is deprecated (see [PEP 594](https://peps.python.org/pep-0594/#sunau) [https://peps.python.org/pep-0594/#sunau] for details).

---

The **sunau** module provides a convenient interface to the Sun AU sound format. Note that this module is interface-compatible with the modules **aifc** and **wave**.

An audio file consists of a header followed by the data. The fields of the header are:

## Fields

<b>File type</b>	File type, e.g. ".snd".
<b>Size of header</b>	Size of header, including info, in bytes.
<b>Physical size</b>	Physical size of the data, in bytes.
<b>Encoding</b>	Encoding how the audio samples are encoded.
<b>Sample rate</b>	Sample rate.
<b>Number of channels</b>	Number of channels in the samples.
<b>ASCII string</b>	ASCII string giving a description of the audio file (padded with null bytes).

Apart from the info field, all header fields are 4 bytes in size. They are all 32-bit unsigned integers encoded in big-endian byte order.

The **sunau** module defines the following functions:

**sunau.open(file, mode)**

If *file* is a string, open the file by that name, otherwise treat it as a seekable file-like object. *mode* can be any of

'r'

Read only mode.

'w'

Write only mode.

Note that it does not allow read/write files.

A *mode* of 'r' returns an **AU\_read** object, while a *mode* of 'w' or 'wb' returns an **AU\_write** object.

The **sunau** module defines the following exception:

*exception* sunau.Error

An error raised when something is impossible because of Sun AU specs or implementation deficiency.

The **sunau** module defines the following data items:

sunau.AUDIO\_FILE\_MAGIC

An integer every valid Sun AU file begins with, stored in big-endian form. This is the string `.snd` interpreted as an integer.

sunau.AUDIO\_FILE\_ENCODING\_MULAW\_8

sunau.AUDIO\_FILE\_ENCODING\_LINEAR\_8

sunau.AUDIO\_FILE\_ENCODING\_LINEAR\_16

sunau.AUDIO\_FILE\_ENCODING\_LINEAR\_24

sunau.AUDIO\_FILE\_ENCODING\_LINEAR\_32

sunau.AUDIO\_FILE\_ENCODING\_ALAW\_8

Values of the encoding field from the AU header which are supported by this module.

sunau.AUDIO\_FILE\_ENCODING\_FLOAT

sunau.AUDIO\_FILE\_ENCODING\_DOUBLE

sunau.AUDIO\_FILE\_ENCODING\_ADPCM\_G721

sunau.AUDIO\_FILE\_ENCODING\_ADPCM\_G722

sunau.AUDIO\_FILE\_ENCODING\_ADPCM\_G723\_3

sunau.AUDIO\_FILE\_ENCODING\_ADPCM\_G723\_5

Additional known values of the encoding field from the AU header, but which are not supported by this module.

## AU\_read Objects

AU\_read objects, as returned by `open()` above, have the following methods:

`AU_read.close()`

Close the stream, and make the instance unusable. (This is called automatically on deletion.)

`AU_read.getnchannels()`

Returns number of audio channels (1 for mono, 2 for stereo).

`AU_read.getsampwidth()`

Returns sample width in bytes.

`AU_read.getframerate()`

Returns sampling frequency.

`AU_read.getnframes()`

Returns number of audio frames.

`AU_read.getcomptype()`

Returns compression type. Supported compression types are 'ULAW', 'ALAW' and 'NONE'.

`AU_read.getcompname()`

Human-readable version of `getcomptype()`. The supported types have the respective names 'CCITT G.711 u-law', 'CCITT G.711 A-law' and 'not compressed'.

`AU_read.getparams()`

Returns a `namedtuple()` (nchannels, sampwidth,

`framerate, nframes, comptype, compname)`, equivalent to output of the **`get*()`** methods.

**`AU_read.readframes(n)`**

Reads and returns at most *n* frames of audio, as a **`bytes`** object. The data will be returned in linear format. If the original data is in u-LAW format, it will be converted.

**`AU_read.rewind()`**

Rewind the file pointer to the beginning of the audio stream.

The following two methods define a term “position” which is compatible between them, and is otherwise implementation dependent.

**`AU_read.setpos(pos)`**

Set the file pointer to the specified position. Only values returned from **`tell()`** should be used for *pos*.

**`AU_read.tell()`**

Return current file pointer position. Note that the returned value has nothing to do with the actual position in the file.

The following two functions are defined for compatibility with the **`aifc`**, and don’t do anything interesting.

**`AU_read.getmarkers()`**

Returns `None`.

**`AU_read.getmark(id)`**

Raise an error.

## AU\_write Objects

AU\_write objects, as returned by **`open()`** above, have the following methods:

`AU_write.setnchannels(n)`

Set the number of channels.

`AU_write.setsampwidth(n)`

Set the sample width (in bytes.)

*Changed in version 3.4:* Added support for 24-bit samples.

`AU_write.setframerate(n)`

Set the frame rate.

`AU_write.setnframes(n)`

Set the number of frames. This can be later changed, when and if more frames are written.

`AU_write.setcomptype(type, name)`

Set the compression type and description. Only 'NONE' and 'ULAW' are supported on output.

`AU_write.setparams(tuple)`

The *tuple* should be (*nchannels*, *sampwidth*, *framerate*, *nframes*, *comptype*, *compname*), with values valid for the **set\*()** methods. Set all parameters.

`AU_write.tell()`

Return current position in the file, with the same disclaimer for the [AU\\_read.tell\(\)](#) and [AU\\_read.setpos\(\)](#) methods.

`AU_write.writeframesraw(data)`

Write audio frames, without correcting *nframes*.

*Changed in version 3.4:* Any [bytes-like object](#) is now accepted.

`AU_write.writeframes(data)`

Write audio frames and make sure *nframes* is correct.

*Changed in version 3.4:* Any [bytes-like object](#) is now accepted.

`AU_write.close()`

Make sure *nframes* is correct, and close the file.

This method is called upon deletion.

Note that it is invalid to set any parameters after calling **`writeframes()`** or **`writeframesraw()`**.

# telnetlib — Telnet client

**Source code:** [Lib/telnetlib.py](https://github.com/python/cpython/tree/3.11/Lib/telnetlib.py) [https://github.com/python/cpython/tree/3.11/Lib/telnetlib.py]

*Deprecated since version 3.11, will be removed in version 3.13:* The **telnetlib** module is deprecated (see [PEP 594](https://peps.python.org/pep-0594/#telnetlib) [https://peps.python.org/pep-0594/#telnetlib] for details and alternatives).

---

The **telnetlib** module provides a **Telnet** class that implements the Telnet protocol. See [RFC 854](https://datatracker.ietf.org/doc/html/rfc854.html) [https://datatracker.ietf.org/doc/html/rfc854.html] for details about the protocol. In addition, it provides symbolic constants for the protocol characters (see below), and for the telnet options. The symbolic names of the telnet options follow the definitions in `arpa/telnet.h`, with the leading `TELOPT_` removed. For symbolic names of options which are traditionally not included in `arpa/telnet.h`, see the module source itself.

The symbolic constants for the telnet commands are: IAC, DONT, DO, WONT, WILL, SE (Subnegotiation End), NOP (No Operation), DM (Data Mark), BRK (Break), IP (Interrupt process), AO (Abort output), AYT (Are You There), EC (Erase Character), EL (Erase Line), GA (Go Ahead), SB (Subnegotiation Begin).

**Availability:** not Emscripten, not WASI.

This module does not work or is not available on WebAssembly platforms `wasm32-emsripten` and `wasm32-wasi`. See [WebAssembly platforms](#) for more information.

`class telnetlib.Telnet(host=None, port=0[, timeout])`

**Telnet** represents a connection to a Telnet server. The instance is initially not connected by default; the **open()** method must be used to establish a connection. Alternatively, the host name and optional port number can be passed to the constructor too, in which case the connection to the server

will be established before the constructor returns. The optional *timeout* parameter specifies a timeout in seconds for blocking operations like the connection attempt (if not specified, the global default timeout setting will be used).

Do not reopen an already connected instance.

This class has many `read_*()` methods. Note that some of them raise `EOFError` when the end of the connection is read, because they can return an empty string for other reasons. See the individual descriptions below.

A `Telnet` object is a context manager and can be used in a `with` statement. When the `with` block ends, the `close()` method is called:

```
>>> from telnetlib import Telnet
>>> with Telnet('localhost', 23) as tn:
...     tn.interact()
...
```

*Changed in version 3.6:* Context manager support added

## See also

**RFC 854** [<https://datatracker.ietf.org/doc/html/rfc854.html>] - **Telnet Protocol Specification**

Definition of the Telnet protocol.

# Telnet Objects

`Telnet` instances have the following methods:

`Telnet.read_until(expected, timeout=None)`

Read until a given byte string, *expected*, is encountered or until *timeout* seconds have passed.

When no match is found, return whatever is available instead, possibly empty bytes. Raise `EOFError` if the connection is

closed and no cooked data is available.

`Telnet.read_all()`

Read all data until EOF as bytes; block until connection closed.

`Telnet.read_some()`

Read at least one byte of cooked data unless EOF is hit. Return `b''` if EOF is hit. Block if no data is immediately available.

`Telnet.read_very_eager()`

Read everything that can be without blocking in I/O (eager).

Raise `EOFError` if connection closed and no cooked data available. Return `b''` if no cooked data available otherwise. Do not block unless in the midst of an IAC sequence.

`Telnet.read_eager()`

Read readily available data.

Raise `EOFError` if connection closed and no cooked data available. Return `b''` if no cooked data available otherwise. Do not block unless in the midst of an IAC sequence.

`Telnet.read_lazy()`

Process and return data already in the queues (lazy).

Raise `EOFError` if connection closed and no data available. Return `b''` if no cooked data available otherwise. Do not block unless in the midst of an IAC sequence.

`Telnet.read_very_lazy()`

Return any data available in the cooked queue (very lazy).

Raise `EOFError` if connection closed and no data available. Return `b''` if no cooked data available otherwise. This

method never blocks.

`Telnet.read_sb_data()`

Return the data collected between a SB/SE pair (suboption begin/end). The callback should access these data when it was invoked with a SE command. This method never blocks.

`Telnet.open(host, port=0[, timeout])`

Connect to a host. The optional second argument is the port number, which defaults to the standard Telnet port (23). The optional *timeout* parameter specifies a timeout in seconds for blocking operations like the connection attempt (if not specified, the global default timeout setting will be used).

Do not try to reopen an already connected instance.

Raises an [auditing event](#) `telnetlib.Telnet.open` with arguments `self`, `host`, `port`.

`Telnet.msg(msg, *args)`

Print a debug message when the debug level is `> 0`. If extra arguments are present, they are substituted in the message using the standard string formatting operator.

`Telnet.set_debuglevel(debuglevel)`

Set the debug level. The higher the value of *debuglevel*, the more debug output you get (on `sys.stdout`).

`Telnet.close()`

Close the connection.

`Telnet.get_socket()`

Return the socket object used internally.

`Telnet.fileno()`

Return the file descriptor of the socket object used internally.

`Telnet.write(buffer)`

Write a byte string to the socket, doubling any IAC characters. This can block if the connection is blocked. May raise **OSError** if the connection is closed.

Raises an **auditing event** `telnetlib.Telnet.write` with arguments `self, buffer`.

*Changed in version 3.3:* This method used to raise **socket.error**, which is now an alias of **OSError**.

`Telnet.interact()`

Interaction function, emulates a very dumb Telnet client.

`Telnet.mt_interact()`

Multithreaded version of **interact()**.

`Telnet.expect(list, timeout=None)`

Read until one from a list of a regular expressions matches.

The first argument is a list of regular expressions, either compiled (**regex objects**) or uncompiled (byte strings). The optional second argument is a timeout, in seconds; the default is to block indefinitely.

Return a tuple of three items: the index in the list of the first regular expression that matches; the match object returned; and the bytes read up till and including the match.

If end of file is found and no bytes were read, raise **EOFError**. Otherwise, when nothing matches, return `(-1, None, data)` where *data* is the bytes received so far (may be empty bytes if a timeout happened).

If a regular expression ends with a greedy match (such as `. *`) or if more than one expression can match the same input, the results are non-deterministic, and may depend on the I/O timing.

Telnet.set\_option\_negotiation\_callback(*callback*)

Each time a telnet option is read on the input flow, this *callback* (if set) is called with the following parameters: `callback(telnet socket, command (DO/DONT/WILL/WONT), option)`. No other action is done afterwards by telnetlib.

## Telnet Example

A simple example illustrating typical use:

```
import getpass
import telnetlib

HOST = "localhost"
user = input("Enter your remote account: ")
password = getpass.getpass()

tn = telnetlib.Telnet(HOST)

tn.read_until(b"login: ")
tn.write(user.encode('ascii') + b"\n")
if password:
    tn.read_until(b"Password: ")
    tn.write(password.encode('ascii') + b"\n")

tn.write(b"ls\n")
tn.write(b"exit\n")

print(tn.read_all().decode('ascii'))
```

# uu — Encode and decode uuencode files

**Source code:** [Lib/uu.py](https://github.com/python/cpython/tree/3.11/Lib/uu.py) [https://github.com/python/cpython/tree/3.11/Lib/uu.py]

*Deprecated since version 3.11, will be removed in version 3.13:* The **uu** module is deprecated (see [PEP 594](https://peps.python.org/pep-0594/#uu-and-the-uu-encoding) [https://peps.python.org/pep-0594/#uu-and-the-uu-encoding] for details). **base64** is a modern alternative.

---

This module encodes and decodes files in uuencode format, allowing arbitrary binary data to be transferred over ASCII-only connections. Wherever a file argument is expected, the methods accept a file-like object. For backwards compatibility, a string containing a pathname is also accepted, and the corresponding file will be opened for reading and writing; the pathname `'-'` is understood to mean the standard input or output. However, this interface is deprecated; it's better for the caller to open the file itself, and be sure that, when required, the mode is `'rb'` or `'wb'` on Windows.

This code was contributed by Lance Ellinghouse, and modified by Jack Jansen.

The **uu** module defines the following functions:

```
uu.encode(in_file, out_file, name=None, mode=None, *,  
backtick=False)
```

Uuencode file *in\_file* into file *out\_file*. The uuencoded file will have the header specifying *name* and *mode* as the defaults for the results of decoding the file. The default defaults are taken from *in\_file*, or `'-'` and `0o666` respectively. If *backtick* is true, zeros are represented by `'`'` instead of spaces.

*Changed in version 3.7:* Added the *backtick* parameter.

`uu.decode(in_file, out_file=None, mode=None, quiet=False)`

This call decodes uuencoded file *in\_file* placing the result on file *out\_file*. If *out\_file* is a pathname, *mode* is used to set the permission bits if the file must be created. Defaults for *out\_file* and *mode* are taken from the uuencode header. However, if the file specified in the header already exists, a `uu.Error` is raised.

`decode()` may print a warning to standard error if the input was produced by an incorrect uuencoder and Python could recover from that error. Setting *quiet* to a true value silences this warning.

*exception* `uu.Error`

Subclass of `Exception`, this can be raised by `uu.decode()` under various situations, such as described above, but also including a badly formatted header, or truncated input file.

**See also**

**Module** `binascii`

Support module containing ASCII-to-binary and binary-to-ASCII conversions.

# **xdrlib** — Encode and decode XDR data

**Source code:** [Lib/xdrlib.py](https://github.com/python/cpython/tree/3.11/Lib/xdrlib.py) [https://github.com/python/cpython/tree/3.11/Lib/xdrlib.py]

*Deprecated since version 3.11, will be removed in version 3.13:* The **xdrlib** module is deprecated (see [PEP 594](https://peps.python.org/pep-0594/#xdrlib) [https://peps.python.org/pep-0594/#xdrlib] for details).

---

The **xdrlib** module supports the External Data Representation Standard as described in [RFC 1014](https://datatracker.ietf.org/doc/html/rfc1014.html) [https://datatracker.ietf.org/doc/html/rfc1014.html], written by Sun Microsystems, Inc. June 1987. It supports most of the data types described in the RFC.

The **xdrlib** module defines two classes, one for packing variables into XDR representation, and another for unpacking from XDR representation. There are also two exception classes.

`class xdrlib.Packer`

**Packer** is the class for packing data into XDR representation. The **Packer** class is instantiated with no arguments.

`class xdrlib.Unpacker(data)`

`Unpacker` is the complementary class which unpacks XDR data values from a string buffer. The input buffer is given as *data*.

[RFC 1014](https://datatracker.ietf.org/doc/html/rfc1014.html) [https://datatracker.ietf.org/doc/html/rfc1014.html] - **XDR: External Data Representation Standard**

This RFC defined the encoding of data which was XDR at

the time this module was originally written. It has apparently been obsoleted by [RFC 1832](https://datatracker.ietf.org/doc/html/rfc1832.html) [https://datatracker.ietf.org/doc/html/rfc1832.html].

[RFC 1832](https://datatracker.ietf.org/doc/html/rfc1832.html) [https://datatracker.ietf.org/doc/html/rfc1832.html] - **XDR: External Data Representation Standard**

Newer RFC that provides a revised definition of XDR.

## Packer Objects

**Packer** instances have the following methods:

`Packer.get_buffer()`

Returns the current pack buffer as a string.

`Packer.reset()`

Resets the pack buffer to the empty string.

In general, you can pack any of the most common XDR data types by calling the appropriate `pack_type()` method. Each method takes a single argument, the value to pack. The following simple data type packing methods are supported: **`pack_uint()`**, **`pack_int()`**, **`pack_enum()`**, **`pack_bool()`**, **`pack_uhyper()`**, and **`pack_hyper()`**.

`Packer.pack_float(value)`

Packs the single-precision floating point number *value*.

`Packer.pack_double(value)`

Packs the double-precision floating point number *value*.

The following methods support packing strings, bytes, and opaque data:

`Packer.pack_fstring(n, s)`

Packs a fixed length string, *s*. *n* is the length of the string but it is *not* packed into the data buffer. The string is padded with

null bytes if necessary to guaranteed 4 byte alignment.

`Packer.pack_fopaque(n, data)`

Packs a fixed length opaque data stream, similarly to `pack_fstring()`.

`Packer.pack_string(s)`

Packs a variable length string, *s*. The length of the string is first packed as an unsigned integer, then the string data is packed with `pack_fstring()`.

`Packer.pack_opaque(data)`

Packs a variable length opaque data string, similarly to `pack_string()`.

`Packer.pack_bytes(bytes)`

Packs a variable length byte stream, similarly to `pack_string()`.

The following methods support packing arrays and lists:

`Packer.pack_list(list, pack_item)`

Packs a *list* of homogeneous items. This method is useful for lists with an indeterminate size; i.e. the size is not available until the entire list has been walked. For each item in the list, an unsigned integer 1 is packed first, followed by the data value from the list. *pack\_item* is the function that is called to pack the individual item. At the end of the list, an unsigned integer 0 is packed.

For example, to pack a list of integers, the code might appear like this:

```
import xdrllib
p = xdrllib.Packer()
p.pack_list([1, 2, 3], p.pack_int)
```

`Packer.pack_farray(n, array, pack_item)`

Packs a fixed length list (*array*) of homogeneous items. *n* is the length of the list; it is *not* packed into the buffer, but a **ValueError** exception is raised if `len(array)` is not equal to *n*. As above, *pack\_item* is the function used to pack each element.

`Packer.pack_array(list, pack_item)`

Packs a variable length *list* of homogeneous items. First, the length of the list is packed as an unsigned integer, then each element is packed as in `pack_farray()` above.

## Unpacker Objects

The **Unpacker** class offers the following methods:

`Unpacker.reset(data)`

Resets the string buffer with the given *data*.

`Unpacker.get_position()`

Returns the current unpack position in the data buffer.

`Unpacker.set_position(position)`

Sets the data buffer unpack position to *position*. You should be careful about using `get_position()` and `set_position()`.

`Unpacker.get_buffer()`

Returns the current unpack data buffer as a string.

`Unpacker.done()`

Indicates unpack completion. Raises an **Error** exception if all of the data has not been unpacked.

In addition, every data type that can be packed with a **Packer**, can be unpacked with an **Unpacker**. Unpacking methods are of

the form `unpack_type()`, and take no arguments. They return the unpacked object.

`Unpacker.unpack_float()`

Unpacks a single-precision floating point number.

`Unpacker.unpack_double()`

Unpacks a double-precision floating point number, similarly to `unpack_float()`.

In addition, the following methods unpack strings, bytes, and opaque data:

`Unpacker.unpack_fstring(n)`

Unpacks and returns a fixed length string. *n* is the number of characters expected. Padding with null bytes to guaranteed 4 byte alignment is assumed.

`Unpacker.unpack_fopaque(n)`

Unpacks and returns a fixed length opaque data stream, similarly to `unpack_fstring()`.

`Unpacker.unpack_string()`

Unpacks and returns a variable length string. The length of the string is first unpacked as an unsigned integer, then the string data is unpacked with `unpack_fstring()`.

`Unpacker.unpack_opaque()`

Unpacks and returns a variable length opaque data string, similarly to `unpack_string()`.

`Unpacker.unpack_bytes()`

Unpacks and returns a variable length byte stream, similarly to `unpack_string()`.

The following methods support unpacking arrays and lists:

`Unpacker.unpack_list(unpack_item)`

Unpacks and returns a list of homogeneous items. The list is unpacked one element at a time by first unpacking an unsigned integer flag. If the flag is 1, then the item is unpacked and appended to the list. A flag of 0 indicates the end of the list. *unpack\_item* is the function that is called to unpack the items.

`Unpacker.unpack_farray(n, unpack_item)`

Unpacks and returns (as a list) a fixed length array of homogeneous items. *n* is number of list elements to expect in the buffer. As above, *unpack\_item* is the function used to unpack each element.

`Unpacker.unpack_array(unpack_item)`

Unpacks and returns a variable length *list* of homogeneous items. First, the length of the list is unpacked as an unsigned integer, then each element is unpacked as in `unpack_farray()` above.

## Exceptions

Exceptions in this module are coded as class instances:

*exception* `xdrlib.Error`

The base exception class. `Error` has a single public attribute `msg` containing the description of the error.

*exception* `xdrlib.ConversionError`

Class derived from `Error`. Contains no additional instance variables.

Here is an example of how you would catch one of these exceptions:

```
import xdrlib
p = xdrlib.Packer()
try:
```

```
    p.pack_double(8.01)
except xdrlib.ConversionError as instance:
    print('packing the double failed:', instance.msg)
```

# Security Considerations

The following modules have specific security considerations:

- **base64**: [base64 security considerations](https://datatracker.ietf.org/doc/html/rfc4648.html) in **RFC 4648** [https://datatracker.ietf.org/doc/html/rfc4648.html]
- **cgi**: [CGI security considerations](#)
- **hashlib**: all constructors take a “usedforsecurity” keyword-only argument disabling known insecure and blocked algorithms
- **http.server** is not suitable for production use, only implementing basic security checks. See the [security considerations](#).
- **logging**: Logging configuration uses eval()
- **multiprocessing**: [Connection.recv\(\)](#) uses pickle
- **pickle**: [Restricting globals in pickle](#)
- **random** shouldn't be used for security purposes, use **secrets** instead
- **shelve**: [shelve is based on pickle and thus unsuitable for dealing with untrusted sources](#)
- **ssl**: [SSL/TLS security considerations](#)
- **subprocess**: [Subprocess security considerations](#)
- **tempfile**: [mktemp is deprecated due to vulnerability to race conditions](#)
- **xml**: [XML vulnerabilities](#)
- **zipfile**: [maliciously prepared .zip files can cause disk volume exhaustion](#)

The **-I** command line option can be used to run Python in isolated mode. When it cannot be used, the **-P** option or the **PYTHONSAFEPATH** environment variable can be used to not prepend a potentially unsafe path to **sys.path** such as the current directory, the script's directory or an empty string.

# Extending and Embedding the Python Interpreter

This document describes how to write modules in C or C++ to extend the Python interpreter with new modules. Those modules can not only define new functions but also new object types and their methods. The document also describes how to embed the Python interpreter in another application, for use as an extension language. Finally, it shows how to compile and link extension modules so that they can be loaded dynamically (at run time) into the interpreter, if the underlying operating system supports this feature.

This document assumes basic knowledge about Python. For an informal introduction to the language, see [The Python Tutorial](#). [The Python Language Reference](#) gives a more formal definition of the language. [The Python Standard Library](#) documents the existing object types, functions and modules (both built-in and written in Python) that give the language its wide application range.

For a detailed description of the whole Python/C API, see the separate [Python/C API Reference Manual](#).

## Recommended third party tools

This guide only covers the basic tools for creating extensions provided as part of this version of CPython. Third party tools like [Cython](https://cython.org/) [https://cython.org/], [cffi](https://cffi.readthedocs.io) [https://cffi.readthedocs.io], [SWIG](https://www.swig.org) [https://www.swig.org] and [Numba](https://numba.pydata.org/) [https://numba.pydata.org/] offer both simpler and more sophisticated approaches to creating C and C++ extensions for Python.

**See also**

**Python Packaging User Guide: Binary Extensions** [<https://packaging.python.org/guides/packaging-binary-extensions/>]

The Python Packaging User Guide not only covers several available tools that simplify the creation of binary extensions, but also discusses the various reasons why creating an extension module may be desirable in the first place.

## Creating extensions without third party tools

This section of the guide covers creating C and C++ extensions without assistance from third party tools. It is intended primarily for creators of those tools, rather than being a recommended way to create your own C extensions.

## Embedding the CPython runtime in a larger application

Sometimes, rather than creating an extension that runs inside the Python interpreter as the main application, it is desirable to instead embed the CPython runtime inside a larger application. This section covers some of the details involved in doing that successfully.

- 1. Embedding Python in Another Application
  - 1.1. Very High Level Embedding
  - 1.2. Beyond Very High Level Embedding: An overview

  - 1.6. Compiling and Linking under Unix-like systems

# 1. Extending Python with C or C++

It is quite easy to add new built-in modules to Python, if you know how to program in C. Such *extension modules* can do two things that can't be done directly in Python: they can implement new built-in object types, and they can call C library functions and system calls.

To support extensions, the Python API (Application Programmers Interface) defines a set of functions, macros and variables that provide access to most aspects of the Python run-time system. The Python API is incorporated in a C source file by including the header `"Python.h"`.

The compilation of an extension module depends on its intended use as well as on your system setup; details are given in later chapters.

## Note

The C extension interface is specific to CPython, and extension modules do not work on other Python implementations. In many cases, it is possible to avoid writing C extensions and preserve portability to other implementations. For example, if your use case is calling C library functions or system calls, you should consider using the `ctypes` module or the `cffi` [<https://cffi.readthedocs.io/>] library rather than writing custom C code. These modules let you write Python code to interface with C code and are more portable between implementations of Python than writing and compiling a C extension module.

## 1.1. A Simple Example

Let's create an extension module called `spam` (the favorite food of

Monty Python fans...) and let's say we want to create a Python interface to the C library function `system()` [1](#). This function takes a null-terminated character string as argument and returns an integer. We want this function to be callable from Python as follows:

```
>>> import spam
>>> status = spam.system("ls -l")
```

Begin by creating a file `spammodule.c`. (Historically, if a module is called `spam`, the C file containing its implementation is called `spammodule.c`; if the module name is very long, like `spammify`, the module name can be just `spammify.c`.)

The first two lines of our file can be:

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>
```

which pulls in the Python API (you can add a comment describing the purpose of the module and a copyright notice if you like).

## Note

Since Python may define some pre-processor definitions which affect the standard headers on some systems, you *must* include `Python.h` before any standard headers are included.

It is recommended to always define `PY_SSIZE_T_CLEAN` before including `Python.h`. See [Extracting Parameters in Extension Functions](#) for a description of this macro.

All user-visible symbols defined by `Python.h` have a prefix of `Py` or `PY`, except those defined in standard header files. For convenience, and since they are used extensively by the Python interpreter, "`Python.h`" includes a few standard header files: `<stdio.h>`, `<string.h>`, `<errno.h>`, and `<stdlib.h>`. If the latter header file does not exist on your system, it declares the functions `malloc()`, `free()` and `realloc()` directly.

The next thing we add to our module file is the C function that will be called when the Python expression `spam.system(string)` is evaluated (we'll see shortly how it ends up being called):

```
static PyObject *
spam_system(PyObject *self, PyObject *args)
{
    const char *command;
    int sts;

    if (!PyArg_ParseTuple(args, "s", &command))
        return NULL;
    sts = system(command);
    return PyLong_FromLong(sts);
}
```

There is a straightforward translation from the argument list in Python (for example, the single expression `"ls -l"`) to the arguments passed to the C function. The C function always has two arguments, conventionally named *self* and *args*.

The *self* argument points to the module object for module-level functions; for a method it would point to the object instance.

The *args* argument will be a pointer to a Python tuple object containing the arguments. Each item of the tuple corresponds to an argument in the call's argument list. The arguments are Python objects — in order to do anything with them in our C function we have to convert them to C values. The function

**`PyArg_ParseTuple()`** in the Python API checks the argument types and converts them to C values. It uses a template string to determine the required types of the arguments as well as the types of the C variables into which to store the converted values. More about this later.

**`PyArg_ParseTuple()`** returns true (nonzero) if all arguments have the right type and its components have been stored in the variables whose addresses are passed. It returns false (zero) if an invalid argument list was passed. In the latter case it also raises an appropriate exception so the calling function can return `NULL`

immediately (as we saw in the example).

## 1.2. Intermezzo: Errors and Exceptions

An important convention throughout the Python interpreter is the following: when a function fails, it should set an exception condition and return an error value (usually `-1` or a `NULL` pointer). Exception information is stored in three members of the interpreter's thread state. These are `NULL` if there is no exception. Otherwise they are the C equivalents of the members of the Python tuple returned by `sys.exc_info()`. These are the exception type, exception instance, and a traceback object. It is important to know about them to understand how errors are passed around.

The Python API defines a number of functions to set various types of exceptions.

The most common one is `PyErr_SetString()`. Its arguments are an exception object and a C string. The exception object is usually a predefined object like `PyExc_ZeroDivisionError`. The C string indicates the cause of the error and is converted to a Python string object and stored as the “associated value” of the exception.

Another useful function is `PyErr_SetFromErrno()`, which only takes an exception argument and constructs the associated value by inspection of the global variable `errno`. The most general function is `PyErr_SetObject()`, which takes two object arguments, the exception and its associated value. You don't need to `Py_INCREF()` the objects passed to any of these functions.

You can test non-destructively whether an exception has been set with `PyErr_Occurred()`. This returns the current exception object, or `NULL` if no exception has occurred. You normally don't need to call `PyErr_Occurred()` to see whether an error occurred in a function call, since you should be able to tell from the return value.

When a function *f* that calls another function *g* detects that the latter fails, *f* should itself return an error value (usually `NULL` or `-1`). It should *not* call one of the `PyErr_*` functions — one has

already been called by *g.f*'s caller is then supposed to also return an error indication to *its* caller, again *without* calling `PyErr_*`, and so on — the most detailed cause of the error was already reported by the function that first detected it. Once the error reaches the Python interpreter's main loop, this aborts the currently executing Python code and tries to find an exception handler specified by the Python programmer.

(There are situations where a module can actually give a more detailed error message by calling another `PyErr_*` function, and in such cases it is fine to do so. As a general rule, however, this is not necessary, and can cause information about the cause of the error to be lost: most operations can fail for a variety of reasons.)

To ignore an exception set by a function call that failed, the exception condition must be cleared explicitly by calling `PyErr_Clear()`. The only time C code should call `PyErr_Clear()` is if it doesn't want to pass the error on to the interpreter but wants to handle it completely by itself (possibly by trying something else, or pretending nothing went wrong).

Every failing `malloc()` call must be turned into an exception — the direct caller of `malloc()` (or `realloc()`) must call `PyErr_NoMemory()` and return a failure indicator itself. All the object-creating functions (for example, `PyLong_FromLong()`) already do this, so this note is only relevant to those who call `malloc()` directly.

Also note that, with the important exception of `PyArg_ParseTuple()` and friends, functions that return an integer status usually return a positive value or zero for success and `-1` for failure, like Unix system calls.

Finally, be careful to clean up garbage (by making `Py_XDECREF()` or `Py_DECREF()` calls for objects you have already created) when you return an error indicator!

The choice of which exception to raise is entirely yours. There are predeclared C objects corresponding to all built-in Python exceptions, such as `PyExc_ZeroDivisionError`, which you can use directly. Of course, you should choose exceptions wisely —

don't use **PyExc\_TypeError** to mean that a file couldn't be opened (that should probably be **PyExc\_IOError**). If something's wrong with the argument list, the **PyArg\_ParseTuple()** function usually raises **PyExc\_TypeError**. If you have an argument whose value must be in a particular range or must satisfy other conditions, **PyExc\_ValueError** is appropriate.

You can also define a new exception that is unique to your module. For this, you usually declare a static object variable at the beginning of your file:

```
static PyObject *SpamError;
```

and initialize it in your module's initialization function (**PyInit\_spam()**) with an exception object:

```
PyMODINIT_FUNC
PyInit_spam(void)
{
    PyObject *m;

    m = PyModule_Create(&spammodule);
    if (m == NULL)
        return NULL;

    SpamError = PyErr_NewException("spam.error", NULL, NULL);
    Py_XINCREF(SpamError);
    if (PyModule_AddObject(m, "error", SpamError) < 0) {
        Py_XDECREF(SpamError);
        Py_CLEAR(SpamError);
        Py_DECREF(m);
        return NULL;
    }

    return m;
}
```

Note that the Python name for the exception object is **spam.error**. The **PyErr\_NewException()** function may create a class with the base class being **Exception** (unless another class

is passed in instead of `NULL`), described in [Built-in Exceptions](#).

Note also that the **`SpamError`** variable retains a reference to the newly created exception class; this is intentional! Since the exception could be removed from the module by external code, an owned reference to the class is needed to ensure that it will not be discarded, causing **`SpamError`** to become a dangling pointer. Should it become a dangling pointer, C code which raises the exception could cause a core dump or other unintended side effects.

We discuss the use of `PyMODINIT_FUNC` as a function return type later in this sample.

The **`spam.error`** exception can be raised in your extension module using a call to **`PyErr_SetString()`** as shown below:

```
static PyObject *
spam_system(PyObject *self, PyObject *args)
{
    const char *command;
    int sts;

    if (!PyArg_ParseTuple(args, "s", &command))
        return NULL;
    sts = system(command);
    if (sts < 0) {
        PyErr_SetString(SpamError, "System command failed");
        return NULL;
    }
    return PyLong_FromLong(sts);
}
```

## 1.3. Back to the Example

Going back to our example function, you should now be able to understand this statement:

```
if (!PyArg_ParseTuple(args, "s", &command))
    return NULL;
```

It returns `NULL` (the error indicator for functions returning object pointers) if an error is detected in the argument list, relying on the exception set by `PyArg_ParseTuple()`. Otherwise the string value of the argument has been copied to the local variable `command`. This is a pointer assignment and you are not supposed to modify the string to which it points (so in Standard C, the variable `command` should properly be declared as `const char *command`).

The next statement is a call to the Unix function `system()`, passing it the string we just got from `PyArg_ParseTuple()`:

```
sts = system(command);
```

Our `spam.system()` function must return the value of `sts` as a Python object. This is done using the function `PyLong_FromLong()`.

```
return PyLong_FromLong(sts);
```

In this case, it will return an integer object. (Yes, even integers are objects on the heap in Python!)

If you have a C function that returns no useful argument (a function returning void), the corresponding Python function must return `None`. You need this idiom to do so (which is implemented by the `Py_RETURN_NONE` macro):

```
Py_INCREF(Py_None);  
return Py_None;
```

`Py_None` is the C name for the special Python object `None`. It is a genuine Python object rather than a `NULL` pointer, which means “error” in most contexts, as we have seen.

## 1.4. The Module’s Method Table and Initialization Function

I promised to show how `spam.system()` is called from Python programs. First, we need to list its name and address in a “method

table”:

```
static PyMethodDef SpamMethods[] = {
    ...
    {"system", spam_system, METH_VARARGS,
     "Execute a shell command."},
    ...
    {NULL, NULL, 0, NULL}           /* Sentinel */
};
```

Note the third entry (`METH_VARARGS`). This is a flag telling the interpreter the calling convention to be used for the C function. It should normally always be `METH_VARARGS` or `METH_VARARGS | METH_KEYWORDS`; a value of `0` means that an obsolete variant of [PyArg\\_ParseTuple\(\)](#) is used.

When using only `METH_VARARGS`, the function should expect the Python-level parameters to be passed in as a tuple acceptable for parsing via [PyArg\\_ParseTuple\(\)](#); more information on this function is provided below.

The **`METH_KEYWORDS`** bit may be set in the third field if keyword arguments should be passed to the function. In this case, the C function should accept a third `PyObject *` parameter which will be a dictionary of keywords. Use [PyArg\\_ParseTupleAndKeywords\(\)](#) to parse the arguments to such a function.

The method table must be referenced in the module definition structure:

```
static struct PyModuleDef spammodule = {
    PyModuleDef_HEAD_INIT,
    "spam", /* name of module */
    spam_doc, /* module documentation, may be NULL */
    -1, /* size of per-interpreter state of the module
         or -1 if the module keeps state in global namespace */
    SpamMethods
};
```

This structure, in turn, must be passed to the interpreter in the module's initialization function. The initialization function must be named **PyInit\_name()**, where *name* is the name of the module, and should be the only non-static item defined in the module file:

```
PyMODINIT_FUNC
PyInit_spam(void)
{
    return PyModule_Create(&spammodule);
}
```

Note that `PyMODINIT_FUNC` declares the function as `PyObject *` return type, declares any special linkage declarations required by the platform, and for C++ declares the function as `extern "C"`.

When the Python program imports module **spam** for the first time, **PyInit\_spam()** is called. (See below for comments about embedding Python.) It calls **PyModule\_Create()**, which returns a module object, and inserts built-in function objects into the newly created module based upon the table (an array of **PyMethodDef** structures) found in the module definition. **PyModule\_Create()** returns a pointer to the module object that it creates. It may abort with a fatal error for certain errors, or return `NULL` if the module could not be initialized satisfactorily. The init function must return the module object to its caller, so that it then gets inserted into `sys.modules`.

When embedding Python, the **PyInit\_spam()** function is not called automatically unless there's an entry in the **PyImport\_Inittab** table. To add the module to the initialization table, use **PyImport\_AppendInittab()**, optionally followed by an import of the module:

```
int
main(int argc, char *argv[])
{
    wchar_t *program = Py_DecodeLocale(argv[0], NULL);
    if (program == NULL) {
        fprintf(stderr, "Fatal error: cannot decode argv[0]\n");
        exit(1);
    }
    Py_Initialize();
    PyImport_AppendInittab("spam", PyInit_spam);
    Py_Import("spam");
    Py_Finalize();
    return 0;
}
```

```

        exit(1);
    }

    /* Add a built-in module, before Py_Initialize */
    if (PyImport_AppendInittab("spam", PyInit_spam) == -1)
        fprintf(stderr, "Error: could not extend in-built\n");
    exit(1);
}

/* Pass argv[0] to the Python interpreter */
Py_SetProgramName(program);

/* Initialize the Python interpreter.  Required.
   If this step fails, it will be a fatal error. */
Py_Initialize();

/* Optionally import the module; alternatively,
   import can be deferred until the embedded script
   imports it. */
PyObject *pmodule = PyImport_ImportModule("spam");
if (!pmodule) {
    PyErr_Print();
    fprintf(stderr, "Error: could not import module\n");
}

...

PyMem_RawFree(program);
return 0;
}

```

## Note

Removing entries from `sys.modules` or importing compiled modules into multiple interpreters within a process (or following a **fork()** without an intervening **exec()**) can create problems for some extension modules. Extension module authors should exercise caution when initializing internal data structures.

A more substantial example module is included in the Python source distribution as `Modules/xxmodule.c`. This file may be used as a template or simply read as an example.

### Note

Unlike our `spam` example, `xxmodule` uses *multi-phase initialization* (new in Python 3.5), where a `PyModuleDef` structure is returned from `PyInit_spam`, and creation of the module is left to the import machinery. For details on multi-phase initialization, see [PEP 489](https://peps.python.org/pep-0489/) [https://peps.python.org/pep-0489/].

## 1.5. Compilation and Linkage

There are two more things to do before you can use your new extension: compiling and linking it with the Python system. If you use dynamic loading, the details may depend on the style of dynamic loading your system uses; see the chapters about building extension modules (chapter [Building C and C++ Extensions](#)) and additional information that pertains only to building on Windows (chapter [Building C and C++ Extensions on Windows](#)) for more information about this.

If you can't use dynamic loading, or if you want to make your module a permanent part of the Python interpreter, you will have to change the configuration setup and rebuild the interpreter. Luckily, this is very simple on Unix: just place your file (`spammodule.c` for example) in the `Modules/` directory of an unpacked source distribution, add a line to the file `Modules/Setup.local` describing your file:

```
spam spammodule.o
```

and rebuild the interpreter by running **make** in the toplevel directory. You can also run **make** in the `Modules/` subdirectory, but then you must first rebuild `Makefile` there by running '**make Makefile**'. (This is necessary each time you change the `Setup` file.)

If your module requires additional libraries to link with, these can

be listed on the line in the configuration file as well, for instance:

```
spam spammodule.o -lX11
```

## 1.6. Calling Python Functions from C

So far we have concentrated on making C functions callable from Python. The reverse is also useful: calling Python functions from C. This is especially the case for libraries that support so-called “callback” functions. If a C interface makes use of callbacks, the equivalent Python often needs to provide a callback mechanism to the Python programmer; the implementation will require calling the Python callback functions from a C callback. Other uses are also imaginable.

Fortunately, the Python interpreter is easily called recursively, and there is a standard interface to call a Python function. (I won’t dwell on how to call the Python parser with a particular string as input — if you’re interested, have a look at the implementation of the `-c` command line option in `Modules/main.c` from the Python source code.)

Calling a Python function is easy. First, the Python program must somehow pass you the Python function object. You should provide a function (or some other interface) to do this. When this function is called, save a pointer to the Python function object (be careful to `Py_INCREF()` it!) in a global variable — or wherever you see fit. For example, the following function might be part of a module definition:

```
static PyObject *my_callback = NULL;

static PyObject *
my_set_callback(PyObject *dummy, PyObject *args)
{
    PyObject *result = NULL;
    PyObject *temp;

    if (PyArg_ParseTuple(args, "O:set_callback", &temp))
        if (!PyCallable_Check(temp)) {
```

```

        PyErr_SetString(PyExc_TypeError, "parameter
        return NULL;
    }
    Py_XINCRREF(temp);           /* Add a reference to
    Py_XDECREF(my_callback);     /* Dispose of previous
    my_callback = temp;         /* Remember new callba
    /* Boilerplate to return "None" */
    Py_INCREF(Py_None);
    result = Py_None;
}
return result;
}

```

This function must be registered with the interpreter using the **METH\_VARARGS** flag; this is described in section [The Module's Method Table and Initialization Function](#). The **PyArg\_ParseTuple()** function and its arguments are documented in section [Extracting Parameters in Extension Functions](#).

The macros **Py\_XINCRREF()** and **Py\_XDECREF()** increment/decrement the reference count of an object and are safe in the presence of `NULL` pointers (but note that *temp* will not be `NULL` in this context). More info on them in section [Reference Counts](#).

Later, when it is time to call the function, you call the C function **PyObject\_CallObject()**. This function has two arguments, both pointers to arbitrary Python objects: the Python function, and the argument list. The argument list must always be a tuple object, whose length is the number of arguments. To call the Python function with no arguments, pass in `NULL`, or an empty tuple; to call it with one argument, pass a singleton tuple.

**Py\_BuildValue()** returns a tuple when its format string consists of zero or more format codes between parentheses. For example:

```

int arg;
PyObject *arglist;
PyObject *result;
...
arg = 123;

```

```
...
/* Time to call the callback */
arglist = Py_BuildValue("(i)", arg);
result = PyObject_CallObject(my_callback, arglist);
Py_DECREF(arglist);
```

**PyObject\_CallObject()** returns a Python object pointer: this is the return value of the Python function.

**PyObject\_CallObject()** is “reference-count-neutral” with respect to its arguments. In the example a new tuple was created to serve as the argument list, which is **Py\_DECREF()**-ed immediately after the **PyObject\_CallObject()** call.

The return value of **PyObject\_CallObject()** is “new”: either it is a brand new object, or it is an existing object whose reference count has been incremented. So, unless you want to save it in a global variable, you should somehow **Py\_DECREF()** the result, even (especially!) if you are not interested in its value.

Before you do this, however, it is important to check that the return value isn’t NULL. If it is, the Python function terminated by raising an exception. If the C code that called **PyObject\_CallObject()** is called from Python, it should now return an error indication to its Python caller, so the interpreter can print a stack trace, or the calling Python code can handle the exception. If this is not possible or desirable, the exception should be cleared by calling **PyErr\_Clear()**. For example:

```
if (result == NULL)
    return NULL; /* Pass error back */
...use result...
Py_DECREF(result);
```

Depending on the desired interface to the Python callback function, you may also have to provide an argument list to **PyObject\_CallObject()**. In some cases the argument list is also provided by the Python program, through the same interface that specified the callback function. It can then be saved and used in the same manner as the function object. In other cases, you may have to construct a new tuple to pass as the argument list. The simplest

way to do this is to call `Py_BuildValue()`. For example, if you want to pass an integral event code, you might use the following code:

```
PyObject *arglist;
...
arglist = Py_BuildValue("(l)", eventcode);
result = PyObject_CallObject(my_callback, arglist);
Py_DECREF(arglist);
if (result == NULL)
    return NULL; /* Pass error back */
/* Here maybe use the result */
Py_DECREF(result);
```

Note the placement of `Py_DECREF(arglist)` immediately after the call, before the error check! Also note that strictly speaking this code is not complete: `Py_BuildValue()` may run out of memory, and this should be checked.

You may also call a function with keyword arguments by using `PyObject_Call()`, which supports arguments and keyword arguments. As in the above example, we use `Py_BuildValue()` to construct the dictionary.

```
PyObject *dict;
...
dict = Py_BuildValue("{s:i}", "name", val);
result = PyObject_Call(my_callback, NULL, dict);
Py_DECREF(dict);
if (result == NULL)
    return NULL; /* Pass error back */
/* Here maybe use the result */
Py_DECREF(result);
```

## 1.7. Extracting Parameters in Extension Functions

The `PyArg_ParseTuple()` function is declared as follows:

```
int PyArg_ParseTuple(PyObject *arg, const char *format,
```

The *arg* argument must be a tuple object containing an argument list passed from Python to a C function. The *format* argument must be a format string, whose syntax is explained in [Parsing arguments and building values](#) in the Python/C API Reference Manual. The remaining arguments must be addresses of variables whose type is determined by the format string.

Note that while `PyArg_ParseTuple()` checks that the Python arguments have the required types, it cannot check the validity of the addresses of C variables passed to the call: if you make mistakes there, your code will probably crash or at least overwrite random bits in memory. So be careful!

Note that any Python object references which are provided to the caller are *borrowed* references; do not decrement their reference count!

Some example calls:

```
#define PY_SSIZE_T_CLEAN /* Make "s#" use Py_ssize_t rather than int */
#include <Python.h>

int ok;
int i, j;
long k, l;
const char *s;
Py_ssize_t size;

ok = PyArg_ParseTuple(args, ""); /* No arguments */
/* Python call: f() */

ok = PyArg_ParseTuple(args, "s", &s); /* A string */
/* Possible Python call: f('whoops!') */

ok = PyArg_ParseTuple(args, "lls", &k, &l, &s); /* Two ints and a string */
/* Possible Python call: f(1, 2, 'three') */

ok = PyArg_ParseTuple(args, "(ii)s#", &i, &j, &s, &size); /* A pair of ints and a string, whose size is also passed */
```

The *arg* and *format* parameters are identical to those of the `PyArg_ParseTuple()` function. The *kwdict* parameter is the dictionary of keywords received as the third parameter from the Python runtime. The *kwlist* parameter is a NULL-terminated list of strings which identify the parameters; the names are matched with the type information from *format* from left to right. On success, `PyArg_ParseTupleAndKeywords()` returns true, otherwise it returns false and raises an appropriate exception.

## Note

Nested tuples cannot be parsed when using keyword arguments! Keyword parameters passed in which are not present in the *kwlist* will cause `TypeError` to be raised.

Here is an example module which uses keywords, based on an example by Geoff Philbrick ([philbrick@hks.com](mailto:philbrick@hks.com)):

```
#define PY_SSIZE_T_CLEAN /* Make "s#" use Py_ssize_t rather than int */
#include <Python.h>

static PyObject *
keywdarg_parrot(PyObject *self, PyObject *args, PyObject *kwlist)
{
    int voltage;
    const char *state = "a stiff";
    const char *action = "voom";
    const char *type = "Norwegian Blue";

    static char *kwlist[] = {"voltage", "state", "action", "type", NULL};

    if (!PyArg_ParseTupleAndKeywords(args, kwlist, "i|ss",
                                      &voltage, &state, &action, &type))
        return NULL;

    printf("-- This parrot wouldn't %s if you put %i Volts\n", action, voltage);
    printf("-- Lovely plumage, the %s -- It's %s!\n", type, state);
}
```

```

        Py_RETURN_NONE;
    }

static PyMethodDef keywdarg_methods[] = {
    /* The cast of the function is necessary since PyCFu
     * only take two PyObject* parameters, and keywdarg_
     * three.
     */
    {"parrot", (PyCFunction) (void(*) (void))keywdarg_parr
     "Print a lovely skit to standard output."},
    {NULL, NULL, 0, NULL} /* sentinel */
};

static struct PyModuleDef keywdargmodule = {
    PyModuleDef_HEAD_INIT,
    "keywdarg",
    NULL,
    -1,
    keywdarg_methods
};

PyMODINIT_FUNC
PyInit_keywdarg(void)
{
    return PyModule_Create(&keywdargmodule);
}

```

## 1.9. Building Arbitrary Values

This function is the counterpart to [PyArg\\_ParseTuple\(\)](#). It is declared as follows:

```
PyObject *Py_BuildValue(const char *format, ...);
```

It recognizes a set of format units similar to the ones recognized by [PyArg\\_ParseTuple\(\)](#), but the arguments (which are input to the function, not output) must not be pointers, just values. It returns a new Python object, suitable for returning from a C function called from Python.

One difference with `PyArg_ParseTuple()`: while the latter requires its first argument to be a tuple (since Python argument lists are always represented as tuples internally), `Py_BuildValue()` does not always build a tuple. It builds a tuple only if its format string contains two or more format units. If the format string is empty, it returns `None`; if it contains exactly one format unit, it returns whatever object is described by that format unit. To force it to return a tuple of size 0 or one, parenthesize the format string.

Examples (to the left the call, to the right the resulting Python value):

<code>Py_BuildValue("")</code>	<code>None</code>
<code>Py_BuildValue("i", 123)</code>	<code>123</code>
<code>Py_BuildValue("iii", 123, 456, 789)</code>	<code>(123, 456, 789)</code>
<code>Py_BuildValue("s", "hello")</code>	<code>'hello'</code>
<code>Py_BuildValue("y", "hello")</code>	<code>b'hello'</code>
<code>Py_BuildValue("ss", "hello", "world")</code>	<code>('hello', 'world')</code>
<code>Py_BuildValue("s#", "hello", 4)</code>	<code>'hell'</code>
<code>Py_BuildValue("y#", "hello", 4)</code>	<code>b'hell'</code>
<code>Py_BuildValue("()")</code>	<code>()</code>
<code>Py_BuildValue("(i)", 123)</code>	<code>(123,)</code>
<code>Py_BuildValue("(ii)", 123, 456)</code>	<code>(123, 456)</code>
<code>Py_BuildValue("(i,i)", 123, 456)</code>	<code>(123, 456)</code>
<code>Py_BuildValue("[i,i]", 123, 456)</code>	<code>[123, 456]</code>
<code>Py_BuildValue("{s:i,s:i}",                     "abc", 123, "def", 456)</code>	<code>{'abc': 123, 'def': 456}</code>
<code>Py_BuildValue("((ii)(ii))(ii)",                     1, 2, 3, 4, 5, 6)</code>	<code>((1, 2), (3, 4), 5, 6)</code>

## 1.10. Reference Counts

In languages like C or C++, the programmer is responsible for dynamic allocation and deallocation of memory on the heap. In C, this is done using the functions `malloc()` and `free()`. In C++, the operators `new` and `delete` are used with essentially the same meaning and we'll restrict the following discussion to the C case.

Every block of memory allocated with `malloc()` should

eventually be returned to the pool of available memory by exactly one call to **free()**. It is important to call **free()** at the right time. If a block's address is forgotten but **free()** is not called for it, the memory it occupies cannot be reused until the program terminates. This is called a *memory leak*. On the other hand, if a program calls **free()** for a block and then continues to use the block, it creates a conflict with re-use of the block through another **malloc()** call. This is called *using freed memory*. It has the same bad consequences as referencing uninitialized data — core dumps, wrong results, mysterious crashes.

Common causes of memory leaks are unusual paths through the code. For instance, a function may allocate a block of memory, do some calculation, and then free the block again. Now a change in the requirements for the function may add a test to the calculation that detects an error condition and can return prematurely from the function. It's easy to forget to free the allocated memory block when taking this premature exit, especially when it is added later to the code. Such leaks, once introduced, often go undetected for a long time: the error exit is taken only in a small fraction of all calls, and most modern machines have plenty of virtual memory, so the leak only becomes apparent in a long-running process that uses the leaking function frequently. Therefore, it's important to prevent leaks from happening by having a coding convention or strategy that minimizes this kind of errors.

Since Python makes heavy use of **malloc()** and **free()**, it needs a strategy to avoid memory leaks as well as the use of freed memory. The chosen method is called *reference counting*. The principle is simple: every object contains a counter, which is incremented when a reference to the object is stored somewhere, and which is decremented when a reference to it is deleted. When the counter reaches zero, the last reference to the object has been deleted and the object is freed.

An alternative strategy is called *automatic garbage collection*. (Sometimes, reference counting is also referred to as a garbage collection strategy, hence my use of “automatic” to distinguish the two.) The big advantage of automatic garbage collection is that the user doesn't need to call **free()** explicitly. (Another claimed

advantage is an improvement in speed or memory usage — this is no hard fact however.) The disadvantage is that for C, there is no truly portable automatic garbage collector, while reference counting can be implemented portably (as long as the functions `malloc()` and `free()` are available — which the C Standard guarantees). Maybe some day a sufficiently portable automatic garbage collector will be available for C. Until then, we'll have to live with reference counts.

While Python uses the traditional reference counting implementation, it also offers a cycle detector that works to detect reference cycles. This allows applications to not worry about creating direct or indirect circular references; these are the weakness of garbage collection implemented using only reference counting. Reference cycles consist of objects which contain (possibly indirect) references to themselves, so that each object in the cycle has a reference count which is non-zero. Typical reference counting implementations are not able to reclaim the memory belonging to any objects in a reference cycle, or referenced from the objects in the cycle, even though there are no further references to the cycle itself.

The cycle detector is able to detect garbage cycles and can reclaim them. The `gc` module exposes a way to run the detector (the `collect()` function), as well as configuration interfaces and the ability to disable the detector at runtime.

### 1.10.1. Reference Counting in Python

There are two macros, `Py_INCREF(x)` and `Py_DECREF(x)`, which handle the incrementing and decrementing of the reference count. `Py_DECREF()` also frees the object when the count reaches zero. For flexibility, it doesn't call `free()` directly — rather, it makes a call through a function pointer in the object's *type object*. For this purpose (and others), every object also contains a pointer to its type object.

The big question now remains: when to use `Py_INCREF(x)` and `Py_DECREF(x)`? Let's first introduce some terms. Nobody “owns” an object; however, you can *own a reference* to an object. An object's

reference count is now defined as the number of owned references to it. The owner of a reference is responsible for calling `Py_DECREF()` when the reference is no longer needed. Ownership of a reference can be transferred. There are three ways to dispose of an owned reference: pass it on, store it, or call `Py_DECREF()`. Forgetting to dispose of an owned reference creates a memory leak.

It is also possible to *borrow* a reference to an object. The borrower of a reference should not call `Py_DECREF()`. The borrower must not hold on to the object longer than the owner from which it was borrowed. Using a borrowed reference after the owner has disposed of it risks using freed memory and should be avoided completely.

The advantage of borrowing over owning a reference is that you don't need to take care of disposing of the reference on all possible paths through the code — in other words, with a borrowed reference you don't run the risk of leaking when a premature exit is taken. The disadvantage of borrowing over owning is that there are some subtle situations where in seemingly correct code a borrowed reference can be used after the owner from which it was borrowed has in fact disposed of it.

A borrowed reference can be changed into an owned reference by calling `Py_INCREF()`. This does not affect the status of the owner from which the reference was borrowed — it creates a new owned reference, and gives full owner responsibilities (the new owner must dispose of the reference properly, as well as the previous owner).

### 1.10.2. Ownership Rules

Whenever an object reference is passed into or out of a function, it is part of the function's interface specification whether ownership is transferred with the reference or not.

Most functions that return a reference to an object pass on ownership with the reference. In particular, all functions whose function it is to create a new object, such as `PyLong_FromLong()` and `Py_BuildValue()`, pass ownership to the receiver. Even if the object is not actually new, you still receive ownership of a new reference to that object. For instance, `PyLong_FromLong()` maintains a cache of popular values and can return a reference to a

cached item.

Many functions that extract objects from other objects also transfer ownership with the reference, for instance

`PyObject_GetAttrString()`. The picture is less clear, here, however, since a few common routines are exceptions:

`PyTuple_GetItem()`, `PyList_GetItem()`, `PyDict_GetItem()`, and `PyDict_GetItemString()` all return references that you borrow from the tuple, list or dictionary.

The function `PyImport_AddModule()` also returns a borrowed reference, even though it may actually create the object it returns: this is possible because an owned reference to the object is stored in `sys.modules`.

When you pass an object reference into another function, in general, the function borrows the reference from you — if it needs to store it, it will use `Py_INCREF()` to become an independent owner. There are exactly two important exceptions to this rule: `PyTuple_SetItem()` and `PyList_SetItem()`. These functions take over ownership of the item passed to them — even if they fail! (Note that `PyDict_SetItem()` and friends don't take over ownership — they are “normal.”)

When a C function is called from Python, it borrows references to its arguments from the caller. The caller owns a reference to the object, so the borrowed reference's lifetime is guaranteed until the function returns. Only when such a borrowed reference must be stored or passed on, it must be turned into an owned reference by calling `Py_INCREF()`.

The object reference returned from a C function that is called from Python must be an owned reference — ownership is transferred from the function to its caller.

### 1.10.3. Thin Ice

There are a few situations where seemingly harmless use of a borrowed reference can lead to problems. These all have to do with implicit invocations of the interpreter, which can cause the owner of a reference to dispose of it.

The first and most important case to know about is using `Py_DECREF()` on an unrelated object while borrowing a reference to a list item. For instance:

```
void
bug(PyObject *list)
{
    PyObject *item = PyList_GetItem(list, 0);

    PyList_SetItem(list, 1, PyLong_FromLong(0L));
    PyObject_Print(item, stdout, 0); /* BUG! */
}
```

This function first borrows a reference to `list[0]`, then replaces `list[1]` with the value `0`, and finally prints the borrowed reference. Looks harmless, right? But it's not!

Let's follow the control flow into `PyList_SetItem()`. The list owns references to all its items, so when item 1 is replaced, it has to dispose of the original item 1. Now let's suppose the original item 1 was an instance of a user-defined class, and let's further suppose that the class defined a `__del__()` method. If this class instance has a reference count of 1, disposing of it will call its `__del__()` method.

Since it is written in Python, the `__del__()` method can execute arbitrary Python code. Could it perhaps do something to invalidate the reference to `item` in `bug()`? You bet! Assuming that the list passed into `bug()` is accessible to the `__del__()` method, it could execute a statement to the effect of `del list[0]`, and assuming this was the last reference to that object, it would free the memory associated with it, thereby invalidating `item`.

The solution, once you know the source of the problem, is easy: temporarily increment the reference count. The correct version of the function reads:

```
void
no_bug(PyObject *list)
{
```

```

PyObject *item = PyList_GetItem(list, 0);

Py_INCREF(item);
PyList_SetItem(list, 1, PyLong_FromLong(0L));
PyObject_Print(item, stdout, 0);
Py_DECREF(item);
}

```

This is a true story. An older version of Python contained variants of this bug and someone spent a considerable amount of time in a C debugger to figure out why his `__del__()` methods would fail...

The second case of problems with a borrowed reference is a variant involving threads. Normally, multiple threads in the Python interpreter can't get in each other's way, because there is a global lock protecting Python's entire object space. However, it is possible to temporarily release this lock using the macro `Py_BEGIN_ALLOW_THREADS`, and to re-acquire it using `Py_END_ALLOW_THREADS`. This is common around blocking I/O calls, to let other threads use the processor while waiting for the I/O to complete. Obviously, the following function has the same problem as the previous one:

```

void
bug(PyObject *list)
{
    PyObject *item = PyList_GetItem(list, 0);
    Py_BEGIN_ALLOW_THREADS
    ...some blocking I/O call...
    Py_END_ALLOW_THREADS
    PyObject_Print(item, stdout, 0); /* BUG! */
}

```

### 1.10.4. NULL Pointers

In general, functions that take object references as arguments do not expect you to pass them `NULL` pointers, and will dump core (or cause later core dumps) if you do so. Functions that return object references generally return `NULL` only to indicate that an exception occurred. The reason for not testing for `NULL` arguments is that

functions often pass the objects they receive on to other function — if each function were to test for `NULL`, there would be a lot of redundant tests and the code would run more slowly.

It is better to test for `NULL` only at the “source:” when a pointer that may be `NULL` is received, for example, from `malloc()` or from a function that may raise an exception.

The macros `Py_INCREF()` and `Py_DECREF()` do not check for `NULL` pointers — however, their variants `Py_XINCREF()` and `Py_XDECREF()` do.

The macros for checking for a particular object type (`Pytype_Check()`) don’t check for `NULL` pointers — again, there is much code that calls several of these in a row to test an object against various different expected types, and this would generate redundant tests. There are no variants with `NULL` checking.

The C function calling mechanism guarantees that the argument list passed to C functions (`args` in the examples) is never `NULL` — in fact it guarantees that it is always a tuple [4](#).

It is a severe error to ever let a `NULL` pointer “escape” to the Python user.

## 1.11. Writing Extensions in C++

It is possible to write extension modules in C++. Some restrictions apply. If the main program (the Python interpreter) is compiled and linked by the C compiler, global or static objects with constructors cannot be used. This is not a problem if the main program is linked by the C++ compiler. Functions that will be called by the Python interpreter (in particular, module initialization functions) have to be declared using `extern "C"`. It is unnecessary to enclose the Python header files in `extern "C" {...}` — they use this form already if the symbol `__cplusplus` is defined (all recent C++ compilers define this symbol).

## 1.12. Providing a C API for an Extension

# Module

Many extension modules just provide new functions and types to be used from Python, but sometimes the code in an extension module can be useful for other extension modules. For example, an extension module could implement a type “collection” which works like lists without order. Just like the standard Python list type has a C API which permits extension modules to create and manipulate lists, this new collection type should have a set of C functions for direct manipulation from other extension modules.

At first sight this seems easy: just write the functions (without declaring them `static`, of course), provide an appropriate header file, and document the C API. And in fact this would work if all extension modules were always linked statically with the Python interpreter. When modules are used as shared libraries, however, the symbols defined in one module may not be visible to another module. The details of visibility depend on the operating system; some systems use one global namespace for the Python interpreter and all extension modules (Windows, for example), whereas others require an explicit list of imported symbols at module link time (AIX is one example), or offer a choice of different strategies (most Unices). And even if symbols are globally visible, the module whose functions one wishes to call might not have been loaded yet!

Portability therefore requires not to make any assumptions about symbol visibility. This means that all symbols in extension modules should be declared `static`, except for the module’s initialization function, in order to avoid name clashes with other extension modules (as discussed in section [The Module’s Method Table and Initialization Function](#)). And it means that symbols that *should* be accessible from other extension modules must be exported in a different way.

Python provides a special mechanism to pass C-level information (pointers) from one extension module to another one: Capsules. A Capsule is a Python data type which stores a pointer (void\*). Capsules can only be created and accessed via their C API, but they can be passed around like any other Python object. In particular, they can be assigned to a name in an extension module’s

namespace. Other extension modules can then import this module, retrieve the value of this name, and then retrieve the pointer from the Capsule.

There are many ways in which Capsules can be used to export the C API of an extension module. Each function could get its own Capsule, or all C API pointers could be stored in an array whose address is published in a Capsule. And the various tasks of storing and retrieving the pointers can be distributed in different ways between the module providing the code and the client modules.

Whichever method you choose, it's important to name your Capsules properly. The function `PyCapsule_New()` takes a name parameter (const char\*); you're permitted to pass in a `NULL` name, but we strongly encourage you to specify a name. Properly named Capsules provide a degree of runtime type-safety; there is no feasible way to tell one unnamed Capsule from another.

In particular, Capsules used to expose C APIs should be given a name following this convention:

```
modulename.attributename
```

The convenience function `PyCapsule_Import()` makes it easy to load a C API provided via a Capsule, but only if the Capsule's name matches this convention. This behavior gives C API users a high degree of certainty that the Capsule they load contains the correct C API.

The following example demonstrates an approach that puts most of the burden on the writer of the exporting module, which is appropriate for commonly used library modules. It stores all C API pointers (just one in the example!) in an array of void pointers which becomes the value of a Capsule. The header file corresponding to the module provides a macro that takes care of importing the module and retrieving its C API pointers; client modules only have to call this macro before accessing the C API.

The exporting module is a modification of the `spam` module from section [A Simple Example](#). The function `spam.system()` does not call the C library function `system()` directly, but a function

**PySpam\_System()**, which would of course do something more complicated in reality (such as adding “spam” to every command). This function **PySpam\_System()** is also exported to other extension modules.

The function **PySpam\_System()** is a plain C function, declared `static` like everything else:

```
static int
PySpam_System(const char *command)
{
    return system(command);
}
```

The function **spam\_system()** is modified in a trivial way:

```
static PyObject *
spam_system(PyObject *self, PyObject *args)
{
    const char *command;
    int sts;

    if (!PyArg_ParseTuple(args, "s", &command))
        return NULL;
    sts = PySpam_System(command);
    return PyLong_FromLong(sts);
}
```

In the beginning of the module, right after the line

```
#include <Python.h>
```

two more lines must be added:

```
#define SPAM_MODULE
#include "spammodule.h"
```

The `#define` is used to tell the header file that it is being included in the exporting module, not a client module. Finally, the module’s initialization function must take care of initializing the C API pointer array:

```

PyMODINIT_FUNC
PyInit_spam(void)
{
    PyObject *m;
    static void *PySpam_API[PySpam_API_pointers];
    PyObject *c_api_object;

    m = PyModule_Create(&spammodule);
    if (m == NULL)
        return NULL;

    /* Initialize the C API pointer array */
    PySpam_API[PySpam_System_NUM] = (void *)PySpam_System;

    /* Create a Capsule containing the API pointer array */
    c_api_object = PyCapsule_New((void *)PySpam_API, "spammodule._C_API");

    if (PyModule_AddObject(m, "_C_API", c_api_object) < 0)
        Py_XDECREF(c_api_object);
        Py_DECREF(m);
        return NULL;
    }

    return m;
}

```

Note that `PySpam_API` is declared `static`; otherwise the pointer array would disappear when **`PyInit_spam()`** terminates!

The bulk of the work is in the header file `spammodule.h`, which looks like this:

```

#ifndef Py_SPAMMODULE_H
#define Py_SPAMMODULE_H
#ifdef __cplusplus
extern "C" {
#endif

/* Header file for spammodule */

```

```

/* C API functions */
#define PySpam_System_NUM 0
#define PySpam_System_RETURN int
#define PySpam_System_PROTO (const char *command)

/* Total number of C API pointers */
#define PySpam_API_pointers 1

#ifdef SPAM_MODULE
/* This section is used when compiling spammodule.c */

static PySpam_System_RETURN PySpam_System PySpam_System_

#else
/* This section is used in modules that use spammodule's

static void **PySpam_API;

#define PySpam_System \
    (*(PySpam_System_RETURN (*)PySpam_System_PROTO) PySpam_

/* Return -1 on error, 0 on success.
 * PyCapsule_Import will set an exception if there's an
 */
static int
import_spam(void)
{
    PySpam_API = (void **)PyCapsule_Import("spam._C_API")
    return (PySpam_API != NULL) ? 0 : -1;
}

#endif

#ifdef __cplusplus
}
#endif

```

```
#endif /* !defined(Py_SPAMMODULE_H) */
```

All that a client module must do in order to have access to the function **PySpam\_System()** is to call the function (or rather macro) **import\_spam()** in its initialization function:

```
PyMODINIT_FUNC
PyInit_client(void)
{
    PyObject *m;

    m = PyModule_Create(&clientmodule);
    if (m == NULL)
        return NULL;
    if (import_spam() < 0)
        return NULL;
    /* additional initialization can happen here */
    return m;
}
```

The main disadvantage of this approach is that the file `spammodule.h` is rather complicated. However, the basic structure is the same for each function that is exported, so it has to be learned only once.

Finally it should be mentioned that Capsules offer additional functionality, which is especially useful for memory allocation and deallocation of the pointer stored in a Capsule. The details are described in the Python/C API Reference Manual in the section [Capsules](#) and in the implementation of Capsules (files `Include/pycapsule.h` and `Objects/pycapsule.c` in the Python source code distribution).

## Footnotes

1

An interface for this function already exists in the standard module **os** — it was chosen as a simple and straightforward

example.

2

The metaphor of “borrowing” a reference is not completely correct: the owner still has a copy of the reference.

3

Checking that the reference count is at least 1 **does not work** — the reference count itself could be in freed memory and may thus be reused for another object!

4

These guarantees don’t hold when you use the “old” style calling convention — this is still found in much existing code.

## 2. Defining Extension Types: Tutorial

Python allows the writer of a C extension module to define new types that can be manipulated from Python code, much like the built-in `str` and `list` types. The code for all extension types follows a pattern, but there are some details that you need to understand before you can get started. This document is a gentle introduction to the topic.

### 2.1. The Basics

The CPython runtime sees all Python objects as variables of type `PyObject*`, which serves as a “base type” for all Python objects. The `PyObject` structure itself only contains the object’s `reference count` and a pointer to the object’s “type object”. This is where the action is; the type object determines which (C) functions get called by the interpreter when, for instance, an attribute gets looked up on an object, a method called, or it is multiplied by another object. These C functions are called “type methods”.

So, if you want to define a new extension type, you need to create a new type object.

This sort of thing can only be explained by example, so here’s a minimal, but complete, module that defines a new type named `Custom` inside a C extension module `custom`:

#### Note

What we’re showing here is the traditional way of defining *static* extension types. It should be adequate for most uses. The C API also allows defining heap-allocated extension types using the `PyType_FromSpec()` function, which isn’t covered in this

tutorial.

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>

typedef struct {
    PyObject_HEAD
    /* Type-specific fields go here. */
} CustomObject;

static PyTypeObject CustomType = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "custom.Custom",
    .tp_doc = PyDoc_STR("Custom objects"),
    .tp_basicsize = sizeof(CustomObject),
    .tp_itemsize = 0,
    .tp_flags = Py_TPFLAGS_DEFAULT,
    .tp_new = PyType_GenericNew,
};

static PyModuleDef custommodule = {
    PyModuleDef_HEAD_INIT,
    .m_name = "custom",
    .m_doc = "Example module that creates an extension t",
    .m_size = -1,
};

PyMODINIT_FUNC
PyInit_custom(void)
{
    PyObject *m;
    if (PyType_Ready(&CustomType) < 0)
        return NULL;

    m = PyModule_Create(&custommodule);
    if (m == NULL)
        return NULL;
```

```

Py_INCREF (&CustomType);
if (PyModule_AddObject(m, "Custom", (PyObject *) &Cu
    Py_DECREF (&CustomType);
    Py_DECREF (m);
    return NULL;
}

return m;
}

```

Now that's quite a bit to take in at once, but hopefully bits will seem familiar from the previous chapter. This file defines three things:

1. What a **Custom object** contains: this is the `CustomObject` struct, which is allocated once for each **Custom** instance.
2. How the **Custom type** behaves: this is the `CustomType` struct, which defines a set of flags and function pointers that the interpreter inspects when specific operations are requested.
3. How to initialize the **custom** module: this is the `PyInit_custom` function and the associated `custommodule` struct.

The first bit is:

```

typedef struct {
    PyObject_HEAD
} CustomObject;

```

This is what a Custom object will contain. `PyObject_HEAD` is mandatory at the start of each object struct and defines a field called `ob_base` of type **PyObject**, containing a pointer to a type object and a reference count (these can be accessed using the macros **Py\_TYPE** and **Py\_REFCNT** respectively). The reason for the macro is to abstract away the layout and to enable additional fields in **debug builds**.

## Note

There is no semicolon above after the `PyObject_HEAD` macro. Be wary of adding one by accident: some compilers will complain.

Of course, objects generally store additional data besides the standard `PyObject_HEAD` boilerplate; for example, here is the definition for standard Python floats:

```
typedef struct {
    PyObject_HEAD
    double ob_fval;
} PyFloatObject;
```

The second bit is the definition of the type object.

```
static PyTypeObject CustomType = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "custom.Custom",
    .tp_doc = PyDoc_STR("Custom objects"),
    .tp_basicsize = sizeof(CustomObject),
    .tp_itemsize = 0,
    .tp_flags = Py_TPFLAGS_DEFAULT,
    .tp_new = PyType_GenericNew,
};
```

## Note

We recommend using C99-style designated initializers as above, to avoid listing all the `PyTypeObject` fields that you don't care about and also to avoid caring about the fields' declaration order.

The actual definition of `PyTypeObject` in `object.h` has many more fields than the definition above. The remaining fields will be filled with zeros by the C compiler, and it's common practice to not specify them explicitly unless you need them.

We're going to pick it apart, one field at a time:

```
PyVarObject_HEAD_INIT(NULL, 0)
```

This line is mandatory boilerplate to initialize the `ob_base` field mentioned above.

```
.tp_name = "custom.Custom",
```

The name of our type. This will appear in the default textual representation of our objects and in some error messages, for example:

```
>>> "" + custom.Custom()
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: can only concatenate str (not "custom.Custom")
```

Note that the name is a dotted name that includes both the module name and the name of the type within the module. The module in this case is `custom` and the type is `Custom`, so we set the type name to `custom.Custom`. Using the real dotted import path is important to make your type compatible with the [pydoc](#) and [pickle](#) modules.

```
.tp_basicsize = sizeof(CustomObject),
.tp_itemsize = 0,
```

This is so that Python knows how much memory to allocate when creating new `Custom` instances. `tp_itemsize` is only used for variable-sized objects and should otherwise be zero.

## Note

If you want your type to be subclassable from Python, and your type has the same `tp_basicsize` as its base type, you may have problems with multiple inheritance. A Python subclass of your type will have to list your type first in its `__bases__`, or else it will not be able to call your type's `__new__()` method without getting an error. You can avoid this problem by ensuring that your type has a larger value for `tp_basicsize` than its base type does. Most of the time, this will be true anyway, because either your base type will be `object`, or else you will

be adding data members to your base type, and therefore increasing its size.

We set the class flags to `Py_TPFLAGS_DEFAULT`.

```
.tp_flags = Py_TPFLAGS_DEFAULT,
```

All types should include this constant in their flags. It enables all of the members defined until at least Python 3.3. If you need further members, you will need to OR the corresponding flags.

We provide a doc string for the type in `tp_doc`.

```
.tp_doc = PyDoc_STR("Custom objects"),
```

To enable object creation, we have to provide a `tp_new` handler. This is the equivalent of the Python method `__new__()`, but has to be specified explicitly. In this case, we can just use the default implementation provided by the API function `PyType_GenericNew()`.

```
.tp_new = PyType_GenericNew,
```

Everything else in the file should be familiar, except for some code in `PyInit_custom()`:

```
if (PyType_Ready(&CustomType) < 0)
    return;
```

This initializes the `Custom` type, filling in a number of members to the appropriate default values, including `ob_type` that we initially set to `NULL`.

```
Py_INCREF(&CustomType);
if (PyModule_AddObject(m, "Custom", (PyObject *) &CustomType) < 0)
    Py_DECREF(&CustomType);
    Py_DECREF(m);
    return NULL;
}
```

This adds the type to the module dictionary. This allows us to

create **Custom** instances by calling the **Custom** class:

```
>>> import custom
>>> mycustom = custom.Custom()
```

That's it! All that remains is to build it; put the above code in a file called `custom.c` and:

```
from distutils.core import setup, Extension
setup(name="custom", version="1.0",
      ext_modules=[Extension("custom", ["custom.c"])])
```

in a file called `setup.py`; then typing

```
$ python setup.py build
```

at a shell should produce a file `custom.so` in a subdirectory; move to that directory and fire up Python — you should be able to import `custom` and play around with `Custom` objects.

That wasn't so hard, was it?

Of course, the current `Custom` type is pretty uninteresting. It has no data and doesn't do anything. It can't even be subclassed.

## Note

While this documentation showcases the standard **distutils** module for building C extensions, it is recommended in real-world use cases to use the newer and better-maintained **setuptools** library. Documentation on how to do this is out of scope for this document and can be found in the [Python Packaging User's Guide](https://packaging.python.org/tutorials/distributing-packages/) [https://packaging.python.org/tutorials/distributing-packages/].

## 2.2. Adding data and methods to the Basic example

Let's extend the basic example to add some data and methods. Let's

also make the type usable as a base class. We'll create a new module, **custom2** that adds these capabilities:

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>
#include "structmember.h"

typedef struct {
    PyObject_HEAD
    PyObject *first; /* first name */
    PyObject *last;  /* last name */
    int number;
} CustomObject;

static void
Custom_dealloc(CustomObject *self)
{
    Py_XDECREF(self->first);
    Py_XDECREF(self->last);
    Py_TYPE(self)->tp_free((PyObject *) self);
}

static PyObject *
Custom_new(PyTypeObject *type, PyObject *args, PyObject
{
    CustomObject *self;
    self = (CustomObject *) type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = PyUnicode_FromString("");
        if (self->first == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->last = PyUnicode_FromString("");
        if (self->last == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->number = 0;
    }
}
```

```

    }
    return (PyObject *) self;
}

static int
Custom_init(CustomObject *self, PyObject *args, PyObject
{
    static char *kwlist[] = {"first", "last", "number",
    PyObject *first = NULL, *last = NULL, *tmp;

    if (!PyArg_ParseTupleAndKeywords(args, kwds, "|OOi",
                                     &first, &last,
                                     &self->number))

        return -1;

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_XDECREF(tmp);
    }
    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_XDECREF(tmp);
    }
    return 0;
}

static PyMemberDef Custom_members[] = {
    {"first", T_OBJECT_EX, offsetof(CustomObject, first),
     "first name"},
    {"last", T_OBJECT_EX, offsetof(CustomObject, last),
     "last name"},
    {"number", T_INT, offsetof(CustomObject, number), 0,
     "custom number"},
    {NULL} /* Sentinel */

```

```
};
```

```
static PyObject *
```

```
Custom_name(CustomObject *self, PyObject *Py_UNUSED(ignore))
```

```
{
    if (self->first == NULL) {
        PyErr_SetString(PyExc_AttributeError, "first");
        return NULL;
    }
    if (self->last == NULL) {
        PyErr_SetString(PyExc_AttributeError, "last");
        return NULL;
    }
    return PyUnicode_FromFormat("%S %S", self->first, self->last);
}
```

```
static PyMethodDef Custom_methods[] = {
```

```
    {"name", (PyCFunction) Custom_name, METH_NOARGS,
     "Return the name, combining the first and last name"},
    {NULL} /* Sentinel */
};
```

```
static PyTypeObject CustomType = {
```

```
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "custom2.Custom",
    .tp_doc = PyDoc_STR("Custom objects"),
    .tp_basicsize = sizeof(CustomObject),
    .tp_itemsize = 0,
    .tp_flags = Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE,
    .tp_new = Custom_new,
    .tp_init = (initproc) Custom_init,
    .tp_dealloc = (destructor) Custom_dealloc,
    .tp_members = Custom_members,
    .tp_methods = Custom_methods,
};
```

```
static PyModuleDef custommodule = {
```

```

PyModuleDef_HEAD_INIT,
.m_name = "custom2",
.m_doc = "Example module that creates an extension t
.m_size = -1,
};

PyMODINIT_FUNC
PyInit_custom2(void)
{
    PyObject *m;
    if (PyType_Ready(&CustomType) < 0)
        return NULL;

    m = PyModule_Create(&custommodule);
    if (m == NULL)
        return NULL;

    Py_INCREF(&CustomType);
    if (PyModule_AddObject(m, "Custom", (PyObject *) &Cu
        Py_DECREF(&CustomType);
        Py_DECREF(m);
        return NULL;
    }

    return m;
}

```

This version of the module has a number of changes.

We've added an extra include:

```
#include <structmember.h>
```

This include provides declarations that we use to handle attributes, as described a bit later.

The **Custom** type now has three data attributes in its C struct, *first*, *last*, and *number*. The *first* and *last* variables are Python strings containing first and last names. The *number* attribute is a C integer.

The object structure is updated accordingly:

```
typedef struct {
    PyObject_HEAD
    PyObject *first; /* first name */
    PyObject *last;  /* last name */
    int number;
} CustomObject;
```

Because we now have data to manage, we have to be more careful about object allocation and deallocation. At a minimum, we need a deallocation method:

```
static void
Custom_dealloc(CustomObject *self)
{
    Py_XDECREF(self->first);
    Py_XDECREF(self->last);
    Py_TYPE(self)->tp_free((PyObject *) self);
}
```

which is assigned to the `tp_dealloc` member:

```
.tp_dealloc = (destructor) Custom_dealloc,
```

This method first clears the reference counts of the two Python attributes. `Py_XDECREF()` correctly handles the case where its argument is `NULL` (which might happen here if `tp_new` failed midway). It then calls the `tp_free` member of the object's type (computed by `Py_TYPE(self)`) to free the object's memory. Note that the object's type might not be `CustomType`, because the object may be an instance of a subclass.

## Note

The explicit cast to `destructor` above is needed because we defined `Custom_dealloc` to take a `CustomObject *` argument, but the `tp_dealloc` function pointer expects to receive a `PyObject *` argument. Otherwise, the compiler will emit a warning. This is object-oriented polymorphism, in C!

We want to make sure that the first and last names are initialized to empty strings, so we provide a `tp_new` implementation:

```
static PyObject *
Custom_new(PyTypeObject *type, PyObject *args, PyObject
{
    CustomObject *self;
    self = (CustomObject *) type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = PyUnicode_FromString("");
        if (self->first == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->last = PyUnicode_FromString("");
        if (self->last == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->number = 0;
    }
    return (PyObject *) self;
}
```

and install it in the `tp_new` member:

```
.tp_new = Custom_new,
```

The `tp_new` handler is responsible for creating (as opposed to initializing) objects of the type. It is exposed in Python as the `__new__()` method. It is not required to define a `tp_new` member, and indeed many extension types will simply reuse `PyType_GenericNew()` as done in the first version of the Custom type above. In this case, we use the `tp_new` handler to initialize the `first` and `last` attributes to non-NULL default values.

`tp_new` is passed the type being instantiated (not necessarily `CustomType`, if a subclass is instantiated) and any arguments passed when the type was called, and is expected to return the

instance created. `tp_new` handlers always accept positional and keyword arguments, but they often ignore the arguments, leaving the argument handling to initializer (a.k.a. `tp_init` in C or `__init__` in Python) methods.

### Note

`tp_new` shouldn't call `tp_init` explicitly, as the interpreter will do it itself.

The `tp_new` implementation calls the `tp_alloc` slot to allocate memory:

```
self = (CustomObject *) type->tp_alloc(type, 0);
```

Since memory allocation may fail, we must check the `tp_alloc` result against `NULL` before proceeding.

### Note

We didn't fill the `tp_alloc` slot ourselves. Rather `PyType_Ready()` fills it for us by inheriting it from our base class, which is `object` by default. Most types use the default allocation strategy.

### Note

If you are creating a co-operative `tp_new` (one that calls a base type's `tp_new` or `__new__()`), you must *not* try to determine what method to call using method resolution order at runtime. Always statically determine what type you are going to call, and call its `tp_new` directly, or via `type->tp_base->tp_new`. If you do not do this, Python subclasses of your type that also inherit from other Python-defined classes may not work correctly. (Specifically, you may not be able to create instances of such subclasses without getting a `TypeError`.)

We also define an initialization function which accepts arguments

to provide initial values for our instance:

```
static int
Custom_init(CustomObject *self, PyObject *args, PyObject
{
    static char *kwlist[] = {"first", "last", "number",
    PyObject *first = NULL, *last = NULL, *tmp;

    if (!PyArg_ParseTupleAndKeywords(args, kwds, "|OOi",
                                     &first, &last,
                                     &self->number))
        return -1;

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_XDECREF(tmp);
    }
    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_XDECREF(tmp);
    }
    return 0;
}
```

by filling the `tp_init` slot.

```
.tp_init = (initproc) Custom_init,
```

The `tp_init` slot is exposed in Python as the `__init__()` method. It is used to initialize an object after it's created. Initializers always accept positional and keyword arguments, and they should return either 0 on success or -1 on error.

Unlike the `tp_new` handler, there is no guarantee that `tp_init` is called at all (for example, the `pickle` module by default doesn't call `__init__()` on unpickled instances). It can also be called

multiple times. Anyone can call the `__init__()` method on our objects. For this reason, we have to be extra careful when assigning the new attribute values. We might be tempted, for example to assign the `first` member like this:

```
if (first) {
    Py_XDECREF(self->first);
    Py_INCREF(first);
    self->first = first;
}
```

But this would be risky. Our type doesn't restrict the type of the `first` member, so it could be any kind of object. It could have a destructor that causes code to be executed that tries to access the `first` member; or that destructor could release the [Global interpreter Lock](#) and let arbitrary code run in other threads that accesses and modifies our object.

To be paranoid and protect ourselves against this possibility, we almost always reassign members before decrementing their reference counts. When don't we have to do this?

- when we absolutely know that the reference count is greater than 1;
- when we know that deallocation of the object [1](#) will neither release the [GIL](#) nor cause any calls back into our type's code;
- when decrementing a reference count in a [tp\\_dealloc](#) handler on a type which doesn't support cyclic garbage collection [2](#).

We want to expose our instance variables as attributes. There are a number of ways to do that. The simplest way is to define member definitions:

```
static PyMemberDef Custom_members[] = {
    {"first", T_OBJECT_EX, offsetof(CustomObject, first),
     "first name"},
    {"last", T_OBJECT_EX, offsetof(CustomObject, last),
     "last name"},
    {"number", T_INT, offsetof(CustomObject, number), 0,
```

```

        "custom number"},
        {NULL} /* Sentinel */
    };

```

and put the definitions in the `tp_members` slot:

```

.tp_members = Custom_members,

```

Each member definition has a member name, type, offset, access flags and documentation string. See the [Generic Attribute Management](#) section below for details.

A disadvantage of this approach is that it doesn't provide a way to restrict the types of objects that can be assigned to the Python attributes. We expect the first and last names to be strings, but any Python objects can be assigned. Further, the attributes can be deleted, setting the C pointers to `NULL`. Even though we can make sure the members are initialized to non-NULL values, the members can be set to `NULL` if the attributes are deleted.

We define a single method, `Custom.name()`, that outputs the objects name as the concatenation of the first and last names.

```

static PyObject *
Custom_name(CustomObject *self, PyObject *Py_UNUSED(ignore))
{
    if (self->first == NULL) {
        PyErr_SetString(PyExc_AttributeError, "first");
        return NULL;
    }
    if (self->last == NULL) {
        PyErr_SetString(PyExc_AttributeError, "last");
        return NULL;
    }
    return PyUnicode_FromFormat("%S %S", self->first, self->last);
}

```

The method is implemented as a C function that takes a `Custom` (or `Custom` subclass) instance as the first argument. Methods always take an instance as the first argument. Methods often take

positional and keyword arguments as well, but in this case we don't take any and don't need to accept a positional argument tuple or keyword argument dictionary. This method is equivalent to the Python method:

```
def name(self):
    return "%s %s" % (self.first, self.last)
```

Note that we have to check for the possibility that our **first** and **last** members are `NULL`. This is because they can be deleted, in which case they are set to `NULL`. It would be better to prevent deletion of these attributes and to restrict the attribute values to be strings. We'll see how to do that in the next section.

Now that we've defined the method, we need to create an array of method definitions:

```
static PyMethodDef Custom_methods[] = {
    {"name", (PyCFunction) Custom_name, METH_NOARGS,
     "Return the name, combining the first and last name"},
    {NULL} /* Sentinel */
};
```

(note that we used the `METH_NOARGS` flag to indicate that the method is expecting no arguments other than *self*)

and assign it to the `tp_methods` slot:

```
.tp_methods = Custom_methods,
```

Finally, we'll make our type usable as a base class for subclassing. We've written our methods carefully so far so that they don't make any assumptions about the type of the object being created or used, so all we need to do is to add the `Py_TPFLAGS_BASETYPE` to our class flag definition:

```
.tp_flags = Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE,
```

We rename `PyInit_custom()` to `PyInit_custom2()`, update the module name in the `PyModuleDef` struct, and update the full

class name in the `PyTypeObject` struct.

Finally, we update our `setup.py` file to build the new module:

```
from distutils.core import setup, Extension
setup(name="custom", version="1.0",
      ext_modules=[
          Extension("custom", ["custom.c"]),
          Extension("custom2", ["custom2.c"]),
      ])
```

## 2.3. Providing finer control over data attributes

In this section, we'll provide finer control over how the **first** and **last** attributes are set in the **Custom** example. In the previous version of our module, the instance variables **first** and **last** could be set to non-string values or even deleted. We want to make sure that these attributes always contain strings.

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>
#include "structmember.h"

typedef struct {
    PyObject_HEAD
    PyObject *first; /* first name */
    PyObject *last;  /* last name */
    int number;
} CustomObject;

static void
Custom_dealloc(CustomObject *self)
{
    Py_XDECREF(self->first);
    Py_XDECREF(self->last);
    Py_TYPE(self)->tp_free((PyObject *) self);
}
```

```

static PyObject *
Custom_new(PyTypeObject *type, PyObject *args, PyObject
{
    CustomObject *self;
    self = (CustomObject *) type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = PyUnicode_FromString("");
        if (self->first == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->last = PyUnicode_FromString("");
        if (self->last == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->number = 0;
    }
    return (PyObject *) self;
}

```

```

static int
Custom_init(CustomObject *self, PyObject *args, PyObject
{
    static char *kwlist[] = {"first", "last", "number",
    PyObject *first = NULL, *last = NULL, *tmp;

    if (!PyArg_ParseTupleAndKeywords(args, kwds, "|UUi",
                                     &first, &last,
                                     &self->number))
        return -1;

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_DECREF(tmp);
    }
}

```

```

    }
    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_DECREF(tmp);
    }
    return 0;
}

static PyMemberDef Custom_members[] = {
    {"number", T_INT, offsetof(CustomObject, number), 0,
     "custom number"},
    {NULL} /* Sentinel */
};

static PyObject *
Custom_getfirst(CustomObject *self, void *closure)
{
    Py_INCREF(self->first);
    return self->first;
}

static int
Custom_setfirst(CustomObject *self, PyObject *value, void
{
    PyObject *tmp;
    if (value == NULL) {
        PyErr_SetString(PyExc_TypeError, "Cannot delete
        return -1;
    }
    if (!PyUnicode_Check(value)) {
        PyErr_SetString(PyExc_TypeError,
                        "The first attribute value must
        return -1;
    }
    tmp = self->first;
    Py_INCREF(value);

```

```

        self->first = value;
        Py_DECREF(tmp);
        return 0;
    }

```

```

static PyObject *
Custom_getlast(CustomObject *self, void *closure)
{
    Py_INCREF(self->last);
    return self->last;
}

```

```

static int
Custom_setlast(CustomObject *self, PyObject *value, void *)
{
    PyObject *tmp;
    if (value == NULL) {
        PyErr_SetString(PyExc_TypeError, "Cannot delete attribute");
        return -1;
    }
    if (!PyUnicode_Check(value)) {
        PyErr_SetString(PyExc_TypeError,
                        "The last attribute value must be a string");
        return -1;
    }
    tmp = self->last;
    Py_INCREF(value);
    self->last = value;
    Py_DECREF(tmp);
    return 0;
}

```

```

static PyGetSetDef Custom_getsetters[] = {
    {"first", (getter) Custom_getfirst, (setter) Custom_setfirst,
     "first name", NULL},
    {"last", (getter) Custom_getlast, (setter) Custom_setlast,
     "last name", NULL},
    {NULL} /* Sentinel */
}

```

```
};
```

```
static PyObject *
```

```
Custom_name(CustomObject *self, PyObject *Py_UNUSED(ignored))
```

```
{  
    return PyUnicode_FromFormat("%S %S", self->first, self->last);  
}
```

```
static PyMethodDef Custom_methods[] = {
```

```
    {"name", (PyCFunction) Custom_name, METH_NOARGS,
```

```
     "Return the name, combining the first and last name",
```

```
    },
```

```
    {NULL} /* Sentinel */
```

```
};
```

```
static PyTypeObject CustomType = {
```

```
    PyVarObject_HEAD_INIT(NULL, 0)
```

```
    .tp_name = "custom3.Custom",
```

```
    .tp_doc = PyDoc_STR("Custom objects"),
```

```
    .tp_basicsize = sizeof(CustomObject),
```

```
    .tp_itemsize = 0,
```

```
    .tp_flags = Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE,
```

```
    .tp_new = Custom_new,
```

```
    .tp_init = (initproc) Custom_init,
```

```
    .tp_dealloc = (destructor) Custom_dealloc,
```

```
    .tp_members = Custom_members,
```

```
    .tp_methods = Custom_methods,
```

```
    .tp_getset = Custom_getsetters,
```

```
};
```

```
static PyModuleDef custommodule = {
```

```
    PyModuleDef_HEAD_INIT,
```

```
    .m_name = "custom3",
```

```
    .m_doc = "Example module that creates an extension type",
```

```
    .m_size = -1,
```

```
};
```

```
PyMODINIT_FUNC
```

```

PyInit_custom3(void)
{
    PyObject *m;
    if (PyType_Ready(&CustomType) < 0)
        return NULL;

    m = PyModule_Create(&custommodule);
    if (m == NULL)
        return NULL;

    Py_INCREF(&CustomType);
    if (PyModule_AddObject(m, "Custom", (PyObject *) &CustomType) < 0)
        Py_DECREF(&CustomType);
        Py_DECREF(m);
        return NULL;
    }

    return m;
}

```

To provide greater control, over the **first** and **last** attributes, we'll use custom getter and setter functions. Here are the functions for getting and setting the **first** attribute:

```

static PyObject *
Custom_getfirst(CustomObject *self, void *closure)
{
    Py_INCREF(self->first);
    return self->first;
}

static int
Custom_setfirst(CustomObject *self, PyObject *value, void *closure)
{
    PyObject *tmp;
    if (value == NULL) {
        PyErr_SetString(PyExc_TypeError, "Cannot delete attribute");
        return -1;
    }
}

```

```

if (!PyUnicode_Check(value)) {
    PyErr_SetString(PyExc_TypeError,
                    "The first attribute value must
    return -1;
}
tmp = self->first;
Py_INCREF(value);
self->first = value;
Py_DECREF(tmp);
return 0;
}

```

The getter function is passed a **Custom** object and a “closure”, which is a void pointer. In this case, the closure is ignored. (The closure supports an advanced usage in which definition data is passed to the getter and setter. This could, for example, be used to allow a single set of getter and setter functions that decide the attribute to get or set based on data in the closure.)

The setter function is passed the **Custom** object, the new value, and the closure. The new value may be `NULL`, in which case the attribute is being deleted. In our setter, we raise an error if the attribute is deleted or if its new value is not a string.

We create an array of **PyGetSetDef** structures:

```

static PyGetSetDef Custom_getsetters[] = {
    {"first", (getter) Custom_getfirst, (setter) Custom_setfirst,
     "first name", NULL},
    {"last", (getter) Custom_getlast, (setter) Custom_setlast,
     "last name", NULL},
    {NULL} /* Sentinel */
};

```

and register it in the **tp\_getset** slot:

```

.tp_getset = Custom_getsetters,

```

The last item in a **PyGetSetDef** structure is the “closure” mentioned above. In this case, we aren’t using a closure, so we just

pass NULL.

We also remove the member definitions for these attributes:

```
static PyMemberDef Custom_members[] = {
    {"number", T_INT, offsetof(CustomObject, number), 0,
     "custom number"},
    {NULL} /* Sentinel */
};
```

We also need to update the `tp_init` handler to only allow strings [3](#) to be passed:

```
static int
Custom_init(CustomObject *self, PyObject *args, PyObject
{
    static char *kwlist[] = {"first", "last", "number",
    PyObject *first = NULL, *last = NULL, *tmp;

    if (!PyArg_ParseTupleAndKeywords(args, kwds, "|UUi",
                                     &first, &last,
                                     &self->number))
        return -1;

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_DECREF(tmp);
    }
    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_DECREF(tmp);
    }
    return 0;
}
```

With these changes, we can assure that the `first` and `last`

members are never `NULL` so we can remove checks for `NULL` values in almost all cases. This means that most of the `Py_XDECREF()` calls can be converted to `Py_DECREF()` calls. The only place we can't change these calls is in the `tp_dealloc` implementation, where there is the possibility that the initialization of these members failed in `tp_new`.

We also rename the module initialization function and module name in the initialization function, as we did before, and we add an extra definition to the `setup.py` file.

## 2.4. Supporting cyclic garbage collection

Python has a [cyclic garbage collector \(GC\)](#) that can identify unneeded objects even when their reference counts are not zero. This can happen when objects are involved in cycles. For example, consider:

```
>>> l = []
>>> l.append(l)
>>> del l
```

In this example, we create a list that contains itself. When we delete it, it still has a reference from itself. Its reference count doesn't drop to zero. Fortunately, Python's cyclic garbage collector will eventually figure out that the list is garbage and free it.

In the second version of the `Custom` example, we allowed any kind of object to be stored in the `first` or `last` attributes [4](#). Besides, in the second and third versions, we allowed subclassing `Custom`, and subclasses may add arbitrary attributes. For any of those two reasons, `Custom` objects can participate in cycles:

```
>>> import custom3
>>> class Derived(custom3.Custom): pass
...
>>> n = Derived()
>>> n.some_attribute = n
```

To allow a `Custom` instance participating in a reference cycle to be

properly detected and collected by the cyclic GC, our **Custom** type needs to fill two additional slots and to enable a flag that enables these slots:

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>
#include "structmember.h"

typedef struct {
    PyObject_HEAD
    PyObject *first; /* first name */
    PyObject *last;  /* last name */
    int number;
} CustomObject;

static int
Custom_traverse(CustomObject *self, visitproc visit, void *arg)
{
    Py_VISIT(self->first);
    Py_VISIT(self->last);
    return 0;
}

static int
Custom_clear(CustomObject *self)
{
    Py_CLEAR(self->first);
    Py_CLEAR(self->last);
    return 0;
}

static void
Custom_dealloc(CustomObject *self)
{
    PyObject_GC_UnTrack(self);
    Custom_clear(self);
    Py_TYPE(self)->tp_free((PyObject *) self);
}
```

```

static PyObject *
Custom_new(PyTypeObject *type, PyObject *args, PyObject
{
    CustomObject *self;
    self = (CustomObject *) type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = PyUnicode_FromString("");
        if (self->first == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->last = PyUnicode_FromString("");
        if (self->last == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->number = 0;
    }
    return (PyObject *) self;
}

```

```

static int
Custom_init(CustomObject *self, PyObject *args, PyObject
{
    static char *kwlist[] = {"first", "last", "number",
    PyObject *first = NULL, *last = NULL, *tmp;

    if (!PyArg_ParseTupleAndKeywords(args, kwds, "|UUi",
                                     &first, &last,
                                     &self->number))
        return -1;

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_DECREF(tmp);
    }
}

```

```

    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_DECREF(tmp);
    }
    return 0;
}

static PyMemberDef Custom_members[] = {
    {"number", T_INT, offsetof(CustomObject, number), 0,
     "custom number"},
    {NULL} /* Sentinel */
};

static PyObject *
Custom_getfirst(CustomObject *self, void *closure)
{
    Py_INCREF(self->first);
    return self->first;
}

static int
Custom_setfirst(CustomObject *self, PyObject *value, void
{
    if (value == NULL) {
        PyErr_SetString(PyExc_TypeError, "Cannot delete
        return -1;
    }
    if (!PyUnicode_Check(value)) {
        PyErr_SetString(PyExc_TypeError,
                        "The first attribute value must
        return -1;
    }
    Py_INCREF(value);
    Py_CLEAR(self->first);
    self->first = value;
    return 0;
}

```

```

}

static PyObject *
Custom_getlast(CustomObject *self, void *closure)
{
    Py_INCREF(self->last);
    return self->last;
}

static int
Custom_setlast(CustomObject *self, PyObject *value, void *closure)
{
    if (value == NULL) {
        PyErr_SetString(PyExc_TypeError, "Cannot delete attribute");
        return -1;
    }
    if (!PyUnicode_Check(value)) {
        PyErr_SetString(PyExc_TypeError,
                        "The last attribute value must be a string");
        return -1;
    }
    Py_INCREF(value);
    Py_CLEAR(self->last);
    self->last = value;
    return 0;
}

static PyGetSetDef Custom_getsetters[] = {
    {"first", (getter) Custom_getfirst, (setter) Custom_setfirst,
     "first name", NULL},
    {"last", (getter) Custom_getlast, (setter) Custom_setlast,
     "last name", NULL},
    {NULL} /* Sentinel */
};

static PyObject *
Custom_name(CustomObject *self, PyObject *Py_UNUSED(ignored))
{
    return PyUnicode_FromObject(self->last);
}

```

```

        return PyUnicode_FromFormat("%S %S", self->first, se
    }

static PyMethodDef Custom_methods[] = {
    {"name", (PyCFunction) Custom_name, METH_NOARGS,
     "Return the name, combining the first and last name
    },
    {NULL} /* Sentinel */
};

static PyTypeObject CustomType = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "custom4.Custom",
    .tp_doc = PyDoc_STR("Custom objects"),
    .tp_basicsize = sizeof(CustomObject),
    .tp_itemsize = 0,
    .tp_flags = Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE
    .tp_new = Custom_new,
    .tp_init = (initproc) Custom_init,
    .tp_dealloc = (destructor) Custom_dealloc,
    .tp_traverse = (traverseproc) Custom_traverse,
    .tp_clear = (inquiry) Custom_clear,
    .tp_members = Custom_members,
    .tp_methods = Custom_methods,
    .tp_getset = Custom_getsetters,
};

static PyModuleDef custommodule = {
    PyModuleDef_HEAD_INIT,
    .m_name = "custom4",
    .m_doc = "Example module that creates an extension t
    .m_size = -1,
};

PyMODINIT_FUNC
PyInit_custom4(void)
{
    PyObject *m;

```

```

    if (PyType_Ready(&CustomType) < 0)
        return NULL;

    m = PyModule_Create(&custommodule);
    if (m == NULL)
        return NULL;

    Py_INCREF(&CustomType);
    if (PyModule_AddObject(m, "Custom", (PyObject *) &CustomType) < 0)
        Py_DECREF(&CustomType);
        Py_DECREF(m);
        return NULL;
    }

    return m;
}

```

First, the traversal method lets the cyclic GC know about subobjects that could participate in cycles:

```

static int
Custom_traverse(CustomObject *self, visitproc visit, void *arg)
{
    int vret;
    if (self->first) {
        vret = visit(self->first, arg);
        if (vret != 0)
            return vret;
    }
    if (self->last) {
        vret = visit(self->last, arg);
        if (vret != 0)
            return vret;
    }
    return 0;
}

```

For each subobject that can participate in cycles, we need to call the **visit ()** function, which is passed to the traversal method. The

**visit()** function takes as arguments the subobject and the extra argument *arg* passed to the traversal method. It returns an integer value that must be returned if it is non-zero.

Python provides a **Py\_VISIT()** macro that automates calling visit functions. With **Py\_VISIT()**, we can minimize the amount of boilerplate in `Custom_traverse`:

```
static int
Custom_traverse(CustomObject *self, visitproc visit, void *arg)
{
    Py_VISIT(self->first);
    Py_VISIT(self->last);
    return 0;
}
```

## Note

The **tp\_traverse** implementation must name its arguments exactly *visit* and *arg* in order to use **Py\_VISIT()**.

Second, we need to provide a method for clearing any subobjects that can participate in cycles:

```
static int
Custom_clear(CustomObject *self)
{
    Py_CLEAR(self->first);
    Py_CLEAR(self->last);
    return 0;
}
```

Notice the use of the **Py\_CLEAR()** macro. It is the recommended and safe way to clear data attributes of arbitrary types while decrementing their reference counts. If you were to call **Py\_XDECREF()** instead on the attribute before setting it to `NULL`, there is a possibility that the attribute's destructor would call back into code that reads the attribute again (*especially* if there is a reference cycle).

## Note

You could emulate `Py_CLEAR()` by writing:

```
PyObject *tmp;
tmp = self->first;
self->first = NULL;
Py_XDECREF(tmp);
```

Nevertheless, it is much easier and less error-prone to always use `Py_CLEAR()` when deleting an attribute. Don't try to micro-optimize at the expense of robustness!

The deallocator `Custom_dealloc` may call arbitrary code when clearing attributes. It means the circular GC can be triggered inside the function. Since the GC assumes reference count is not zero, we need to untrack the object from the GC by calling `PyObject_GC_UnTrack()` before clearing members. Here is our reimplemented deallocator using `PyObject_GC_UnTrack()` and `Custom_clear`:

```
static void
Custom_dealloc(CustomObject *self)
{
    PyObject_GC_UnTrack(self);
    Custom_clear(self);
    Py_TYPE(self)->tp_free((PyObject *) self);
}
```

Finally, we add the `Py_TPFLAGS_HAVE_GC` flag to the class flags:

```
.tp_flags = Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE | Py_TPFLAGS_HAVE_GC
```

That's pretty much it. If we had written custom `tp_alloc` or `tp_free` handlers, we'd need to modify them for cyclic garbage collection. Most extensions will use the versions automatically provided.

## 2.5. Subclassing other types

It is possible to create new extension types that are derived from existing types. It is easiest to inherit from the built in types, since an extension can easily use the `PyTypeObject` it needs. It can be difficult to share these `PyTypeObject` structures between extension modules.

In this example we will create a `SubList` type that inherits from the built-in `list` type. The new type will be completely compatible with regular lists, but will have an additional `increment()` method that increases an internal counter:

```
>>> import sublist
>>> s = sublist.SubList(range(3))
>>> s.extend(s)
>>> print(len(s))
6
>>> print(s.increment())
1
>>> print(s.increment())
2
```

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>
```

```
typedef struct {
    PyListObject list;
    int state;
} SubListObject;
```

```
static PyObject *
SubList_increment(SubListObject *self, PyObject *unused)
{
    self->state++;
    return PyLong_FromLong(self->state);
}
```

```
static PyMethodDef SubList_methods[] = {
    {"increment", (PyCFunction) SubList_increment, METH_
    PyDoc_STR("increment state counter")},
```

```

        {NULL},
    };

static int
SubList_init(SubListObject *self, PyObject *args, PyObject
{
    if (PyList_Type.tp_init((PyObject *) self, args, kwo
        return -1;
    self->state = 0;
    return 0;
}

static PyTypeObject SubListType = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "sublist.SubList",
    .tp_doc = PyDoc_STR("SubList objects"),
    .tp_basicsize = sizeof(SubListObject),
    .tp_itemsize = 0,
    .tp_flags = Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE
    .tp_init = (initproc) SubList_init,
    .tp_methods = SubList_methods,
};

static PyModuleDef sublistmodule = {
    PyModuleDef_HEAD_INIT,
    .m_name = "sublist",
    .m_doc = "Example module that creates an extension t
    .m_size = -1,
};

PyMODINIT_FUNC
PyInit_sublist(void)
{
    PyObject *m;
    SubListType.tp_base = &PyList_Type;
    if (PyType_Ready(&SubListType) < 0)
        return NULL;

```

```

m = PyModule_Create(&sublistmodule);
if (m == NULL)
    return NULL;

Py_INCREF(&SubListType);
if (PyModule_AddObject(m, "SubList", (PyObject *) &SubListType) != 0)
    Py_DECREF(&SubListType);
    Py_DECREF(m);
    return NULL;
}

return m;
}

```

As you can see, the source code closely resembles the **Custom** examples in previous sections. We will break down the main differences between them.

```

typedef struct {
    PyListObject list;
    int state;
} SubListObject;

```

The primary difference for derived type objects is that the base type's object structure must be the first value. The base type will already include the **`PyObject_HEAD()`** at the beginning of its structure.

When a Python object is a **SubList** instance, its `PyObject *` pointer can be safely cast to both `PyListObject *` and `SubListObject *`:

```

static int
SubList_init(SubListObject *self, PyObject *args, PyObject *kwargs)
{
    if (PyList_Type.tp_init((PyObject *) self, args, kwargs) != 0)
        return -1;
    self->state = 0;
    return 0;
}

```

We see above how to call through to the `__init__` method of the base type.

This pattern is important when writing a type with custom `tp_new` and `tp_dealloc` members. The `tp_new` handler should not actually create the memory for the object with its `tp_alloc`, but let the base class handle it by calling its own `tp_new`.

The `PyTypeObject` struct supports a `tp_base` specifying the type's concrete base class. Due to cross-platform compiler issues, you can't fill that field directly with a reference to `PyList_Type`; it should be done later in the module initialization function:

```
PyMODINIT_FUNC
PyInit_sublist(void)
{
    PyObject* m;
    SubListType.tp_base = &PyList_Type;
    if (PyType_Ready(&SubListType) < 0)
        return NULL;

    m = PyModule_Create(&sublistmodule);
    if (m == NULL)
        return NULL;

    Py_INCREF(&SubListType);
    if (PyModule_AddObject(m, "SubList", (PyObject *) &SubListType) < 0)
        Py_DECREF(&SubListType);
    Py_DECREF(m);
    return NULL;
}

return m;
}
```

Before calling `PyType_Ready()`, the type structure must have the `tp_base` slot filled in. When we are deriving an existing type, it is not necessary to fill out the `tp_alloc` slot with `PyType_GenericNew()` – the allocation function from the base type will be inherited.

After that, calling `PyType_Ready()` and adding the type object to the module is the same as with the basic `Custom` examples.

## Footnotes

- 1  
This is true when we know that the object is a basic type, like a string or a float.
- 2  
We relied on this in the `tp_dealloc` handler in this example, because our type doesn't support garbage collection.
- 3  
We now know that the first and last members are strings, so perhaps we could be less careful about decrementing their reference counts, however, we accept instances of string subclasses. Even though deallocating normal strings won't call back into our objects, we can't guarantee that deallocating an instance of a string subclass won't call back into our objects.
- 4  
Also, even with our attributes restricted to strings instances, the user could pass arbitrary `str` subclasses and therefore still create reference cycles.

## 3. Defining Extension Types: Assorted Topics

This section aims to give a quick fly-by on the various type methods you can implement and what they do.

Here is the definition of `PyTypeObject`, with some fields only used in `debug builds` omitted:

```
typedef struct _typeobject {
    PyObject_VAR_HEAD
    const char *tp_name; /* For printing, in format "<mod>.<name>" */
    Py_ssize_t tp_basicsize, tp_itemsize; /* For allocation */

    /* Methods to implement standard operations */

    destructor tp_dealloc;
    Py_ssize_t tp_vectorcall_offset;
    getattrofunc tp_getattr;
    setattrofunc tp_setattr;
    PyAsyncMethods *tp_as_async; /* formerly known as tp_as_async (Python 3.0)
                                   or tp_reserved (Python 2.x) */
    reprfunc tp_repr;

    /* Method suites for standard classes */

    PyNumberMethods *tp_as_number;
    PySequenceMethods *tp_as_sequence;
    PyMappingMethods *tp_as_mapping;

    /* More standard operations (here for binary compatibility)
     *
     * ...
     */

    hashfunc tp_hash;
    ternaryfunc tp_call;
```

```

reprfunc tp_str;
getattrofunc tp_getattro;
setattrofunc tp_setattro;

/* Functions to access object as input/output buffer
PyBufferProcs *tp_as_buffer;

/* Flags to define presence of optional/expanded features
unsigned long tp_flags;

const char *tp_doc; /* Documentation string */

/* Assigned meaning in release 2.0 */
/* call function for all accessible objects */
traverseproc tp_traverse;

/* delete references to contained objects */
inquiry tp_clear;

/* Assigned meaning in release 2.1 */
/* rich comparisons */
richcmpfunc tp_richcompare;

/* weak reference enabler */
Py_ssize_t tp_weaklistoffset;

/* Iterators */
getiterfunc tp_iter;
iternextfunc tp_iternext;

/* Attribute descriptor and subclassing stuff */
struct PyMethodDef *tp_methods;
struct PyMemberDef *tp_members;
struct PyGetSetDef *tp_getset;
// Strong reference on a heap type, borrowed reference
struct _typeobject *tp_base;
PyObject *tp_dict;
descrgetfunc tp_descr_get;

```

```

    descrsetfunc tp_descr_set;
    Py_ssize_t tp_dictoffset;
    initproc tp_init;
    allocfunc tp_alloc;
    newfunc tp_new;
    freefunc tp_free; /* Low-level free-memory routine */
    inquiry tp_is_gc; /* For PyObject_IS_GC */
    PyObject *tp_bases;
    PyObject *tp_mro; /* method resolution order */
    PyObject *tp_cache;
    PyObject *tp_subclasses;
    PyObject *tp_weaklist;
    destructor tp_del;

    /* Type attribute cache version tag. Added in version 3.0 */
    unsigned int tp_version_tag;

    destructor tp_finalize;
    vectorcallfunc tp_vectorcall;
} PyTypeObject;

```

Now that's a *lot* of methods. Don't worry too much though – if you have a type you want to define, the chances are very good that you will only implement a handful of these.

As you probably expect by now, we're going to go over this and give more information about the various handlers. We won't go in the order they are defined in the structure, because there is a lot of historical baggage that impacts the ordering of the fields. It's often easiest to find an example that includes the fields you need and then change the values to suit your new type.

```
const char *tp_name; /* For printing */
```

The name of the type – as mentioned in the previous chapter, this will appear in various places, almost entirely for diagnostic purposes. Try to choose something that will be helpful in such a situation!

```
Py_ssize_t tp_basicsize, tp_itemsize; /* For allocation
```

These fields tell the runtime how much memory to allocate when new objects of this type are created. Python has some built-in support for variable length structures (think: strings, tuples) which is where the `tp_itemsize` field comes in. This will be dealt with later.

```
const char *tp_doc;
```

Here you can put a string (or its address) that you want returned when the Python script references `obj.__doc__` to retrieve the doc string.

Now we come to the basic type methods – the ones most extension types will implement.

## 3.1. Finalization and De-allocation

```
destructor tp_dealloc;
```

This function is called when the reference count of the instance of your type is reduced to zero and the Python interpreter wants to reclaim it. If your type has memory to free or other clean-up to perform, you can put it here. The object itself needs to be freed here as well. Here is an example of this function:

```
static void
newdatatype_dealloc(newdatatypeobject *obj)
{
    free(obj->obj_UnderlyingDatatypePtr);
    Py_TYPE(obj)->tp_free((PyObject *)obj);
}
```

If your type supports garbage collection, the destructor should call `PyObject_GC_UnTrack()` before clearing any member fields:

```
static void
newdatatype_dealloc(newdatatypeobject *obj)
{
    PyObject_GC_UnTrack(obj);
    Py_CLEAR(obj->other_obj);
}
```

```

    ...
    Py_TYPE(obj) -> tp_free((PyObject *)obj);
}

```

One important requirement of the deallocator function is that it leaves any pending exceptions alone. This is important since deallocators are frequently called as the interpreter unwinds the Python stack; when the stack is unwound due to an exception (rather than normal returns), nothing is done to protect the deallocators from seeing that an exception has already been set. Any actions which a deallocator performs which may cause additional Python code to be executed may detect that an exception has been set. This can lead to misleading errors from the interpreter. The proper way to protect against this is to save a pending exception before performing the unsafe action, and restoring it when done. This can be done using the `PyErr_Fetch()` and `PyErr_Restore()` functions:

```

static void
my_dealloc(PyObject *obj)
{
    PyObject *self = (PyObject *) obj;
    PyObject *cbresult;

    if (self->my_callback != NULL) {
        PyObject *err_type, *err_value, *err_traceback;

        /* This saves the current exception state */
        PyErr_Fetch(&err_type, &err_value, &err_traceback);

        cbresult = PyObject_CallNoArgs(self->my_callback);
        if (cbresult == NULL)
            PyErr_WriteUnraisable(self->my_callback);
        else
            Py_DECREF(cbresult);

        /* This restores the saved exception state */
        PyErr_Restore(err_type, err_value, err_traceback);
    }
}

```

```

        Py_DECREF(self->my_callback);
    }
    Py_TYPE(obj)->tp_free((PyObject*)self);
}

```

## Note

There are limitations to what you can safely do in a deallocator function. First, if your type supports garbage collection (using `tp_traverse` and/or `tp_clear`), some of the object's members can have been cleared or finalized by the time `tp_dealloc` is called. Second, in `tp_dealloc`, your object is in an unstable state: its reference count is equal to zero. Any call to a non-trivial object or API (as in the example above) might end up calling `tp_dealloc` again, causing a double free and a crash.

Starting with Python 3.4, it is recommended not to put any complex finalization code in `tp_dealloc`, and instead use the new `tp_finalize` type method.

## See also

[PEP 442](https://peps.python.org/pep-0442/) [https://peps.python.org/pep-0442/] explains the new finalization scheme.

## 3.2. Object Presentation

In Python, there are two ways to generate a textual representation of an object: the `repr()` function, and the `str()` function. (The `print()` function just calls `str()`.) These handlers are both optional.

```

reprfunc tp_repr;
reprfunc tp_str;

```

The `tp_repr` handler should return a string object containing a

representation of the instance for which it is called. Here is a simple example:

```
static PyObject *
newdatatype_repr(newdatatypeobject * obj)
{
    return PyUnicode_FromFormat("Repr-ified_newdatatype{
                                obj->obj_UnderlyingData
```

If no `tp_repr` handler is specified, the interpreter will supply a representation that uses the type's `tp_name` and a uniquely identifying value for the object.

The `tp_str` handler is to `str()` what the `tp_repr` handler described above is to `repr()`; that is, it is called when Python code calls `str()` on an instance of your object. Its implementation is very similar to the `tp_repr` function, but the resulting string is intended for human consumption. If `tp_str` is not specified, the `tp_repr` handler is used instead.

Here is a simple example:

```
static PyObject *
newdatatype_str(newdatatypeobject * obj)
{
    return PyUnicode_FromFormat("Stringified_newdatatype
                                obj->obj_UnderlyingData
```

### 3.3. Attribute Management

For every object which can support attributes, the corresponding type must provide the functions that control how the attributes are resolved. There needs to be a function which can retrieve attributes (if any are defined), and another to set attributes (if setting attributes is allowed). Removing an attribute is a special case, for which the new value passed to the handler is `NULL`.

Python supports two pairs of attribute handlers; a type that

supports attributes only needs to implement the functions for one pair. The difference is that one pair takes the name of the attribute as a `char*`, while the other accepts a `PyObject*`. Each type can use whichever pair makes more sense for the implementation's convenience.

```
getattrfunc  tp_getattr;           /* char * version */
setattrfunc  tp_setattr;
/* ... */
getattrofunc tp_getattro;         /* PyObject * version */
setattrofunc tp_setattro;
```

If accessing attributes of an object is always a simple operation (this will be explained shortly), there are generic implementations which can be used to provide the `PyObject*` version of the attribute management functions. The actual need for type-specific attribute handlers almost completely disappeared starting with Python 2.2, though there are many examples which have not been updated to use some of the new generic mechanism that is available.

### 3.3.1. Generic Attribute Management

Most extension types only use *simple* attributes. So, what makes the attributes simple? There are only a couple of conditions that must be met:

1. The name of the attributes must be known when `PyType_Ready()` is called.
2. No special processing is needed to record that an attribute was looked up or set, nor do actions need to be taken based on the value.

Note that this list does not place any restrictions on the values of the attributes, when the values are computed, or how relevant data is stored.

When `PyType_Ready()` is called, it uses three tables referenced by the type object to create `descriptors` which are placed in the dictionary of the type object. Each descriptor controls access to one attribute of the instance object. Each of the tables is optional; if all

three are `NULL`, instances of the type will only have attributes that are inherited from their base type, and should leave the `tp_getattro` and `tp_setattro` fields `NULL` as well, allowing the base type to handle attributes.

The tables are declared as three fields of the type object:

```
struct PyMethodDef *tp_methods;  
struct PyMemberDef *tp_members;  
struct PyGetSetDef *tp_getset;
```

If `tp_methods` is not `NULL`, it must refer to an array of `PyMethodDef` structures. Each entry in the table is an instance of this structure:

```
typedef struct PyMethodDef {  
    const char *ml_name;           /* method name */  
    PyCFunction ml_meth;           /* implementation function */  
    int ml_flags;                  /* flags */  
    const char *ml_doc;            /* docstring */  
} PyMethodDef;
```

One entry should be defined for each method provided by the type; no entries are needed for methods inherited from a base type. One additional entry is needed at the end; it is a sentinel that marks the end of the array. The `ml_name` field of the sentinel must be `NULL`.

The second table is used to define attributes which map directly to data stored in the instance. A variety of primitive C types are supported, and access may be read-only or read-write. The structures in the table are defined as:

```
typedef struct PyMemberDef {  
    const char *name;  
    int type;  
    int offset;  
    int flags;  
    const char *doc;  
} PyMemberDef;
```

For each entry in the table, a `descriptor` will be constructed and

added to the type which will be able to extract a value from the instance structure. The `type` field should contain one of the type codes defined in the `structmember.h` header; the value will be used to determine how to convert Python values to and from C values. The `flags` field is used to store flags which control how the attribute can be accessed.

The following flag constants are defined in `structmember.h`; they may be combined using bitwise-OR.

#### ~~Warning~~

---

~~READONLY~~able.

---

~~Py\_AUDIT\_READ~~. `__getattr__` `audit events` before reading.

---

*Changed in version 3.10:* **RESTRICTED**, **READ\_RESTRICTED** and **WRITE\_RESTRICTED** are deprecated. However, **READ\_RESTRICTED** is an alias for **PY\_AUDIT\_READ**, so fields that specify either **RESTRICTED** or **READ\_RESTRICTED** will also raise an audit event.

An interesting advantage of using the `tp_members` table to build descriptors that are used at runtime is that any attribute defined this way can have an associated doc string simply by providing the text in the table. An application can use the introspection API to retrieve the descriptor from the class object, and get the doc string using its `__doc__` attribute.

As with the `tp_methods` table, a sentinel entry with a `name` value of `NULL` is required.

### 3.3.2. Type-specific Attribute Management

For simplicity, only the `char*` version will be demonstrated here; the type of the `name` parameter is the only difference between the `char*` and `PyObject*` flavors of the interface. This example effectively does the same thing as the generic example above, but does not use the generic support added in Python 2.2. It explains how the handler functions are called, so that if you do need to extend their functionality, you'll understand what needs to be done.

The `tp_getattr` handler is called when the object requires an

attribute look-up. It is called in the same situations where the `__getattr__()` method of a class would be called.

Here is an example:

```
static PyObject *
newdatatype_getattr(newdatatypeobject *obj, char *name)
{
    if (strcmp(name, "data") == 0)
    {
        return PyLong_FromLong(obj->data);
    }

    PyErr_Format(PyExc_AttributeError,
                 "'%.50s' object has no attribute '%.40s'",
                 tp->tp_name, name);
    return NULL;
}
```

The `tp_setattr` handler is called when the `__setattr__()` or `__delattr__()` method of a class instance would be called. When an attribute should be deleted, the third parameter will be `NULL`. Here is an example that simply raises an exception; if this were really all you wanted, the `tp_setattr` handler should be set to `NULL`.

```
static int
newdatatype_setattr(newdatatypeobject *obj, char *name,
{
    PyErr_Format(PyExc_RuntimeError, "Read-only attribute");
    return -1;
}
```

## 3.4. Object Comparison

```
richcmpfunc tp_richcompare;
```

The `tp_richcompare` handler is called when comparisons are needed. It is analogous to the [rich comparison methods](#), like

`__lt__()`, and also called by `PyObject_RichCompare()` and `PyObject_RichCompareBool()`.

This function is called with two Python objects and the operator as arguments, where the operator is one of `Py_EQ`, `Py_NE`, `Py_LE`, `Py_GE`, `Py_LT` or `Py_GT`. It should compare the two objects with respect to the specified operator and return `Py_True` or `Py_False` if the comparison is successful, `Py_NotImplemented` to indicate that comparison is not implemented and the other object's comparison method should be tried, or `NULL` if an exception was set.

Here is a sample implementation, for a datatype that is considered equal if the size of an internal pointer is equal:

```
static PyObject *
newdatatype_richcmp(PyObject *obj1, PyObject *obj2, int
{
    PyObject *result;
    int c, size1, size2;

    /* code to make sure that both arguments are of type
       newdatatype omitted */

    size1 = obj1->obj_UnderlyingDatatypePtr->size;
    size2 = obj2->obj_UnderlyingDatatypePtr->size;

    switch (op) {
    case Py_LT: c = size1 < size2; break;
    case Py_LE: c = size1 <= size2; break;
    case Py_EQ: c = size1 == size2; break;
    case Py_NE: c = size1 != size2; break;
    case Py_GT: c = size1 > size2; break;
    case Py_GE: c = size1 >= size2; break;
    }
    result = c ? Py_True : Py_False;
    Py_INCREF(result);
    return result;
}
```

## 3.5. Abstract Protocol Support

Python supports a variety of *abstract* ‘protocols;’ the specific interfaces provided to use these interfaces are documented in [Abstract Objects Layer](#).

A number of these abstract interfaces were defined early in the development of the Python implementation. In particular, the number, mapping, and sequence protocols have been part of Python since the beginning. Other protocols have been added over time. For protocols which depend on several handler routines from the type implementation, the older protocols have been defined as optional blocks of handlers referenced by the type object. For newer protocols there are additional slots in the main type object, with a flag bit being set to indicate that the slots are present and should be checked by the interpreter. (The flag bit does not indicate that the slot values are non-NULL. The flag may be set to indicate the presence of a slot, but a slot may still be unfilled.)

```
PyNumberMethods    *tp_as_number;  
PySequenceMethods  *tp_as_sequence;  
PyMappingMethods    *tp_as_mapping;
```

If you wish your object to be able to act like a number, a sequence, or a mapping object, then you place the address of a structure that implements the C type [PyNumberMethods](#), [PySequenceMethods](#), or [PyMappingMethods](#), respectively. It is up to you to fill in this structure with appropriate values. You can find examples of the use of each of these in the `Objects` directory of the Python source distribution.

```
hashfunc tp_hash;
```

This function, if you choose to provide it, should return a hash number for an instance of your data type. Here is a simple example:

```
static Py_hash_t  
newdatatype_hash(newdatatypeobject *obj)  
{  
    Py_hash_t result;
```

```

    result = obj->some_size + 32767 * obj->some_number;
    if (result == -1)
        result = -2;
    return result;
}

```

**Py\_hash\_t** is a signed integer type with a platform-varying width. Returning `-1` from **tp\_hash** indicates an error, which is why you should be careful to avoid returning it when hash computation is successful, as seen above.

```
ternaryfunc tp_call;
```

This function is called when an instance of your data type is “called”, for example, if `obj1` is an instance of your data type and the Python script contains `obj1('hello')`, the **tp\_call** handler is invoked.

This function takes three arguments:

1. *self* is the instance of the data type which is the subject of the call. If the call is `obj1('hello')`, then *self* is `obj1`.
2. *args* is a tuple containing the arguments to the call. You can use **PyArg\_ParseTuple()** to extract the arguments.
3. *kwds* is a dictionary of keyword arguments that were passed. If this is non-NULL and you support keyword arguments, use **PyArg\_ParseTupleAndKeywords()** to extract the arguments. If you do not want to support keyword arguments and this is non-NULL, raise a **TypeError** with a message saying that keyword arguments are not supported.

Here is a toy `tp_call` implementation:

```

static PyObject *
newdatatype_call(newdatatypeobject *self, PyObject *args)
{
    PyObject *result;
    const char *arg1;
    const char *arg2;
    const char *arg3;

```

```

    if (!PyArg_ParseTuple(args, "sss:call", &arg1, &arg2, &arg3))
        return NULL;
}

result = PyUnicode_FromFormat(
    "Returning -- value: [%d] arg1: [%s] arg2: [%s] arg3: [%s]\n",
    obj->obj_UnderlyingDatatypePtr->size,
    arg1, arg2, arg3);
return result;
}

/* Iterators */
getiterfunc tp_iter;
iternextfunc tp_iternext;

```

These functions provide support for the iterator protocol. Both handlers take exactly one parameter, the instance for which they are being called, and return a new reference. In the case of an error, they should set an exception and return `NULL`. `tp_iter` corresponds to the Python `__iter__()` method, while `tp_iternext` corresponds to the Python `__next__()` method.

Any `iterable` object must implement the `tp_iter` handler, which must return an `iterator` object. Here the same guidelines apply as for Python classes:

- For collections (such as lists and tuples) which can support multiple independent iterators, a new iterator should be created and returned by each call to `tp_iter`.
- Objects which can only be iterated over once (usually due to side effects of iteration, such as file objects) can implement `tp_iter` by returning a new reference to themselves – and should also therefore implement the `tp_iternext` handler.

Any `iterator` object should implement both `tp_iter` and `tp_iternext`. An iterator's `tp_iter` handler should return a new reference to the iterator. Its `tp_iternext` handler should return a new reference to the next object in the iteration, if there is one. If the iteration has reached the end, `tp_iternext` may return `NULL` without setting an exception, or it may set `StopIteration` in addition to returning `NULL`; avoiding the exception can yield

slightly better performance. If an actual error occurs, `tp_internext` should always set an exception and return `NULL`.

## 3.6. Weak Reference Support

One of the goals of Python's weak reference implementation is to allow any type to participate in the weak reference mechanism without incurring the overhead on performance-critical objects (such as numbers).

### See also

Documentation for the `weakref` module.

For an object to be weakly referencable, the extension type must do two things:

1. Include a `PyObject*` field in the C object structure dedicated to the weak reference mechanism. The object's constructor should leave it `NULL` (which is automatic when using the default `tp_alloc`).
2. Set the `tp_weaklistoffset` type member to the offset of the aforementioned field in the C object structure, so that the interpreter knows how to access and modify that field.

Concretely, here is how a trivial object structure would be augmented with the required field:

```
typedef struct {  
    PyObject_HEAD  
    PyObject *weakreflist; /* List of weak references */  
} TrivialObject;
```

And the corresponding member in the statically declared type object:

```
static PyTypeObject TrivialType = {  
    PyVarObject_HEAD_INIT(NULL, 0)  
    /* ... other members omitted for brevity ... */  
};
```

```

        .tp_weaklistoffset = offsetof(TrivialObject, weakref
    };

```

The only further addition is that `tp_dealloc` needs to clear any weak references (by calling `PyObject_ClearWeakRefs()`) if the field is non-NULL:

```

static void
Trivial_dealloc(TrivialObject *self)
{
    /* Clear weakrefs first before calling any destructo
    if (self->weakreflist != NULL)
        PyObject_ClearWeakRefs((PyObject *) self);
    /* ... remainder of destruction code omitted for bre
    Py_TYPE(self)->tp_free((PyObject *) self);
}

```

## 3.7. More Suggestions

In order to learn how to implement any specific method for your new data type, get the [CPython](#) source code. Go to the `Objects` directory, then search the C source files for `tp_` plus the function you want (for example, `tp_richcompare`). You will find examples of the function you want to implement.

When you need to verify that an object is a concrete instance of the type you are implementing, use the `PyObject_TypeCheck()` function. A sample of its use might be something like the following:

```

if (!PyObject_TypeCheck(some_object, &MyType)) {
    PyErr_SetString(PyExc_TypeError, "arg #1 not a mythi
    return NULL;
}

```

## 4. Building C and C++ Extensions

A C extension for CPython is a shared library (e.g. a `.so` file on Linux, `.pyd` on Windows), which exports an *initialization function*.

To be importable, the shared library must be available on [PYTHONPATH](#), and must be named after the module name, with an appropriate extension. When using `distutils`, the correct filename is generated automatically.

The initialization function has the signature:

```
PyObject *PyInit_modulename(void)
```

It returns either a fully initialized module, or a [PyModuleDef](#) instance. See [Initializing C modules](#) for details.

For modules with ASCII-only names, the function must be named `PyInit_<modulename>`, with `<modulename>` replaced by the name of the module. When using [Multi-phase initialization](#), non-ASCII module names are allowed. In this case, the initialization function name is `PyInitU_<modulename>`, with `<modulename>` encoded using Python's *punycode* encoding with hyphens replaced by underscores. In Python:

```
def initfunc_name(name):
    try:
        suffix = b'_' + name.encode('ascii')
    except UnicodeEncodeError:
        suffix = b'U_' + name.encode('punycode').replace(
            '-', '_')
    return b'PyInit' + suffix
```

It is possible to export multiple modules from a single shared library by defining multiple initialization functions. However,

importing them requires using symbolic links or a custom importer, because by default only the function corresponding to the filename is found. See the “*Multiple modules in one library*” section in [PEP 489](https://peps.python.org/pep-0489/) [https://peps.python.org/pep-0489/] for details.

## 4.1. Building C and C++ Extensions with distutils

Extension modules can be built using distutils, which is included in Python. Since distutils also supports creation of binary packages, users don’t necessarily need a compiler and distutils to install the extension.

A distutils package contains a driver script, `setup.py`. This is a plain Python file, which, in the most simple case, could look like this:

```
from distutils.core import setup, Extension

module1 = Extension('demo',
                    sources = ['demo.c'])

setup (name = 'PackageName',
       version = '1.0',
       description = 'This is a demo package',
       ext_modules = [module1])
```

With this `setup.py`, and a file `demo.c`, running

```
python setup.py build
```

will compile `demo.c`, and produce an extension module named `demo` in the `build` directory. Depending on the system, the module file will end up in a subdirectory `build/lib.system`, and may have a name like `demo.so` or `demo.pyd`.

In the `setup.py`, all execution is performed by calling the `setup` function. This takes a variable number of keyword arguments, of which the example above uses only a subset. Specifically, the

example specifies meta-information to build packages, and it specifies the contents of the package. Normally, a package will contain additional modules, like Python source modules, documentation, subpackages, etc. Please refer to the distutils documentation in [Distributing Python Modules \(Legacy version\)](#) to learn more about the features of distutils; this section explains building extension modules only.

It is common to pre-compute arguments to `setup()`, to better structure the driver script. In the example above, the `ext_modules` argument to `setup()` is a list of extension modules, each of which is an instance of the `Extension`. In the example, the instance defines an extension named `demo` which is build by compiling a single source file, `demo.c`.

In many cases, building an extension is more complex, since additional preprocessor defines and libraries may be needed. This is demonstrated in the example below.

```
from distutils.core import setup, Extension

module1 = Extension('demo',
                    define_macros = [('MAJOR_VERSION', '1'),
                                     ('MINOR_VERSION', '0')],
                    include_dirs = ['/usr/local/include'],
                    libraries = ['tcl83'],
                    library_dirs = ['/usr/local/lib'],
                    sources = ['demo.c'])

setup (name = 'PackageName',
      version = '1.0',
      description = 'This is a demo package',
      author = 'Martin v. Loewis',
      author_email = 'martin@v.loewis.de',
      url = 'https://docs.python.org/extending/building',
      long_description = '''
This is really just a demo package.
''',
      ext_modules = [module1])
```

In this example, `setup()` is called with additional meta-information, which is recommended when distribution packages have to be built. For the extension itself, it specifies preprocessor defines, include directories, library directories, and libraries. Depending on the compiler, distutils passes this information in different ways to the compiler. For example, on Unix, this may result in the compilation commands

```
gcc -DNDEBUG -g -O3 -Wall -Wstrict-prototypes -fPIC -DMA
```

```
gcc -shared build/temp.linux-i686-2.2/demo.o -L/usr/loca
```

These lines are for demonstration purposes only; distutils users should trust that distutils gets the invocations right.

## 4.2. Distributing your extension modules

When an extension has been successfully built, there are three ways to use it.

End-users will typically want to install the module, they do so by running

```
python setup.py install
```

Module maintainers should produce source packages; to do so, they run

```
python setup.py sdist
```

In some cases, additional files need to be included in a source distribution; this is done through a `MANIFEST.in` file; see [Specifying the files to distribute](#) for details.

If the source distribution has been built successfully, maintainers can also create binary distributions. Depending on the platform, one of the following commands can be used to do so.

```
python setup.py bdist_rpm
python setup.py bdist_dumb
```

## 5. Building C and C++ Extensions on Windows

This chapter briefly explains how to create a Windows extension module for Python using Microsoft Visual C++, and follows with more detailed background information on how it works. The explanatory material is useful for both the Windows programmer learning to build Python extensions and the Unix programmer interested in producing software which can be successfully built on both Unix and Windows.

Module authors are encouraged to use the `distutils` approach for building extension modules, instead of the one described in this section. You will still need the C compiler that was used to build Python; typically Microsoft Visual C++.

### Note

This chapter mentions a number of filenames that include an encoded Python version number. These filenames are represented with the version number shown as `XY`; in practice, 'X' will be the major version number and 'Y' will be the minor version number of the Python release you're working with. For example, if you are using Python 2.2.1, `XY` will actually be `22`.

### 5.1. A Cookbook Approach

There are two approaches to building extension modules on Windows, just as there are on Unix: use the `distutils` package to control the build process, or do things manually. The `distutils` approach works well for most extensions; documentation on using `distutils` to build and package extension modules is available in [Distributing Python Modules \(Legacy version\)](#). If you find you really

need to do things manually, it may be instructive to study the project file for the [winsound](https://github.com/python/cpython/tree/3.11/PCbuild/winsound.vcxproj) [https://github.com/python/cpython/tree/3.11/PCbuild/winsound.vcxproj] standard library module.

## 5.2. Differences Between Unix and Windows

Unix and Windows use completely different paradigms for run-time loading of code. Before you try to build a module that can be dynamically loaded, be aware of how your system works.

In Unix, a shared object (`.so`) file contains code to be used by the program, and also the names of functions and data that it expects to find in the program. When the file is joined to the program, all references to those functions and data in the file's code are changed to point to the actual locations in the program where the functions and data are placed in memory. This is basically a link operation.

In Windows, a dynamic-link library (`.dll`) file has no dangling references. Instead, an access to functions or data goes through a lookup table. So the DLL code does not have to be fixed up at runtime to refer to the program's memory; instead, the code already uses the DLL's lookup table, and the lookup table is modified at runtime to point to the functions and data.

In Unix, there is only one type of library file (`.a`) which contains code from several object files (`.o`). During the link step to create a shared object file (`.so`), the linker may find that it doesn't know where an identifier is defined. The linker will look for it in the object files in the libraries; if it finds it, it will include all the code from that object file.

In Windows, there are two types of library, a static library and an import library (both called `.lib`). A static library is like a Unix `.a` file; it contains code to be included as necessary. An import library is basically used only to reassure the linker that a certain identifier is legal, and will be present in the program when the DLL is loaded. So the linker uses the information from the import library to build the lookup table for using identifiers that are not included in the DLL. When an application or a DLL is linked, an import library may

be generated, which will need to be used for all future DLLs that depend on the symbols in the application or DLL.

Suppose you are building two dynamic-load modules, B and C, which should share another block of code A. On Unix, you would *not* pass `A.a` to the linker for `B.so` and `C.so`; that would cause it to be included twice, so that B and C would each have their own copy. In Windows, building `A.dll` will also build `A.lib`. You *do* pass `A.lib` to the linker for B and C. `A.lib` does not contain code; it just contains information which will be used at runtime to access A's code.

In Windows, using an import library is sort of like using `import spam`; it gives you access to spam's names, but does not create a separate copy. On Unix, linking with a library is more like `from spam import *`; it does create a separate copy.

## 5.3. Using DLLs in Practice

Windows Python is built in Microsoft Visual C++; using other compilers may or may not work. The rest of this section is MSVC++ specific.

When creating DLLs in Windows, you must pass `pythonXY.lib` to the linker. To build two DLLs, `spam` and `ni` (which uses C functions found in `spam`), you could use these commands:

```
cl /LD /I/python/include spam.c ../libs/pythonXY.lib
cl /LD /I/python/include ni.c spam.lib ../libs/pythonXY.lib
```

The first command created three files: `spam.obj`, `spam.dll` and `spam.lib`. `Spam.dll` does not contain any Python functions (such as `PyArg_ParseTuple()`), but it does know how to find the Python code thanks to `pythonXY.lib`.

The second command created `ni.dll` (and `.obj` and `.lib`), which knows how to find the necessary functions from `spam`, and also from the Python executable.

Not every identifier is exported to the lookup table. If you want any

other modules (including Python) to be able to see your identifiers, you have to say `_declspec(dllexport)`, as in `void _declspec(dllexport) initspam(void)` or `PyObject _declspec(dllexport) *NiGetSpamData(void)`.

Developer Studio will throw in a lot of import libraries that you do not really need, adding about 100K to your executable. To get rid of them, use the Project Settings dialog, Link tab, to specify *ignore default libraries*. Add the correct `msvcrtxx.lib` to the list of libraries.

# 1. Embedding Python in Another Application

The previous chapters discussed how to extend Python, that is, how to extend the functionality of Python by attaching a library of C functions to it. It is also possible to do it the other way around: enrich your C/C++ application by embedding Python in it. Embedding provides your application with the ability to implement some of the functionality of your application in Python rather than C or C++. This can be used for many purposes; one example would be to allow users to tailor the application to their needs by writing some scripts in Python. You can also use it yourself if some of the functionality can be written in Python more easily.

Embedding Python is similar to extending it, but not quite. The difference is that when you extend Python, the main program of the application is still the Python interpreter, while if you embed Python, the main program may have nothing to do with Python — instead, some parts of the application occasionally call the Python interpreter to run some Python code.

So if you are embedding Python, you are providing your own main program. One of the things this main program has to do is initialize the Python interpreter. At the very least, you have to call the function `Py_Initialize()`. There are optional calls to pass command line arguments to Python. Then later you can call the interpreter from any part of the application.

There are several different ways to call the interpreter: you can pass a string containing Python statements to `PyRun_SimpleString()`, or you can pass a stdio file pointer and a file name (for identification in error messages only) to `PyRun_SimpleFile()`. You can also call the lower-level operations described in the previous chapters to construct and use Python objects.

See also

### Python/C API Reference Manual

The details of Python's C interface are given in this manual. A great deal of necessary information can be found [here](#).

## 1.1. Very High Level Embedding

The simplest form of embedding Python is the use of the very high level interface. This interface is intended to execute a Python script without needing to interact with the application directly. This can for example be used to perform some operation on a file.

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>

int
main(int argc, char *argv[])
{
    wchar_t *program = Py_DecodeLocale(argv[0], NULL);
    if (program == NULL) {
        fprintf(stderr, "Fatal error: cannot decode argv[0]\n");
        exit(1);
    }
    Py_SetProgramName(program); /* optional but recommended */
    Py_Initialize();
    PyRun_SimpleString("from time import time,ctime\n"
                      "print('Today is', ctime(time()))");
    if (Py_FinalizeEx() < 0) {
        exit(120);
    }
    PyMem_RawFree(program);
    return 0;
}
```

The `Py_SetProgramName()` function should be called before `Py_Initialize()` to inform the interpreter about paths to Python

run-time libraries. Next, the Python interpreter is initialized with `Py_Initialize()`, followed by the execution of a hard-coded Python script that prints the date and time. Afterwards, the `Py_FinalizeEx()` call shuts the interpreter down, followed by the end of the program. In a real program, you may want to get the Python script from another source, perhaps a text-editor routine, a file, or a database. Getting the Python code from a file can better be done by using the `PyRun_SimpleFile()` function, which saves you the trouble of allocating memory space and loading the file contents.

## 1.2. Beyond Very High Level Embedding: An overview

The high level interface gives you the ability to execute arbitrary pieces of Python code from your application, but exchanging data values is quite cumbersome to say the least. If you want that, you should use lower level calls. At the cost of having to write more C code, you can achieve almost anything.

It should be noted that extending Python and embedding Python is quite the same activity, despite the different intent. Most topics discussed in the previous chapters are still valid. To show this, consider what the extension code from Python to C really does:

1. Convert data values from Python to C,
2. Perform a function call to a C routine using the converted values, and
3. Convert the data values from the call from C to Python.

When embedding Python, the interface code does:

1. Convert data values from C to Python,
2. Perform a function call to a Python interface routine using the converted values, and
3. Convert the data values from the call from Python to C.

As you can see, the data conversion steps are simply swapped to accommodate the different direction of the cross-language transfer. The only difference is the routine that you call between both data

conversions. When extending, you call a C routine, when embedding, you call a Python routine.

This chapter will not discuss how to convert data from Python to C and vice versa. Also, proper use of references and dealing with errors is assumed to be understood. Since these aspects do not differ from extending the interpreter, you can refer to earlier chapters for the required information.

## 1.3. Pure Embedding

The first program aims to execute a function in a Python script. Like in the section about the very high level interface, the Python interpreter does not directly interact with the application (but that will change in the next section).

The code to run a function defined in a Python script is:

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>

int
main(int argc, char *argv[])
{
    PyObject *pName, *pModule, *pFunc;
    PyObject *pArgs, *pValue;
    int i;

    if (argc < 3) {
        fprintf(stderr, "Usage: call pythonfile funcname\n");
        return 1;
    }

    Py_Initialize();
    pName = PyUnicode_DecodeFSDefault(argv[1]);
    /* Error checking of pName left out */

    pModule = PyImport_Import(pName);
    Py_DECREF(pName);
```

```

if (pModule != NULL) {
    pFunc = PyObject_GetAttrString(pModule, argv[2])
    /* pFunc is a new reference */

    if (pFunc && PyCallable_Check(pFunc)) {
        pArgs = PyTuple_New(argc - 3);
        for (i = 0; i < argc - 3; ++i) {
            pValue = PyLong_FromLong(atoi(argv[i + 3]));
            if (!pValue) {
                Py_DECREF(pArgs);
                Py_DECREF(pModule);
                fprintf(stderr, "Cannot convert argument\n");
                return 1;
            }
            /* pValue reference stolen here: */
            PyTuple_SetItem(pArgs, i, pValue);
        }
        pValue = PyObject_CallObject(pFunc, pArgs);
        Py_DECREF(pArgs);
        if (pValue != NULL) {
            printf("Result of call: %ld\n", PyLong_AsLong(pValue));
            Py_DECREF(pValue);
        }
        else {
            Py_DECREF(pFunc);
            Py_DECREF(pModule);
            PyErr_Print();
            fprintf(stderr, "Call failed\n");
            return 1;
        }
    }
    else {
        if (PyErr_Occurred())
            PyErr_Print();
        fprintf(stderr, "Cannot find function \"%s\"\n", argv[2]);
    }
    Py_XDECREF(pFunc);
}

```

```

        Py_DECREF(pModule);
    }
    else {
        PyErr_Print();
        fprintf(stderr, "Failed to load \"%s\"\n", argv[1]);
        return 1;
    }
    if (Py_FinalizeEx() < 0) {
        return 120;
    }
    return 0;
}

```

This code loads a Python script using `argv[1]`, and calls the function named in `argv[2]`. Its integer arguments are the other values of the `argv` array. If you [compile and link](#) this program (let's call the finished executable **call**), and use it to execute a Python script, such as:

```

def multiply(a,b):
    print("Will compute", a, "times", b)
    c = 0
    for i in range(0, a):
        c = c + b
    return c

```

then the result should be:

```

$ call multiply multiply 3 2
Will compute 3 times 2
Result of call: 6

```

Although the program is quite large for its functionality, most of the code is for data conversion between Python and C, and for error reporting. The interesting part with respect to embedding Python starts with

```

Py_Initialize();
pName = PyUnicode_DecodeFSDefault(argv[1]);
/* Error checking of pName left out */

```

```
pModule = PyImport_Import(pName);
```

After initializing the interpreter, the script is loaded using `PyImport_Import()`. This routine needs a Python string as its argument, which is constructed using the `PyUnicode_FromString()` data conversion routine.

```
pFunc = PyObject_GetAttrString(pModule, argv[2]);  
/* pFunc is a new reference */
```

```
if (pFunc && PyCallable_Check(pFunc)) {  
    ...  
}  
Py_XDECREF(pFunc);
```

Once the script is loaded, the name we're looking for is retrieved using `PyObject_GetAttrString()`. If the name exists, and the object returned is callable, you can safely assume that it is a function. The program then proceeds by constructing a tuple of arguments as normal. The call to the Python function is then made with:

```
pValue = PyObject_CallObject(pFunc, pArgs);
```

Upon return of the function, `pValue` is either `NULL` or it contains a reference to the return value of the function. Be sure to release the reference after examining the value.

## 1.4. Extending Embedded Python

Until now, the embedded Python interpreter had no access to functionality from the application itself. The Python API allows this by extending the embedded interpreter. That is, the embedded interpreter gets extended with routines provided by the application. While it sounds complex, it is not so bad. Simply forget for a while that the application starts the Python interpreter. Instead, consider the application to be a set of subroutines, and write some glue code that gives Python access to those routines, just like you would write a normal Python extension. For example:

```

static int numargs=0;

/* Return the number of arguments of the application command line
static PyObject*
emb_numargs(PyObject *self, PyObject *args)
{
    if(!PyArg_ParseTuple(args, ":numargs"))
        return NULL;
    return PyLong_FromLong(numargs);
}

static PyMethodDef EmbMethods[] = {
    {"numargs", emb_numargs, METH_VARARGS,
     "Return the number of arguments received by the process",
     {NULL, NULL, 0, NULL}}
};

static PyModuleDef EmbModule = {
    PyModuleDef_HEAD_INIT, "emb", NULL, -1, EmbMethods,
    NULL, NULL, NULL, NULL
};

static PyObject*
PyInit_emb(void)
{
    return PyModule_Create(&EmbModule);
}

```

Insert the above code just above the **main()** function. Also, insert the following two statements before the call to **Py\_Initialize()**:

```

numargs = argc;
PyImport_AppendInittab("emb", &PyInit_emb);

```

These two lines initialize the `numargs` variable, and make the **emb.numargs()** function accessible to the embedded Python interpreter. With these extensions, the Python script can do things like

```
import emb
print("Number of arguments", emb.numargs())
```

In a real application, the methods will expose an API of the application to Python.

## 1.5. Embedding Python in C++

It is also possible to embed Python in a C++ program; precisely how this is done will depend on the details of the C++ system used; in general you will need to write the main program in C++, and use the C++ compiler to compile and link your program. There is no need to recompile Python itself using C++.

## 1.6. Compiling and Linking under Unix-like systems

It is not necessarily trivial to find the right flags to pass to your compiler (and linker) in order to embed the Python interpreter into your application, particularly because Python needs to load library modules implemented as C dynamic extensions (.so files) linked against it.

To find out the required compiler and linker flags, you can execute the `pythonX.Y-config` script which is generated as part of the installation process (a `python3-config` script may also be available). This script has several options, of which the following will be directly useful to you:

- `pythonX.Y-config --cflags` will give you the recommended flags when compiling:

```
$ /opt/bin/python3.11-config --cflags
-I/opt/include/python3.11 -I/opt/include/python3.11
```

- `pythonX.Y-config --ldflags --embed` will give you the recommended flags when linking:

```
$ /opt/bin/python3.11-config --ldflags --embed
```

```
-L/opt/lib/python3.11/config-3.11-x86_64-linux-gnu
```

## Note

To avoid confusion between several Python installations (and especially between the system Python and your own compiled Python), it is recommended that you use the absolute path to `pythonX.Y-config`, as in the above example.

If this procedure doesn't work for you (it is not guaranteed to work for all Unix-like platforms; however, we welcome [bug reports](#)) you will have to read your system's documentation about dynamic linking and/or examine Python's `Makefile` (use `sysconfig.get_makefile_filename()` to find its location) and compilation options. In this case, the `sysconfig` module is a useful tool to programmatically extract the configuration values that you will want to combine together. For example:

```
>>> import sysconfig
>>> sysconfig.get_config_var('LIBS')
'-lpthread -ldl -lutil'
>>> sysconfig.get_config_var('LINKFORSHARED')
'-Xlinker -export-dynamic'
```

# Python/C API Reference Manual

This manual documents the API used by C and C++ programmers who want to write extension modules or embed Python. It is a companion to [Extending and Embedding the Python Interpreter](#), which describes the general principles of extension writing but does not document the API functions in detail.

# Introduction

The Application Programmer's Interface to Python gives C and C++ programmers access to the Python interpreter at a variety of levels. The API is equally usable from C++, but for brevity it is generally referred to as the Python/C API. There are two fundamentally different reasons for using the Python/C API. The first reason is to write *extension modules* for specific purposes; these are C modules that extend the Python interpreter. This is probably the most common use. The second reason is to use Python as a component in a larger application; this technique is generally referred to as *embedding* Python in an application.

Writing an extension module is a relatively well-understood process, where a “cookbook” approach works well. There are several tools that automate the process to some extent. While people have embedded Python in other applications since its early existence, the process of embedding Python is less straightforward than writing an extension.

Many API functions are useful independent of whether you're embedding or extending Python; moreover, most applications that embed Python will need to provide a custom extension as well, so it's probably a good idea to become familiar with writing an extension before attempting to embed Python in a real application.

## Coding standards

If you're writing C code for inclusion in CPython, you **must** follow the guidelines and standards defined in [PEP 7](https://peps.python.org/pep-0007/) [https://peps.python.org/pep-0007/]. These guidelines apply regardless of the version of Python you are contributing to. Following these conventions is not necessary for your own third party extension modules, unless you eventually expect to contribute them to Python.

# Include Files

All function, type and macro definitions needed to use the Python/C API are included in your code by the following line:

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>
```

This implies inclusion of the following standard headers:

`<stdio.h>`, `<string.h>`, `<errno.h>`, `<limits.h>`,  
`<assert.h>` and `<stdlib.h>` (if available).

## Note

Since Python may define some pre-processor definitions which affect the standard headers on some systems, you *must* include `Python.h` before any standard headers are included.

It is recommended to always define `PY_SSIZE_T_CLEAN` before including `Python.h`. See [Parsing arguments and building values](#) for a description of this macro.

All user visible names defined by `Python.h` (except those defined by the included standard headers) have one of the prefixes `Py` or `_Py`. Names beginning with `_Py` are for internal use by the Python implementation and should not be used by extension writers. Structure member names do not have a reserved prefix.

## Note

User code should never define names that begin with `Py` or `_Py`. This confuses the reader, and jeopardizes the portability of the user code to future Python versions, which may define additional names beginning with one of these prefixes.

The header files are typically installed with Python. On Unix, these are located in the directories `prefix/include/pythonversion/` and `exec_prefix/include/pythonversion/`, where `prefix` and `exec_prefix` are defined

by the corresponding parameters to Python's **configure** script and *version* is `'%d.%d' % sys.version_info[:2]`. On Windows, the headers are installed in *prefix/include*, where *prefix* is the installation directory specified to the installer.

To include the headers, place both directories (if different) on your compiler's search path for includes. Do *not* place the parent directories on the search path and then use `#include <pythonX.Y/Python.h>`; this will break on multi-platform builds since the platform independent headers under **prefix** include the platform specific headers from **exec\_prefix**.

C++ users should note that although the API is defined entirely using C, the header files properly declare the entry points to be `extern "C"`. As a result, there is no need to do anything special to use the API from C++.

## Useful macros

Several useful macros are defined in the Python header files. Many are defined closer to where they are useful (e.g. **Py\_RETURN\_NONE**). Others of a more general utility are defined here. This is not necessarily a complete listing.

**Py\_ABS(x)**

Return the absolute value of *x*.

*New in version 3.3.*

**Py\_ALWAYS\_INLINE**

Ask the compiler to always inline a static inline function. The compiler can ignore it and decides to not inline the function.

It can be used to inline performance critical static inline functions when building Python in debug mode with function inlining disabled. For example, MSC disables function inlining when building in debug mode.

Marking blindly a static inline function with **Py\_ALWAYS\_INLINE** can result in worse performances (due to

increased code size for example). The compiler is usually smarter than the developer for the cost/benefit analysis.

If Python is [built in debug mode](#) (if the `Py_DEBUG` macro is defined), the `Py_ALWAYS_INLINE` macro does nothing.

It must be specified before the function return type. Usage:

```
static inline Py_ALWAYS_INLINE int random(void) { r
```

*New in version 3.11.*

### `Py_CHARMASK(c)`

Argument must be a character or an integer in the range `[-128, 127]` or `[0, 255]`. This macro returns `c` cast to an unsigned char.

### `Py_DEPRECATED(version)`

Use this for deprecated declarations. The macro must be placed before the symbol name.

Example:

```
Py_DEPRECATED(3.8) PyAPI_FUNC(int) Py_OldFunction(v
```

*Changed in version 3.8:* MSVC support was added.

### `Py_GETENV(s)`

Like `getenv(s)`, but returns `NULL` if `-E` was passed on the command line (i.e. if `Py_IgnoreEnvironmentFlag` is set).

### `Py_MAX(x, y)`

Return the maximum value between `x` and `y`.

*New in version 3.3.*

### `Py_MEMBER_SIZE(type, member)`

Return the size of a structure (type) member in bytes.

*New in version 3.6.*

**Py\_MIN(x, y)**

Return the minimum value between `x` and `y`.

*New in version 3.3.*

**Py\_NO\_INLINE**

Disable inlining on a function. For example, it reduces the C stack consumption: useful on LTO + PGO builds which heavily inline code (see [bpo-33720](https://bugs.python.org/issue?@action=redirect&bpo=33720) [https://bugs.python.org/issue?@action=redirect&bpo=33720]).

Usage:

```
Py_NO_INLINE static int random(void) { return 4; }
```

*New in version 3.11.*

**Py\_STRINGIFY(x)**

Convert `x` to a C string. E.g. `Py_STRINGIFY(123)` returns `"123"`.

*New in version 3.4.*

**Py\_UNREACHABLE()**

Use this when you have a code path that cannot be reached by design. For example, in the `default:` clause in a `switch` statement for which all possible values are covered in `case` statements. Use this in places where you might be tempted to put an `assert(0)` or `abort()` call.

In release mode, the macro helps the compiler to optimize the code, and avoids a warning about unreachable code. For example, the macro is implemented with `__builtin_unreachable()` on GCC in release mode.

A use for `Py_UNREACHABLE()` is following a call a function that never returns but that is not declared `_Py_NO_RETURN`.

If a code path is very unlikely code but can be reached under exceptional case, this macro must not be used. For example, under low memory condition or if a system call returns a value out of the expected range. In this case, it's better to report the error to the caller. If the error cannot be reported to caller, `Py_FatalError()` can be used.

*New in version 3.7.*

## Py\_UNUSED(arg)

Use this for unused arguments in a function definition to silence compiler warnings. Example: `int func(int a, int Py_UNUSED(b)) { return a; }.`

*New in version 3.4.*

## PyDoc\_STRVAR(name, str)

Creates a variable with name `name` that can be used in docstrings. If Python is built without docstrings, the value will be empty.

Use `PyDoc_STRVAR` for docstrings to support building Python without docstrings, as specified in [PEP 7](https://peps.python.org/pep-0007/) [https://peps.python.org/pep-0007/].

Example:

```
PyDoc_STRVAR(pop_doc, "Remove and return the rightmost element")

static PyMethodDef deque_methods[] = {
    // ...
    {"pop", (PyCFunction)deque_pop, METH_NOARGS, pop_doc},
    // ...
}
```

## PyDoc\_STR(str)

Creates a docstring for the given input string or an empty string if docstrings are disabled.

Use `PyDoc_STR` in specifying docstrings to support building Python without docstrings, as specified in [PEP 7](https://peps.python.org/pep-0007/) [https://peps.python.org/pep-0007/].

Example:

```
static PyMethodDef pysqlite_row_methods[] = {
    {"keys", (PyCFunction)pysqlite_row_keys, METH_N
        PyDoc_STR("Returns the keys of the row.")},
    {NULL, NULL}
};
```

## Objects, Types and Reference Counts

Most Python/C API functions have one or more arguments as well as a return value of type `PyObject*`. This type is a pointer to an opaque data type representing an arbitrary Python object. Since all Python object types are treated the same way by the Python language in most situations (e.g., assignments, scope rules, and argument passing), it is only fitting that they should be represented by a single C type. Almost all Python objects live on the heap: you never declare an automatic or static variable of type `PyObject`, only pointer variables of type `PyObject*` can be declared. The sole exception are the type objects; since these must never be deallocated, they are typically static `PyTypeObject` objects.

All Python objects (even Python integers) have a *type* and a *reference count*. An object's type determines what kind of object it is (e.g., an integer, a list, or a user-defined function; there are many more as explained in [The standard type hierarchy](#)). For each of the well-known types there is a macro to check whether an object is of that type; for instance, `PyList_Check(a)` is true if (and only if) the object pointed to by `a` is a Python list.

## Reference Counts

The reference count is important because today's computers have a finite (and often severely limited) memory size; it counts how many different places there are that have a reference to an object. Such a

place could be another object, or a global (or static) C variable, or a local variable in some C function. When an object's reference count becomes zero, the object is deallocated. If it contains references to other objects, their reference count is decremented. Those other objects may be deallocated in turn, if this decrement makes their reference count become zero, and so on. (There's an obvious problem with objects that reference each other here; for now, the solution is "don't do that.")

Reference counts are always manipulated explicitly. The normal way is to use the macro `Py_INCREF()` to increment an object's reference count by one, and `Py_DECREF()` to decrement it by one. The `Py_DECREF()` macro is considerably more complex than the `Py_INCREF()` one, since it must check whether the reference count becomes zero and then cause the object's deallocator to be called. The deallocator is a function pointer contained in the object's type structure. The type-specific deallocator takes care of decrementing the reference counts for other objects contained in the object if this is a compound object type, such as a list, as well as performing any additional finalization that's needed. There's no chance that the reference count can overflow; at least as many bits are used to hold the reference count as there are distinct memory locations in virtual memory (assuming `sizeof(Py_ssize_t) >= sizeof(void*)`). Thus, the reference count increment is a simple operation.

It is not necessary to increment an object's reference count for every local variable that contains a pointer to an object. In theory, the object's reference count goes up by one when the variable is made to point to it and it goes down by one when the variable goes out of scope. However, these two cancel each other out, so at the end the reference count hasn't changed. The only real reason to use the reference count is to prevent the object from being deallocated as long as our variable is pointing to it. If we know that there is at least one other reference to the object that lives at least as long as our variable, there is no need to increment the reference count temporarily. An important situation where this arises is in objects that are passed as arguments to C functions in an extension module that are called from Python; the call mechanism guarantees to hold a reference to every argument for the duration of the call.

However, a common pitfall is to extract an object from a list and hold on to it for a while without incrementing its reference count. Some other operation might conceivably remove the object from the list, decrementing its reference count and possibly deallocating it. The real danger is that innocent-looking operations may invoke arbitrary Python code which could do this; there is a code path which allows control to flow back to the user from a `Py_DECREF()`, so almost any operation is potentially dangerous.

A safe approach is to always use the generic operations (functions whose name begins with `PyObject_`, `PyNumber_`, `PySequence_` or `PyMapping_`). These operations always increment the reference count of the object they return. This leaves the caller with the responsibility to call `Py_DECREF()` when they are done with the result; this soon becomes second nature.

## Reference Count Details

The reference count behavior of functions in the Python/C API is best explained in terms of *ownership of references*. Ownership pertains to references, never to objects (objects are not owned: they are always shared). “Owning a reference” means being responsible for calling `Py_DECREF` on it when the reference is no longer needed. Ownership can also be transferred, meaning that the code that receives ownership of the reference then becomes responsible for eventually decref’ing it by calling `Py_DECREF()` or `Py_XDECREF()` when it’s no longer needed—or passing on this responsibility (usually to its caller). When a function passes ownership of a reference on to its caller, the caller is said to receive a *new* reference. When no ownership is transferred, the caller is said to *borrow* the reference. Nothing needs to be done for a *borrowed reference*.

Conversely, when a calling function passes in a reference to an object, there are two possibilities: the function *steals* a reference to the object, or it does not. *Stealing a reference* means that when you pass a reference to a function, that function assumes that it now owns that reference, and you are not responsible for it any longer.

Few functions steal references; the two notable exceptions are

`PyList_SetItem()` and `PyTuple_SetItem()`, which steal a reference to the item (but not to the tuple or list into which the item is put!). These functions were designed to steal a reference because of a common idiom for populating a tuple or list with newly created objects; for example, the code to create the tuple `(1, 2, "three")` could look like this (forgetting about error handling for the moment; a better way to code this is shown below):

```
PyObject *t;

t = PyTuple_New(3);
PyTuple_SetItem(t, 0, PyLong_FromLong(1L));
PyTuple_SetItem(t, 1, PyLong_FromLong(2L));
PyTuple_SetItem(t, 2, PyUnicode_FromString("three"));
```

Here, `PyLong_FromLong()` returns a new reference which is immediately stolen by `PyTuple_SetItem()`. When you want to keep using an object although the reference to it will be stolen, use `Py_INCREF()` to grab another reference before calling the reference-stealing function.

Incidentally, `PyTuple_SetItem()` is the *only* way to set tuple items; `PySequence_SetItem()` and `PyObject_SetItem()` refuse to do this since tuples are an immutable data type. You should only use `PyTuple_SetItem()` for tuples that you are creating yourself.

Equivalent code for populating a list can be written using `PyList_New()` and `PyList_SetItem()`.

However, in practice, you will rarely use these ways of creating and populating a tuple or list. There's a generic function, `Py_BuildValue()`, that can create most common objects from C values, directed by a *format string*. For example, the above two blocks of code could be replaced by the following (which also takes care of the error checking):

```
PyObject *tuple, *list;

tuple = Py_BuildValue("(iis)", 1, 2, "three");
```

```
list = Py_BuildValue("[iis]", 1, 2, "three");
```

It is much more common to use `PyObject_SetItem()` and friends with items whose references you are only borrowing, like arguments that were passed in to the function you are writing. In that case, their behaviour regarding reference counts is much saner, since you don't have to increment a reference count so you can give a reference away ("have it be stolen"). For example, this function sets all items of a list (actually, any mutable sequence) to a given item:

```
int
set_all(PyObject *target, PyObject *item)
{
    Py_ssize_t i, n;

    n = PyObject_Length(target);
    if (n < 0)
        return -1;
    for (i = 0; i < n; i++) {
        PyObject *index = PyLong_FromSsize_t(i);
        if (!index)
            return -1;
        if (PyObject_SetItem(target, index, item) < 0) {
            Py_DECREF(index);
            return -1;
        }
        Py_DECREF(index);
    }
    return 0;
}
```

The situation is slightly different for function return values. While passing a reference to most functions does not change your ownership responsibilities for that reference, many functions that return a reference to an object give you ownership of the reference. The reason is simple: in many cases, the returned object is created on the fly, and the reference you get is the only reference to the object. Therefore, the generic functions that return object references, like `PyObject_GetItem()` and

`PySequence_GetItem()`, always return a new reference (the caller becomes the owner of the reference).

It is important to realize that whether you own a reference returned by a function depends on which function you call only — *the plumage* (the type of the object passed as an argument to the function) *doesn't enter into it!* Thus, if you extract an item from a list using `PyList_GetItem()`, you don't own the reference — but if you obtain the same item from the same list using `PySequence_GetItem()` (which happens to take exactly the same arguments), you do own a reference to the returned object.

Here is an example of how you could write a function that computes the sum of the items in a list of integers; once using `PyList_GetItem()`, and once using `PySequence_GetItem()`.

```
long
sum_list(PyObject *list)
{
    Py_ssize_t i, n;
    long total = 0, value;
    PyObject *item;

    n = PyList_Size(list);
    if (n < 0)
        return -1; /* Not a list */
    for (i = 0; i < n; i++) {
        item = PyList_GetItem(list, i); /* Can't fail */
        if (!PyLong_Check(item)) continue; /* Skip non-integers */
        value = PyLong_AsLong(item);
        if (value == -1 && PyErr_Occurred())
            /* Integer too big to fit in a C long, bail */
            return -1;
        total += value;
    }
    return total;
}

long
sum_sequence(PyObject *sequence)
```

```

{
    Py_ssize_t i, n;
    long total = 0, value;
    PyObject *item;
    n = PySequence_Length(sequence);
    if (n < 0)
        return -1; /* Has no length */
    for (i = 0; i < n; i++) {
        item = PySequence_GetItem(sequence, i);
        if (item == NULL)
            return -1; /* Not a sequence, or other failure */
        if (PyLong_Check(item)) {
            value = PyLong_AsLong(item);
            Py_DECREF(item);
            if (value == -1 && PyErr_Occurred())
                /* Integer too big to fit in a C long, b
                return -1;
            total += value;
        }
        else {
            Py_DECREF(item); /* Discard reference owners
        }
    }
    return total;
}

```

## Types

There are few other data types that play a significant role in the Python/C API; most are simple C types such as `int`, `long`, `double` and `char*`. A few structure types are used to describe static tables used to list the functions exported by a module or the data attributes of a new object type, and another is used to describe the value of a complex number. These will be discussed together with the functions that use them.

type `Py_ssize_t`

*Part of the [Stable ABI](#).*

A signed integral type such that `sizeof(Py_ssize_t) ==`

`sizeof(size_t)`. C99 doesn't define such a thing directly (`size_t` is an unsigned integral type). See [PEP 353](https://peps.python.org/pep-0353/) [https://peps.python.org/pep-0353/] for details. `PY_SSIZE_T_MAX` is the largest positive value of type `Py_ssize_t`.

## Exceptions

The Python programmer only needs to deal with exceptions if specific error handling is required; unhandled exceptions are automatically propagated to the caller, then to the caller's caller, and so on, until they reach the top-level interpreter, where they are reported to the user accompanied by a stack traceback.

For C programmers, however, error checking always has to be explicit. All functions in the Python/C API can raise exceptions, unless an explicit claim is made otherwise in a function's documentation. In general, when a function encounters an error, it sets an exception, discards any object references that it owns, and returns an error indicator. If not documented otherwise, this indicator is either `NULL` or `-1`, depending on the function's return type. A few functions return a Boolean true/false result, with false indicating an error. Very few functions return no explicit error indicator or have an ambiguous return value, and require explicit testing for errors with `PyErr_Occurred()`. These exceptions are always explicitly documented.

Exception state is maintained in per-thread storage (this is equivalent to using global storage in an unthreaded application). A thread can be in one of two states: an exception has occurred, or not. The function `PyErr_Occurred()` can be used to check for this: it returns a borrowed reference to the exception type object when an exception has occurred, and `NULL` otherwise. There are a number of functions to set the exception state:

`PyErr_SetString()` is the most common (though not the most general) function to set the exception state, and `PyErr_Clear()` clears the exception state.

The full exception state consists of three objects (all of which can be `NULL`): the exception type, the corresponding exception value, and the traceback. These have the same meanings as the Python result

of `sys.exc_info()`; however, they are not the same: the Python objects represent the last exception being handled by a Python `try ... except` statement, while the C level exception state only exists while an exception is being passed on between C functions until it reaches the Python bytecode interpreter's main loop, which takes care of transferring it to `sys.exc_info()` and friends.

Note that starting with Python 1.5, the preferred, thread-safe way to access the exception state from Python code is to call the function `sys.exc_info()`, which returns the per-thread exception state for Python code. Also, the semantics of both ways to access the exception state have changed so that a function which catches an exception will save and restore its thread's exception state so as to preserve the exception state of its caller. This prevents common bugs in exception handling code caused by an innocent-looking function overwriting the exception being handled; it also reduces the often unwanted lifetime extension for objects that are referenced by the stack frames in the traceback.

As a general principle, a function that calls another function to perform some task should check whether the called function raised an exception, and if so, pass the exception state on to its caller. It should discard any object references that it owns, and return an error indicator, but it should *not* set another exception — that would overwrite the exception that was just raised, and lose important information about the exact cause of the error.

A simple example of detecting exceptions and passing them on is shown in the `sum_sequence()` example above. It so happens that this example doesn't need to clean up any owned references when it detects an error. The following example function shows some error cleanup. First, to remind you why you like Python, we show the equivalent Python code:

```
def incr_item(dict, key):
    try:
        item = dict[key]
    except KeyError:
        item = 0
    dict[key] = item + 1
```

Here is the corresponding C code, in all its glory:

```
int
incr_item(PyObject *dict, PyObject *key)
{
    /* Objects all initialized to NULL for Py_XDECREF */
    PyObject *item = NULL, *const_one = NULL, *incremented_item = NULL;
    int rv = -1; /* Return value initialized to -1 (failure) */

    item = PyObject_GetItem(dict, key);
    if (item == NULL) {
        /* Handle KeyError only: */
        if (!PyErr_ExceptionMatches(PyExc_KeyError))
            goto error;

        /* Clear the error and use zero: */
        PyErr_Clear();
        item = PyLong_FromLong(0L);
        if (item == NULL)
            goto error;
    }
    const_one = PyLong_FromLong(1L);
    if (const_one == NULL)
        goto error;

    incremented_item = PyNumber_Add(item, const_one);
    if (incremented_item == NULL)
        goto error;

    if (PyObject_SetItem(dict, key, incremented_item) < 0)
        goto error;
    rv = 0; /* Success */
    /* Continue with cleanup code */

error:
    /* Cleanup code, shared by success and failure path */

    /* Use Py_XDECREF() to ignore NULL references */
    Py_XDECREF(item);
}
```

```

Py_XDECREF(const_one);
Py_XDECREF(incremented_item);

return rv; /* -1 for error, 0 for success */
}

```

This example represents an endorsed use of the `goto` statement in C! It illustrates the use of `PyErr_ExceptionMatches()` and `PyErr_Clear()` to handle specific exceptions, and the use of `Py_XDECREF()` to dispose of owned references that may be `NULL` (note the 'X' in the name; `Py_DECREF()` would crash when confronted with a `NULL` reference). It is important that the variables used to hold owned references are initialized to `NULL` for this to work; likewise, the proposed return value is initialized to `-1` (failure) and only set to success after the final call made is successful.

## Embedding Python

The one important task that only embedders (as opposed to extension writers) of the Python interpreter have to worry about is the initialization, and possibly the finalization, of the Python interpreter. Most functionality of the interpreter can only be used after the interpreter has been initialized.

The basic initialization function is `Py_Initialize()`. This initializes the table of loaded modules, and creates the fundamental modules `builtins`, `__main__`, and `sys`. It also initializes the module search path (`sys.path`).

`Py_Initialize()` does not set the “script argument list” (`sys.argv`). If this variable is needed by Python code that will be executed later, setting `PyConfig.argv` and `PyConfig.parse_argv` must be set: see [Python Initialization Configuration](#).

On most systems (in particular, on Unix and Windows, although the details are slightly different), `Py_Initialize()` calculates the module search path based upon its best guess for the location of the standard Python interpreter executable, assuming that the Python

library is found in a fixed location relative to the Python interpreter executable. In particular, it looks for a directory named `lib/pythonX.Y` relative to the parent directory where the executable named `python` is found on the shell command search path (the environment variable **PATH**).

For instance, if the Python executable is found in `/usr/local/bin/python`, it will assume that the libraries are in `/usr/local/lib/pythonX.Y`. (In fact, this particular path is also the “fallback” location, used when no executable file named `python` is found along **PATH**.) The user can override this behavior by setting the environment variable **PYTHONHOME**, or insert additional directories in front of the standard path by setting **PYTHONPATH**.

The embedding application can steer the search by calling `Py_SetProgramName(file)` *before* calling **Py\_Initialize()**. Note that **PYTHONHOME** still overrides this and **PYTHONPATH** is still inserted in front of the standard path. An application that requires total control has to provide its own implementation of **Py\_GetPath()**, **Py\_GetPrefix()**, **Py\_GetExecPrefix()**, and **Py\_GetProgramFullPath()** (all defined in `Modules/getpath.c`).

Sometimes, it is desirable to “uninitialize” Python. For instance, the application may want to start over (make another call to **Py\_Initialize()**) or the application is simply done with its use of Python and wants to free memory allocated by Python. This can be accomplished by calling **Py\_FinalizeEx()**. The function **Py\_IsInitialized()** returns true if Python is currently in the initialized state. More information about these functions is given in a later chapter. Notice that **Py\_FinalizeEx()** does *not* free all memory allocated by the Python interpreter, e.g. memory allocated by extension modules currently cannot be released.

## Debugging Builds

Python can be built with several macros to enable extra checks of the interpreter and extension modules. These checks tend to add a large amount of overhead to the runtime so they are not enabled by default.

A full list of the various types of debugging builds is in the file `Misc/SpecialBuilds.txt` in the Python source distribution. Builds are available that support tracing of reference counts, debugging the memory allocator, or low-level profiling of the main interpreter loop. Only the most frequently used builds will be described in the remainder of this section.

Compiling the interpreter with the **Py\_DEBUG** macro defined produces what is generally meant by [a debug build of Python](#). **Py\_DEBUG** is enabled in the Unix build by adding **--with-pydebug** to the `./configure` command. It is also implied by the presence of the not-Python-specific **\_DEBUG** macro. When **Py\_DEBUG** is enabled in the Unix build, compiler optimization is disabled.

In addition to the reference count debugging described below, extra checks are performed, see [Python Debug Build](#).

Defining **Py\_TRACE\_REFS** enables reference tracing (see the [configure --with-trace-refs option](#)). When defined, a circular doubly linked list of active objects is maintained by adding two extra fields to every **PyObject**. Total allocations are tracked as well. Upon exit, all existing references are printed. (In interactive mode this happens after every statement run by the interpreter.)

Please refer to `Misc/SpecialBuilds.txt` in the Python source distribution for more detailed information.

# C API Stability

Python's C API is covered by the Backwards Compatibility Policy, [PEP 387](https://peps.python.org/pep-0387/) [https://peps.python.org/pep-0387/]. While the C API will change with every minor release (e.g. from 3.9 to 3.10), most changes will be source-compatible, typically by only adding new API. Changing existing API or removing API is only done after a deprecation period or to fix serious issues.

CPython's Application Binary Interface (ABI) is forward- and backwards-compatible across a minor release (if these are compiled the same way; see [Platform Considerations](#) below). So, code compiled for Python 3.10.0 will work on 3.10.8 and vice versa, but will need to be compiled separately for 3.9.x and 3.10.x.

Names prefixed by an underscore, such as `_Py_InternalState`, are private API that can change without notice even in patch releases.

## Stable Application Binary Interface

Python 3.2 introduced the *Limited API*, a subset of Python's C API. Extensions that only use the Limited API can be compiled once and work with multiple versions of Python. Contents of the Limited API are [listed below](#).

To enable this, Python provides a *Stable ABI*: a set of symbols that will remain compatible across Python 3.x versions. The Stable ABI contains symbols exposed in the Limited API, but also other ones – for example, functions necessary to support older versions of the Limited API.

(For simplicity, this document talks about *extensions*, but the Limited API and Stable ABI work the same way for all uses of the API – for example, embedding Python.)

## Py\_LIMITED\_API

Define this macro before including `Python.h` to opt in to only use the Limited API, and to select the Limited API version.

Define `Py_LIMITED_API` to the value of `PY_VERSION_HEX` corresponding to the lowest Python version your extension supports. The extension will work without recompilation with all Python 3 releases from the specified one onward, and can use Limited API introduced up to that version.

Rather than using the `PY_VERSION_HEX` macro directly, hardcode a minimum minor version (e.g. `0x030A0000` for Python 3.10) for stability when compiling with future Python versions.

You can also define `Py_LIMITED_API` to `3`. This works the same as `0x03020000` (Python 3.2, the version that introduced Limited API).

On Windows, extensions that use the Stable ABI should be linked against `python3.dll` rather than a version-specific library such as `python39.dll`.

On some platforms, Python will look for and load shared library files named with the `abi3` tag (e.g. `mymodule.abi3.so`). It does not check if such extensions conform to a Stable ABI. The user (or their packaging tools) need to ensure that, for example, extensions built with the 3.10+ Limited API are not installed for lower versions of Python.

All functions in the Stable ABI are present as functions in Python's shared library, not solely as macros. This makes them usable from languages that don't use the C preprocessor.

## Limited API Scope and Performance

The goal for the Limited API is to allow everything that is possible with the full C API, but possibly with a performance penalty.

For example, while `PyList_GetItem()` is available, its “unsafe” macro variant `PyList_GET_ITEM()` is not. The macro can be faster because it can rely on version-specific implementation details of the list object.

Without `Py_LIMITED_API` defined, some C API functions are inlined or replaced by macros. Defining `Py_LIMITED_API` disables this inlining, allowing stability as Python’s data structures are improved, but possibly reducing performance.

By leaving out the `Py_LIMITED_API` definition, it is possible to compile a Limited API extension with a version-specific ABI. This can improve performance for that Python version, but will limit compatibility. Compiling with `Py_LIMITED_API` will then yield an extension that can be distributed where a version-specific one is not available – for example, for prereleases of an upcoming Python version.

## Limited API Caveats

Note that compiling with `Py_LIMITED_API` is *not* a complete guarantee that code conforms to the Limited API or the Stable ABI. `Py_LIMITED_API` only covers definitions, but an API also includes other issues, such as expected semantics.

One issue that `Py_LIMITED_API` does not guard against is calling a function with arguments that are invalid in a lower Python version. For example, consider a function that starts accepting `NULL` for an argument. In Python 3.9, `NULL` now selects a default behavior, but in Python 3.8, the argument will be used directly, causing a `NULL` dereference and crash. A similar argument works for fields of structs.

Another issue is that some struct fields are currently not hidden when `Py_LIMITED_API` is defined, even though they’re part of the Limited API.

For these reasons, we recommend testing an extension with *all* minor Python versions it supports, and preferably to build with the *lowest* such version.

We also recommend reviewing documentation of all used API to check if it is explicitly part of the Limited API. Even with `Py_LIMITED_API` defined, a few private declarations are exposed for technical reasons (or even unintentionally, as bugs).

Also note that the Limited API is not necessarily stable: compiling with `Py_LIMITED_API` with Python 3.8 means that the extension will run with Python 3.12, but it will not necessarily *compile* with Python 3.12. In particular, parts of the Limited API may be deprecated and removed, provided that the Stable ABI stays stable.

## Platform Considerations

ABI stability depends not only on Python, but also on the compiler used, lower-level libraries and compiler options. For the purposes of the Stable ABI, these details define a “platform”. They usually depend on the OS type and processor architecture

It is the responsibility of each particular distributor of Python to ensure that all Python versions on a particular platform are built in a way that does not break the Stable ABI. This is the case with Windows and macOS releases from `python.org` and many third-party distributors.

## Contents of Limited API

Currently, the Limited API includes the following items:

- `PyAIter_Check()`
- `PyArg_Parse()`
- `PyArg_ParseTuple()`
- `PyArg_ParseTupleAndKeywords()`
- `PyArg_UnpackTuple()`
- `PyArg_VaParse()`
- `PyArg_VaParseTupleAndKeywords()`
- `PyArg_ValidateKeywordArguments()`
- `PyBaseObject_Type`
- `PyBool_FromLong()`
- `PyBool_Type`

- `PyBuffer_FillContiguousStrides()`
- `PyBuffer_FillInfo()`
- `PyBuffer_FromContiguous()`
- `PyBuffer_GetPointer()`
- `PyBuffer_IsContiguous()`
- `PyBuffer_Release()`
- `PyBuffer_SizeFromFormat()`
- `PyBuffer_ToContiguous()`
- `PyByteArrayIter_Type`
- `PyByteArray_AsString()`
- `PyByteArray_Concat()`
- `PyByteArray_FromObject()`
- `PyByteArray_FromStringAndSize()`
- `PyByteArray_Resize()`
- `PyByteArray_Size()`
- `PyByteArray_Type`
- `PyBytesIter_Type`
- `PyBytes_AsString()`
- `PyBytes_AsStringAndSize()`
- `PyBytes_Concat()`
- `PyBytes_ConcatAndDel()`
- `PyBytes_DecodeEscape()`
- `PyBytes_FromFormat()`
- `PyBytes_FromFormatV()`
- `PyBytes_FromObject()`
- `PyBytes_FromString()`
- `PyBytes_FromStringAndSize()`
- `PyBytes_Repr()`
- `PyBytes_Size()`
- `PyBytes_Type`
- `PyCFunction`
- `PyCFunctionWithKeywords`
- `PyCFunction_Call()`
- `PyCFunction_GetFlags()`
- `PyCFunction_GetFunction()`
- `PyCFunction_GetSelf()`
- `PyCFunction_New()`
- `PyCFunction_NewEx()`
- `PyCFunction_Type`
- `PyCMethod_New()`

- `PyCallIter_New()`
- `PyCallIter_Type`
- `PyCallable_Check()`
- `PyCapsule_Destructor`
- `PyCapsule_GetContext()`
- `PyCapsule_GetDestructor()`
- `PyCapsule_GetName()`
- `PyCapsule_GetPointer()`
- `PyCapsule_Import()`
- `PyCapsule_IsValid()`
- `PyCapsule_New()`
- `PyCapsule_SetContext()`
- `PyCapsule_SetDestructor()`
- `PyCapsule_SetName()`
- `PyCapsule_SetPointer()`
- `PyCapsule_Type`
- `PyClassMethodDescr_Type`
- `PyCodec_BackslashReplaceErrors()`
- `PyCodec_Decode()`
- `PyCodec_Decoder()`
- `PyCodec_Encode()`
- `PyCodec_Encoder()`
- `PyCodec_IgnoreErrors()`
- `PyCodec_IncrementalDecoder()`
- `PyCodec_IncrementalEncoder()`
- `PyCodec_KnownEncoding()`
- `PyCodec_LookupError()`
- `PyCodec_NameReplaceErrors()`
- `PyCodec_Register()`
- `PyCodec_RegisterError()`
- `PyCodec_ReplaceErrors()`
- `PyCodec_StreamReader()`
- `PyCodec_StreamWriter()`
- `PyCodec_StrictErrors()`
- `PyCodec_Unregister()`
- `PyCodec_XMLCharRefReplaceErrors()`
- `PyComplex_FromDoubles()`
- `PyComplex_ImagAsDouble()`
- `PyComplex_RealAsDouble()`
- `PyComplex_Type`

- `PyDescr_NewClassMethod()`
- `PyDescr_NewGetSet()`
- `PyDescr_NewMember()`
- `PyDescr_NewMethod()`
- `PyDictItems_Type`
- `PyDictIterItem_Type`
- `PyDictIterKey_Type`
- `PyDictIterValue_Type`
- `PyDictKeys_Type`
- `PyDictProxy_New()`
- `PyDictProxy_Type`
- `PyDictRevIterItem_Type`
- `PyDictRevIterKey_Type`
- `PyDictRevIterValue_Type`
- `PyDictValues_Type`
- `PyDict_Clear()`

# The Very High Level Layer

The functions in this chapter will let you execute Python source code given in a file or a buffer, but they will not let you interact in a more detailed way with the interpreter.

Several of these functions accept a start symbol from the grammar as a parameter. The available start symbols are **Py\_eval\_input**, **Py\_file\_input**, and **Py\_single\_input**. These are described following the functions which accept them as parameters.

Note also that several of these functions take FILE\* parameters. One particular issue which needs to be handled carefully is that the FILE structure for different C libraries can be different and incompatible. Under Windows (at least), it is possible for dynamically linked extensions to actually use different libraries, so care should be taken that FILE\* parameters are only passed to these functions if it is certain that they were created by the same library that the Python runtime is using.

```
int Py_Main(int argc, wchar_t **argv)
```

*Part of the [Stable ABI](#).*

The main program for the standard interpreter. This is made available for programs which embed Python. The *argc* and *argv* parameters should be prepared exactly as those which are passed to a C program's **main()** function (converted to `wchar_t` according to the user's locale). It is important to note that the argument list may be modified (but the contents of the strings pointed to by the argument list are not). The return value will be 0 if the interpreter exits normally (i.e., without an exception), 1 if the interpreter exits due to an exception, or 2 if the parameter list does not represent a valid Python command line.

Note that if an otherwise unhandled [SystemExit](#) is raised, this function will not return 1, but exit the process, as long

as `Py_InspectFlag` is not set.

`int Py_BytesMain(int argc, char **argv)`

Part of the *Stable ABI* since version 3.8.

Similar to `Py_Main()` but *argv* is an array of bytes strings.

*New in version 3.8.*

`int PyRun_AnyFile(FILE *fp, const char *filename)`

This is a simplified interface to `PyRun_AnyFileExFlags()` below, leaving *closeit* set to 0 and *flags* set to `NULL`.

`int PyRun_AnyFileFlags(FILE *fp, const char *filename,  
PyCompilerFlags *flags)`

This is a simplified interface to `PyRun_AnyFileExFlags()` below, leaving the *closeit* argument set to 0.

`int PyRun_AnyFileEx(FILE *fp, const char *filename, int closeit)`

This is a simplified interface to `PyRun_AnyFileExFlags()` below, leaving the *flags* argument set to `NULL`.

`int PyRun_AnyFileExFlags(FILE *fp, const char *filename, int  
closeit, PyCompilerFlags *flags)`

If *fp* refers to a file associated with an interactive device (console or terminal input or Unix pseudo-terminal), return the value of `PyRun_InteractiveLoop()`, otherwise return the result of `PyRun_SimpleFile()`. *filename* is decoded from the filesystem encoding (`sys.getfilesystemencoding()`). If *filename* is `NULL`, this function uses `"???"` as the filename. If *closeit* is true, the file is closed before `PyRun_SimpleFileExFlags()` returns.

`int PyRun_SimpleString(const char *command)`

This is a simplified interface to `PyRun_SimpleStringFlags()` below, leaving the

`PyCompilerFlags`\* argument set to `NULL`.

`int PyRun_SimpleStringFlags(const char *command,  
PyCompilerFlags *flags)`

Executes the Python source code from *command* in the `__main__` module according to the *flags* argument. If `__main__` does not already exist, it is created. Returns `0` on success or `-1` if an exception was raised. If there was an error, there is no way to get the exception information. For the meaning of *flags*, see below.

Note that if an otherwise unhandled `SystemExit` is raised, this function will not return `-1`, but exit the process, as long as `Py_InspectFlag` is not set.

`int PyRun_SimpleFile(FILE *fp, const char *filename)`

This is a simplified interface to `PyRun_SimpleFileExFlags()` below, leaving *closeit* set to `0` and *flags* set to `NULL`.

`int PyRun_SimpleFileEx(FILE *fp, const char *filename, int closeit)`

This is a simplified interface to `PyRun_SimpleFileExFlags()` below, leaving *flags* set to `NULL`.

`int PyRun_SimpleFileExFlags(FILE *fp, const char *filename, int closeit, PyCompilerFlags *flags)`

Similar to `PyRun_SimpleStringFlags()`, but the Python source code is read from *fp* instead of an in-memory string. *filename* should be the name of the file, it is decoded from [filesystem encoding and error handler](#). If *closeit* is true, the file is closed before `PyRun_SimpleFileExFlags()` returns.

### Note

On Windows, *fp* should be opened as binary mode (e.g. `fopen(filename, "rb")`). Otherwise, Python may not

handle script file with LF line ending correctly.

`int PyRun_InteractiveOne(FILE *fp, const char *filename)`

This is a simplified interface to

`PyRun_InteractiveOneFlags()` below, leaving *flags* set to `NULL`.

`int PyRun_InteractiveOneFlags(FILE *fp, const char *filename,  
PyCompilerFlags *flags)`

Read and execute a single statement from a file associated with an interactive device according to the *flags* argument. The user will be prompted using `sys.ps1` and `sys.ps2`. *filename* is decoded from the [filesystem encoding and error handler](#).

Returns `0` when the input was executed successfully, `-1` if there was an exception, or an error code from the `errcode.h` include file distributed as part of Python if there was a parse error. (Note that `errcode.h` is not included by `Python.h`, so must be included specifically if needed.)

`int PyRun_InteractiveLoop(FILE *fp, const char *filename)`

This is a simplified interface to

`PyRun_InteractiveLoopFlags()` below, leaving *flags* set to `NULL`.

`int PyRun_InteractiveLoopFlags(FILE *fp, const char *filename,  
PyCompilerFlags *flags)`

Read and execute statements from a file associated with an interactive device until EOF is reached. The user will be prompted using `sys.ps1` and `sys.ps2`. *filename* is decoded from the [filesystem encoding and error handler](#). Returns `0` at EOF or a negative number upon failure.

`int (*PyOS_InputHook)(void)`

Part of the [Stable ABI](#).

Can be set to point to a function with the prototype `int func(void)`. The function will be called when Python's interpreter prompt is about to become idle and wait for user input from the terminal. The return value is ignored. Overriding this hook can be used to integrate the interpreter's prompt with other event loops, as done in the `Modules/_tkinter.c` in the Python source code.

`char *(*PyOS_ReadlineFunctionPointer)(FILE*, FILE*, const char*)`

Can be set to point to a function with the prototype `char *func(FILE *stdin, FILE *stdout, char *prompt)`, overriding the default function used to read a single line of input at the interpreter's prompt. The function is expected to output the string *prompt* if it's not `NULL`, and then read a line of input from the provided standard input file, returning the resulting string. For example, The [readline](#) module sets this hook to provide line-editing and tab-completion features.

The result must be a string allocated by [PyMem\\_RawMalloc\(\)](#) or [PyMem\\_RawRealloc\(\)](#), or `NULL` if an error occurred.

*Changed in version 3.4:* The result must be allocated by [PyMem\\_RawMalloc\(\)](#) or [PyMem\\_RawRealloc\(\)](#), instead of being allocated by [PyMem\\_Malloc\(\)](#) or [PyMem\\_Realloc\(\)](#).

[PyObject](#) \*PyRun\_String(const char \*str, int start, [PyObject](#) \*globals, [PyObject](#) \*locals)

*Return value:* New reference.

This is a simplified interface to [PyRun\\_StringFlags\(\)](#) below, leaving *flags* set to `NULL`.

[PyObject](#) \*PyRun\_StringFlags(const char \*str, int start, [PyObject](#) \*globals, [PyObject](#) \*locals, [PyCompilerFlags](#) \*flags)

*Return value:* New reference.

Execute Python source code from *str* in the context specified

by the objects *globals* and *locals* with the compiler flags specified by *flags*. *globals* must be a dictionary; *locals* can be any object that implements the mapping protocol. The parameter *start* specifies the start token that should be used to parse the source code.

Returns the result of executing the code as a Python object, or NULL if an exception was raised.

```
PyObject *PyRun_File(FILE *fp, const char *filename, int start,  
PyObject *globals, PyObject *locals)
```

*Return value:* New reference.

This is a simplified interface to `PyRun_FileExFlags()` below, leaving *closeit* set to 0 and *flags* set to NULL.

```
PyObject *PyRun_FileEx(FILE *fp, const char *filename, int start,  
PyObject *globals, PyObject *locals, int closeit)
```

*Return value:* New reference.

This is a simplified interface to `PyRun_FileExFlags()` below, leaving *flags* set to NULL.

```
PyObject *PyRun_FileFlags(FILE *fp, const char *filename, int start,  
PyObject *globals, PyObject *locals, PyCompilerFlags *flags)
```

*Return value:* New reference.

This is a simplified interface to `PyRun_FileExFlags()` below, leaving *closeit* set to 0.

```
PyObject *PyRun_FileExFlags(FILE *fp, const char *filename, int  
start, PyObject *globals, PyObject *locals, int closeit,  
PyCompilerFlags *flags)
```

*Return value:* New reference.

Similar to `PyRun_StringFlags()`, but the Python source code is read from *fp* instead of an in-memory string. *filename* should be the name of the file, it is decoded from the [filesystem encoding and error handler](#). If *closeit* is true, the file is closed before `PyRun_FileExFlags()` returns.

**PyObject** \*Py\_CompileString(const char \*str, const char \*filename, int start)

*Return value:* New reference. Part of the [Stable ABI](#).

This is a simplified interface to

**Py\_CompileStringFlags()** below, leaving *flags* set to `NULL`.

**PyObject** \*Py\_CompileStringFlags(const char \*str, const char \*filename, int start, **PyCompilerFlags** \*flags)

*Return value:* New reference.

This is a simplified interface to

**Py\_CompileStringExFlags()** below, with *optimize* set to `-1`.

**PyObject** \*Py\_CompileStringObject(const char \*str, **PyObject** \*filename, int start, **PyCompilerFlags** \*flags, int optimize)

*Return value:* New reference.

Parse and compile the Python source code in *str*, returning the resulting code object. The start token is given by *start*; this can be used to constrain the code which can be compiled and should be **Py\_eval\_input**, **Py\_file\_input**, or **Py\_single\_input**. The filename specified by *filename* is used to construct the code object and may appear in tracebacks or **SyntaxError** exception messages. This returns `NULL` if the code cannot be parsed or compiled.

The integer *optimize* specifies the optimization level of the compiler; a value of `-1` selects the optimization level of the interpreter as given by `-O` options. Explicit levels are `0` (no optimization; `__debug__` is true), `1` (asserts are removed, `__debug__` is false) or `2` (docstrings are removed too).

*New in version 3.4.*

**PyObject** \*Py\_CompileStringExFlags(const char \*str, const char \*filename, int start, **PyCompilerFlags** \*flags, int optimize)

*Return value:* New reference.

Like `Py_CompileStringObject()`, but *filename* is a byte string decoded from the `filesystem encoding and error handler`.

*New in version 3.2.*

`PyObject *PyEval_EvalCode(PyObject *co, PyObject *globals, PyObject *locals)`

*Return value: New reference. Part of the [Stable ABI](#).*

This is a simplified interface to `PyEval_EvalCodeEx()`, with just the code object, and global and local variables. The other arguments are set to `NULL`.

`PyObject *PyEval_EvalCodeEx(PyObject *co, PyObject *globals, PyObject *locals, PyObject *const *args, int argcount, PyObject *const *kws, int kwcount, PyObject *const *defs, int defcount, PyObject *kwdefs, PyObject *closure)`

*Return value: New reference. Part of the [Stable ABI](#).*

Evaluate a precompiled code object, given a particular environment for its evaluation. This environment consists of a dictionary of global variables, a mapping object of local variables, arrays of arguments, keywords and defaults, a dictionary of default values for [keyword-only](#) arguments and a closure tuple of cells.

`PyObject *PyEval_EvalFrame(PyFrameObject *f)`

*Return value: New reference. Part of the [Stable ABI](#).*

Evaluate an execution frame. This is a simplified interface to `PyEval_EvalFrameEx()`, for backward compatibility.

`PyObject *PyEval_EvalFrameEx(PyFrameObject *f, int throwflag)`

*Return value: New reference. Part of the [Stable ABI](#).*

This is the main, unvarnished function of Python interpretation. The code object associated with the execution frame *f* is executed, interpreting bytecode and executing calls as needed. The additional *throwflag* parameter can mostly be ignored - if true, then it causes an exception to immediately

be thrown; this is used for the `throw()` methods of generator objects.

*Changed in version 3.4:* This function now includes a debug assertion to help ensure that it does not silently discard an active exception.

`int PyEval_MergeCompilerFlags(PyCompilerFlags *cf)`

This function changes the flags of the current evaluation frame, and returns true on success, false on failure.

`int Py_eval_input`

The start symbol from the Python grammar for isolated expressions; for use with `Py_CompileString()`.

`int Py_file_input`

The start symbol from the Python grammar for sequences of statements as read from a file or other source; for use with `Py_CompileString()`. This is the symbol to use when compiling arbitrarily long Python source code.

`int Py_single_input`

The start symbol from the Python grammar for a single statement; for use with `Py_CompileString()`. This is the symbol used for the interactive interpreter loop.

`struct PyCompilerFlags`

This is the structure used to hold compiler flags. In cases where code is only being compiled, it is passed as `int flags`, and in cases where code is being executed, it is passed as `PyCompilerFlags *flags`. In this case, `from __future__ import can modify flags`.

Whenever `PyCompilerFlags *flags` is `NULL`, **cf\_flags** is treated as equal to 0, and any modification due to `from __future__ import` is discarded.

`int cf_flags`

## Compiler flags.

`int cf_feature_version`

*cf\_feature\_version* is the minor Python version. It should be initialized to `PY_MINOR_VERSION`.

The field is ignored by default, it is used if and only if `PyCF_ONLY_AST` flag is set in *cf\_flags*.

*Changed in version 3.8:* Added *cf\_feature\_version* field.

`int CO_FUTURE_DIVISION`

This bit can be set in *flags* to cause division operator `/` to be interpreted as “true division” according to [PEP 238](https://peps.python.org/pep-0238/) [https://peps.python.org/pep-0238/].

# Reference Counting

The macros in this section are used for managing reference counts of Python objects.

`void Py_INCREF(PyObject *o)`

Increment the reference count for object *o*.

This function is usually used to convert a [borrowed reference](#) to a [strong reference](#) in-place. The `Py_NewRef()` function can be used to create a new [strong reference](#).

The object must not be `NULL`; if you aren't sure that it isn't `NULL`, use `Py_XINCREF()`.

`void Py_XINCREF(PyObject *o)`

Increment the reference count for object *o*. The object may be `NULL`, in which case the macro has no effect.

See also `Py_XNewRef()`.

`PyObject *Py_NewRef(PyObject *o)`

*Part of the [Stable ABI](#) since version 3.10.*

Create a new [strong reference](#) to an object: increment the reference count of the object *o* and return the object *o*.

When the [strong reference](#) is no longer needed, `Py_DECREF()` should be called on it to decrement the object reference count.

The object *o* must not be `NULL`; use `Py_XNewRef()` if *o* can be `NULL`.

For example:

```
Py_INCREF(obj);
```

```
self->attr = obj;
```

can be written as:

```
self->attr = Py_NewRef(obj);
```

See also `Py_INCREF()`.

*New in version 3.10.*

`PyObject *Py_XNewRef(PyObject *o)`

Part of the *Stable ABI* since version 3.10.

Similar to `Py_NewRef()`, but the object `o` can be `NULL`.

If the object `o` is `NULL`, the function just returns `NULL`.

*New in version 3.10.*

`void Py_DECREF(PyObject *o)`

Decrement the reference count for object `o`.

If the reference count reaches zero, the object's type's deallocation function (which must not be `NULL`) is invoked.

This function is usually used to delete a [strong reference](#) before exiting its scope.

The object must not be `NULL`; if you aren't sure that it isn't `NULL`, use `Py_XDECREF()`.

## Warning

The deallocation function can cause arbitrary Python code to be invoked (e.g. when a class instance with a `__del__()` method is deallocated). While exceptions in such code are not propagated, the executed code has free access to all Python global variables. This means that any object that is reachable from a global variable should be in a consistent state before `Py_DECREF()` is invoked. For example, code to delete an object from a list should copy a reference to the deleted object in a temporary variable,

update the list data structure, and then call `Py_DECREF()` for the temporary variable.

`void Py_XDECREF(PyObject *o)`

Decrement the reference count for object *o*. The object may be `NULL`, in which case the macro has no effect; otherwise the effect is the same as for `Py_DECREF()`, and the same warning applies.

`void Py_CLEAR(PyObject *o)`

Decrement the reference count for object *o*. The object may be `NULL`, in which case the macro has no effect; otherwise the effect is the same as for `Py_DECREF()`, except that the argument is also set to `NULL`. The warning for `Py_DECREF()` does not apply with respect to the object passed because the macro carefully uses a temporary variable and sets the argument to `NULL` before decrementing its reference count.

It is a good idea to use this macro whenever decrementing the reference count of an object that might be traversed during garbage collection.

`void Py_IncRef(PyObject *o)`

*Part of the [Stable ABI](#).*

Increment the reference count for object *o*. A function version of `Py_XINCREF()`. It can be used for runtime dynamic embedding of Python.

`void Py_DecRef(PyObject *o)`

*Part of the [Stable ABI](#).*

Decrement the reference count for object *o*. A function version of `Py_XDECREF()`. It can be used for runtime dynamic embedding of Python.

The following functions or macros are only for use within the

interpreter core: `_Py_Dealloc()`, `_Py_ForgetReference()`,  
`_Py_NewReference()`, as well as the global variable  
`_Py_RefTotal`.

# Exception Handling

The functions described in this chapter will let you handle and raise Python exceptions. It is important to understand some of the basics of Python exception handling. It works somewhat like the POSIX `errno` variable: there is a global indicator (per thread) of the last error that occurred. Most C API functions don't clear this on success, but will set it to indicate the cause of the error on failure. Most C API functions also return an error indicator, usually `NULL` if they are supposed to return a pointer, or `-1` if they return an integer (exception: the `PyArg_*` functions return `1` for success and `0` for failure).

Concretely, the error indicator consists of three object pointers: the exception's type, the exception's value, and the traceback object. Any of those pointers can be `NULL` if non-set (although some combinations are forbidden, for example you can't have a non-`NULL` traceback if the exception type is `NULL`).

When a function must fail because some function it called failed, it generally doesn't set the error indicator; the function it called already set it. It is responsible for either handling the error and clearing the exception or returning after cleaning up any resources it holds (such as object references or memory allocations); it should *not* continue normally if it is not prepared to handle the error. If returning due to an error, it is important to indicate to the caller that an error has been set. If the error is not handled or carefully propagated, additional calls into the Python/C API may not behave as intended and may fail in mysterious ways.

## Note

The error indicator is **not** the result of `sys.exc_info()`. The former corresponds to an exception that is not yet caught (and is therefore still propagating), while the latter returns an exception after it is caught (and has therefore stopped propagating).

# Printing and clearing

`void PyErr_Clear()`

*Part of the [Stable ABI](#).*

Clear the error indicator. If the error indicator is not set, there is no effect.

`void PyErr_PrintEx(int set_sys_last_vars)`

*Part of the [Stable ABI](#).*

Print a standard traceback to `sys.stderr` and clear the error indicator. **Unless** the error is a `SystemExit`, in that case no traceback is printed and the Python process will exit with the error code specified by the `SystemExit` instance.

Call this function **only** when the error indicator is set. Otherwise it will cause a fatal error!

If `set_sys_last_vars` is nonzero, the variables `sys.last_type`, `sys.last_value` and `sys.last_traceback` will be set to the type, value and traceback of the printed exception, respectively.

`void PyErr_Print()`

*Part of the [Stable ABI](#).*

Alias for `PyErr_PrintEx(1)`.

`void PyErr_WriteUnraisable(PyObject *obj)`

*Part of the [Stable ABI](#).*

Call `sys.unraisablehook()` using the current exception and `obj` argument.

This utility function prints a warning message to `sys.stderr` when an exception has been set but it is impossible for the interpreter to actually raise the exception. It is used, for example, when an exception occurs in an `__del__()` method.

The function is called with a single argument `obj` that

identifies the context in which the unraisable exception occurred. If possible, the repr of *obj* will be printed in the warning message.

An exception must be set when calling this function.

## Raising exceptions

These functions help you set the current thread's error indicator. For convenience, some of these functions will always return a `NULL` pointer for use in a `return` statement.

`void PyErr_SetString(PyObject *type, const char *message)`

*Part of the [Stable ABI](#).*

This is the most common way to set the error indicator. The first argument specifies the exception type; it is normally one of the standard exceptions, e.g. `PyExc_RuntimeError`. You need not increment its reference count. The second argument is an error message; it is decoded from `'utf-8'`.

`void PyErr_SetObject(PyObject *type, PyObject *value)`

*Part of the [Stable ABI](#).*

This function is similar to `PyErr_SetString()` but lets you specify an arbitrary Python object for the “value” of the exception.

`PyObject *PyErr_Format(PyObject *exception, const char *format, ...)`

*Return value: Always NULL. Part of the [Stable ABI](#).*

This function sets the error indicator and returns `NULL`. *exception* should be a Python exception class. The *format* and subsequent parameters help format the error message; they have the same meaning and values as in `PyUnicode_FromFormat()`. *format* is an ASCII-encoded string.

`PyObject *PyErr_FormatV(PyObject *exception, const char *format,`

`va_list` `vargs`)

*Return value:* Always `NULL`. Part of the [Stable ABI](#) since version 3.5.

Same as `PyErr_Format()`, but taking a `va_list` argument rather than a variable number of arguments.

*New in version 3.5.*

`void PyErr_SetNone(PyObject *type)`

*Part of the [Stable ABI](#).*

This is a shorthand for `PyErr_SetObject(type, Py_None)`.

`int PyErr_BadArgument()`

*Part of the [Stable ABI](#).*

This is a shorthand for

`PyErr_SetString(PyExc_TypeError, message)`, where *message* indicates that a built-in operation was invoked with an illegal argument. It is mostly for internal use.

`PyObject *PyErr_NoMemory()`

*Return value:* Always `NULL`. Part of the [Stable ABI](#).

This is a shorthand for

`PyErr_SetNone(PyExc_MemoryError)`; it returns `NULL` so an object allocation function can write `return PyErr_NoMemory()`; when it runs out of memory.

`PyObject *PyErr_SetFromErrno(PyObject *type)`

*Return value:* Always `NULL`. Part of the [Stable ABI](#).

This is a convenience function to raise an exception when a C library function has returned an error and set the C variable **errno**. It constructs a tuple object whose first item is the integer **errno** value and whose second item is the corresponding error message (gotten from `strerror()`), and then calls `PyErr_SetObject(type, object)`. On Unix, when the **errno** value is **EINTR**, indicating an interrupted system call, this calls `PyErr_CheckSignals()`,

and if that set the error indicator, leaves it set to that. The function always returns `NULL`, so a wrapper function around a system call can write `return PyErr_SetFromErrno(type);` when the system call returns an error.

`PyObject *PyErr_SetFromErrnoWithFilenameObject(PyObject *type, PyObject *filenameObject)`

*Return value:* Always `NULL`. Part of the [Stable ABI](#).

Similar to `PyErr_SetFromErrno()`, with the additional behavior that if `filenameObject` is not `NULL`, it is passed to the constructor of `type` as a third parameter. In the case of `OSError` exception, this is used to define the `filename` attribute of the exception instance.

`PyObject *PyErr_SetFromErrnoWithFilenameObjects(PyObject *type, PyObject *filenameObject, PyObject *filenameObject2)`

*Return value:* Always `NULL`. Part of the [Stable ABI](#) since version 3.7.

Similar to

`PyErr_SetFromErrnoWithFilenameObject()`, but takes a second filename object, for raising errors when a function that takes two filenames fails.

*New in version 3.4.*

`PyObject *PyErr_SetFromErrnoWithFilename(PyObject *type, const char *filename)`

*Return value:* Always `NULL`. Part of the [Stable ABI](#).

Similar to

`PyErr_SetFromErrnoWithFilenameObject()`, but the filename is given as a C string. `filename` is decoded from the filesystem encoding and error handler.

`PyObject *PyErr_SetFromWindowsErr(int ierr)`

*Return value:* Always `NULL`. Part of the [Stable ABI](#) on Windows since version 3.7.

This is a convenience function to raise **WindowsError**. If called with *ierr* of 0, the error code returned by a call to **GetLastError()** is used instead. It calls the Win32 function **FormatMessage()** to retrieve the Windows description of error code given by *ierr* or **GetLastError()**, then it constructs a tuple object whose first item is the *ierr* value and whose second item is the corresponding error message (gotten from **FormatMessage()**), and then calls `PyErr_SetObject(PyExc_WindowsError, object)`. This function always returns `NULL`.

**Availability:** Windows.

**PyObject \***`PyErr_SetExcFromWindowsErr(PyObject *type, int ierr)`

*Return value:* Always `NULL`. Part of the **Stable ABI** on Windows since version 3.7.

Similar to **PyErr\_SetFromWindowsErr()**, with an additional parameter specifying the exception type to be raised.

**Availability:** Windows.

**PyObject \***`PyErr_SetFromWindowsErrWithFilename(int ierr, const char *filename)`

*Return value:* Always `NULL`. Part of the **Stable ABI** on Windows since version 3.7.

Similar to

**PyErr\_SetFromWindowsErrWithFilenameObject()**, but the filename is given as a C string. *filename* is decoded from the filesystem encoding (**os.fsdecode()**).

**Availability:** Windows.

**PyObject**

**\*PyErr\_SetExcFromWindowsErrWithFilenameObject(PyObject \*type, int ierr, PyObject \*filename)**

*Return value:* Always `NULL`. Part of the **Stable ABI** on Windows since version 3.7.

Similar to

**PyErr\_SetFromWindowsErrWithFilenameObject()**,  
with an additional parameter specifying the exception type to  
be raised.

**Availability:** Windows.

## PyObject

**\*PyErr\_SetExcFromWindowsErrWithFilenameObjects(PyObject**  
**\*type, int ierr, PyObject \*filename, PyObject \*filename2)**

*Return value:* Always NULL. Part of the [Stable ABI](#) on Windows  
since version 3.7.

Similar to

**PyErr\_SetExcFromWindowsErrWithFilenameObject()**,  
but accepts a second filename object.

**Availability:** Windows.

*New in version 3.4.*

**PyObject \*PyErr\_SetExcFromWindowsErrWithFilename(PyObject**  
**\*type, int ierr, const char \*filename)**

*Return value:* Always NULL. Part of the [Stable ABI](#) on Windows  
since version 3.7.

Similar to **PyErr\_SetFromWindowsErrWithFilename()**,  
with an additional parameter specifying the exception type to  
be raised.

**Availability:** Windows.

**PyObject \*PyErr\_SetImportError(PyObject \*msg, PyObject \*name,**  
**PyObject \*path)**

*Return value:* Always NULL. Part of the [Stable ABI](#) since version  
3.7.

This is a convenience function to raise **ImportError**. *msg*  
will be set as the exception's message string. *name* and *path*,  
both of which can be NULL, will be set as the  
**ImportError**'s respective *name* and *path* attributes.

*New in version 3.3.*

`PyObject *PyErr_SetImportErrorSubclass(PyObject *exception,  
PyObject *msg, PyObject *name, PyObject *path)`

*Return value: Always NULL. Part of the [Stable ABI](#) since version 3.6.*

Much like `PyErr_SetImportError()` but this function allows for specifying a subclass of `ImportError` to raise.

*New in version 3.6.*

`void PyErr_SyntaxLocationObject(PyObject *filename, int lineno,  
int col_offset)`

Set file, line, and offset information for the current exception. If the current exception is not a `SyntaxError`, then it sets additional attributes, which make the exception printing subsystem think the exception is a `SyntaxError`.

*New in version 3.4.*

`void PyErr_SyntaxLocationEx(const char *filename, int lineno, int  
col_offset)`

*Part of the [Stable ABI](#) since version 3.7.*

Like `PyErr_SyntaxLocationObject()`, but *filename* is a byte string decoded from the [filesystem encoding and error handler](#).

*New in version 3.2.*

`void PyErr_SyntaxLocation(const char *filename, int lineno)`

*Part of the [Stable ABI](#).*

Like `PyErr_SyntaxLocationEx()`, but the *col\_offset* parameter is omitted.

`void PyErr_BadInternalCall()`

*Part of the [Stable ABI](#).*

This is a shorthand for

`PyErr_SetString(PyExc_SystemError, message)`, where *message* indicates that an internal operation (e.g. a Python/C API function) was invoked with an illegal argument. It is mostly for internal use.

## Issuing warnings

Use these functions to issue warnings from C code. They mirror similar functions exported by the Python `warnings` module. They normally print a warning message to `sys.stderr`; however, it is also possible that the user has specified that warnings are to be turned into errors, and in that case they will raise an exception. It is also possible that the functions raise an exception because of a problem with the warning machinery. The return value is `0` if no exception is raised, or `-1` if an exception is raised. (It is not possible to determine whether a warning message is actually printed, nor what the reason is for the exception; this is intentional.) If an exception is raised, the caller should do its normal exception handling (for example, `Py_DECREF()` owned references and return an error value).

```
int PyErr_WarnEx(PyObject *category, const char *message,  
Py_ssize_t stack_level)
```

*Part of the [Stable ABI](#).*

Issue a warning message. The *category* argument is a warning category (see below) or `NULL`; the *message* argument is a UTF-8 encoded string. *stack\_level* is a positive number giving a number of stack frames; the warning will be issued from the currently executing line of code in that stack frame. A *stack\_level* of 1 is the function calling `PyErr_WarnEx()`, 2 is the function above that, and so forth.

Warning categories must be subclasses of `PyExc_Warning`; `PyExc_Warning` is a subclass of `PyExc_Exception`; the default warning category is `PyExc_RuntimeWarning`. The standard Python warning categories are available as global variables whose names are enumerated at [Standard Warning Categories](#).

For information about warning control, see the documentation for the `warnings` module and the `-W` option in the command line documentation. There is no C API for warning control.

```
int PyErr_WarnExplicitObject(PyObject *category, PyObject
*message, PyObject *filename, int lineno, PyObject *module,
PyObject *registry)
```

Issue a warning message with explicit control over all warning attributes. This is a straightforward wrapper around the Python function `warnings.warn_explicit()`; see there for more information. The *module* and *registry* arguments may be set to `NULL` to get the default effect described there.

*New in version 3.4.*

```
int PyErr_WarnExplicit(PyObject *category, const char *message,
const char *filename, int lineno, const char *module, PyObject
*registry)
```

*Part of the [Stable ABI](#).*

Similar to `PyErr_WarnExplicitObject()` except that *message* and *module* are UTF-8 encoded strings, and *filename* is decoded from the [filesystem encoding and error handler](#).

```
int PyErr_WarnFormat(PyObject *category, Py_ssize_t stack_level,
const char *format, ...)
```

*Part of the [Stable ABI](#).*

Function similar to `PyErr_WarnEx()`, but use `PyUnicode_FromFormat()` to format the warning message. *format* is an ASCII-encoded string.

*New in version 3.2.*

```
int PyErr_ResourceWarning(PyObject *source, Py_ssize_t stack_level,
const char *format, ...)
```

*Part of the [Stable ABI](#) since version 3.6.*

Function similar to `PyErr_WarnFormat()`, but *category* is `ResourceWarning` and it passes *source* to `warnings.WarningMessage()`.

*New in version 3.6.*

## Querying the error indicator

`PyObject *PyErr_Occurred()`

*Return value: Borrowed reference. Part of the [Stable ABI](#).*

Test whether the error indicator is set. If set, return the exception *type* (the first argument to the last call to one of the `PyErr_Set*` functions or to `PyErr_Restore()`). If not set, return `NULL`. You do not own a reference to the return value, so you do not need to `Py_DECREF()` it.

The caller must hold the GIL.

### Note

Do not compare the return value to a specific exception; use `PyErr_ExceptionMatches()` instead, shown below. (The comparison could easily fail since the exception may be an instance instead of a class, in the case of a class exception, or it may be a subclass of the expected exception.)

`int PyErr_ExceptionMatches(PyObject *exc)`

*Part of the [Stable ABI](#).*

Equivalent to

`PyErr_GivenExceptionMatches(PyErr_Occurred(), exc)`. This should only be called when an exception is actually set; a memory access violation will occur if no exception has been raised.

`int PyErr_GivenExceptionMatches(PyObject *given, PyObject *exc)`

*Part of the [Stable ABI](#).*

Return true if the *given* exception matches the exception type in *exc*. If *exc* is a class object, this also returns true when *given* is an instance of a subclass. If *exc* is a tuple, all exception types in the tuple (and recursively in subtuples) are searched for a match.

```
void PyErr_Fetch(PyObject **ptype, PyObject **pvalue, PyObject
**ptraceback)
```

*Part of the [Stable ABI](#).*

Retrieve the error indicator into three variables whose addresses are passed. If the error indicator is not set, set all three variables to `NULL`. If it is set, it will be cleared and you own a reference to each object retrieved. The value and traceback object may be `NULL` even when the type object is not.

### Note

This function is normally only used by code that needs to catch exceptions or by code that needs to save and restore the error indicator temporarily, e.g.:

```
{
    PyObject *type, *value, *traceback;
    PyErr_Fetch(&type, &value, &traceback);

    /* ... code that might produce other errors ...

    PyErr_Restore(type, value, traceback);
}
```

```
void PyErr_Restore(PyObject *type, PyObject *value, PyObject
*traceback)
```

*Part of the [Stable ABI](#).*

Set the error indicator from the three objects. If the error indicator is already set, it is cleared first. If the objects are `NULL`, the error indicator is cleared. Do not pass a `NULL` type

and non-NULL value or traceback. The exception type should be a class. Do not pass an invalid exception type or value. (Violating these rules will cause subtle problems later.) This call takes away a reference to each object: you must own a reference to each object before the call and after the call you no longer own these references. (If you don't understand this, don't use this function. I warned you.)

### Note

This function is normally only used by code that needs to save and restore the error indicator temporarily. Use `PyErr_Fetch()` to save the current error indicator.

```
void PyErr_NormalizeException(PyObject **exc, PyObject **val,  
PyObject **tb)
```

*Part of the [Stable ABI](#).*

Under certain circumstances, the values returned by `PyErr_Fetch()` below can be “unnormalized”, meaning that `*exc` is a class object but `*val` is not an instance of the same class. This function can be used to instantiate the class in that case. If the values are already normalized, nothing happens. The delayed normalization is implemented to improve performance.

### Note

This function *does not* implicitly set the `__traceback__` attribute on the exception value. If setting the traceback appropriately is desired, the following additional snippet is needed:

```
if (tb != NULL) {  
    PyException_SetTraceback(val, tb);  
}
```

```
PyObject *PyErr_GetHandledException(void)
```

Part of the *Stable ABI* since version 3.11.

Retrieve the active exception instance, as would be returned by `sys.exception()`. This refers to an exception that was *already caught*, not to an exception that was freshly raised. Returns a new reference to the exception or `NULL`. Does not modify the interpreter's exception state.

### Note

This function is not normally used by code that wants to handle exceptions. Rather, it can be used when code needs to save and restore the exception state temporarily. Use `PyErr_SetHandledException()` to restore or clear the exception state.

*New in version 3.11.*

`void PyErr_SetHandledException(PyObject *exc)`

Part of the *Stable ABI* since version 3.11.

Set the active exception, as known from `sys.exception()`. This refers to an exception that was *already caught*, not to an exception that was freshly raised. To clear the exception state, pass `NULL`.

### Note

This function is not normally used by code that wants to handle exceptions. Rather, it can be used when code needs to save and restore the exception state temporarily. Use `PyErr_GetHandledException()` to get the exception state.

*New in version 3.11.*

`void PyErr_GetExcInfo(PyObject **ptype, PyObject **pvalue, PyObject **ptraceback)`

Part of the *Stable ABI* since version 3.7.

Retrieve the old-style representation of the exception info, as

known from `sys.exc_info()`. This refers to an exception that was *already caught*, not to an exception that was freshly raised. Returns new references for the three objects, any of which may be `NULL`. Does not modify the exception info state. This function is kept for backwards compatibility. Prefer using `PyErr_GetHandledException()`.

### Note

This function is not normally used by code that wants to handle exceptions. Rather, it can be used when code needs to save and restore the exception state temporarily. Use `PyErr_SetExcInfo()` to restore or clear the exception state.

*New in version 3.3.*

`void PyErr_SetExcInfo(PyObject *type, PyObject *value, PyObject *traceback)`

*Part of the [Stable ABI](#) since version 3.7.*

Set the exception info, as known from `sys.exc_info()`. This refers to an exception that was *already caught*, not to an exception that was freshly raised. This function steals the references of the arguments. To clear the exception state, pass `NULL` for all three arguments. This function is kept for backwards compatibility. Prefer using `PyErr_SetHandledException()`.

### Note

This function is not normally used by code that wants to handle exceptions. Rather, it can be used when code needs to save and restore the exception state temporarily. Use `PyErr_GetExcInfo()` to read the exception state.

*New in version 3.3.*

*Changed in version 3.11:* The `type` and `traceback` arguments are no longer used and can be `NULL`. The

interpreter now derives them from the exception instance (the `value` argument). The function still steals references of all three arguments.

## Signal Handling

`int PyErr_CheckSignals()`

*Part of the [Stable ABI](#).*

This function interacts with Python's signal handling.

If the function is called from the main thread and under the main Python interpreter, it checks whether a signal has been sent to the processes and if so, invokes the corresponding signal handler. If the [signal](#) module is supported, this can invoke a signal handler written in Python.

The function attempts to handle all pending signals, and then returns `0`. However, if a Python signal handler raises an exception, the error indicator is set and the function returns `-1` immediately (such that other pending signals may not have been handled yet: they will be on the next [PyErr\\_CheckSignals\(\)](#) invocation).

If the function is called from a non-main thread, or under a non-main Python interpreter, it does nothing and returns `0`.

This function can be called by long-running C code that wants to be interruptible by user requests (such as by pressing Ctrl-C).

### Note

The default Python signal handler for **SIGINT** raises the [KeyboardInterrupt](#) exception.

`void PyErr_SetInterrupt()`

*Part of the [Stable ABI](#).*

Simulate the effect of a **SIGINT** signal arriving. This is

equivalent to `PyErr_SetInterruptEx(SIGINT)`.

### Note

This function is async-signal-safe. It can be called without the [GIL](#) and from a C signal handler.

`int PyErr_SetInterruptEx(int signum)`

*Part of the [Stable ABI](#) since version 3.10.*

Simulate the effect of a signal arriving. The next time `PyErr_CheckSignals()` is called, the Python signal handler for the given signal number will be called.

This function can be called by C code that sets up its own signal handling and wants Python signal handlers to be invoked as expected when an interruption is requested (for example when the user presses Ctrl-C to interrupt an operation).

If the given signal isn't handled by Python (it was set to `signal.SIG_DFL` or `signal.SIG_IGN`), it will be ignored.

If *signum* is outside of the allowed range of signal numbers, `-1` is returned. Otherwise, `0` is returned. The error indicator is never changed by this function.

### Note

This function is async-signal-safe. It can be called without the [GIL](#) and from a C signal handler.

*New in version 3.10.*

`int PySignal_SetWakeupFd(int fd)`

This utility function specifies a file descriptor to which the signal number is written as a single byte whenever a signal is received. *fd* must be non-blocking. It returns the previous such file descriptor.

The value `-1` disables the feature; this is the initial state. This is equivalent to `signal.set_wakeup_fd()` in Python, but without any error checking. `fd` should be a valid file descriptor. The function should only be called from the main thread.

*Changed in version 3.5:* On Windows, the function now also supports socket handles.

## Exception Classes

`PyObject *PyErr_NewException(const char *name, PyObject *base, PyObject *dict)`

*Return value:* New reference. Part of the [Stable ABI](#).

This utility function creates and returns a new exception class. The *name* argument must be the name of the new exception, a C string of the form `module.classname`. The *base* and *dict* arguments are normally `NULL`. This creates a class object derived from `Exception` (accessible in C as `PyExc_Exception`).

The `__module__` attribute of the new class is set to the first part (up to the last dot) of the *name* argument, and the class name is set to the last part (after the last dot). The *base* argument can be used to specify alternate base classes; it can either be only one class or a tuple of classes. The *dict* argument can be used to specify a dictionary of class variables and methods.

`PyObject *PyErr_NewExceptionWithDoc(const char *name, const char *doc, PyObject *base, PyObject *dict)`

*Return value:* New reference. Part of the [Stable ABI](#).

Same as `PyErr_NewException()`, except that the new exception class can easily be given a docstring: If *doc* is non-`NULL`, it will be used as the docstring for the exception class.

*New in version 3.2.*

# Exception Objects

`PyObject *``PyException_GetTraceback(PyObject *ex)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return the traceback associated with the exception as a new reference, as accessible from Python through `__traceback__`. If there is no traceback associated, this returns `NULL`.

`int` `PyException_SetTraceback(PyObject *ex, PyObject *tb)`

*Part of the [Stable ABI](#).*

Set the traceback associated with the exception to `tb`. Use `Py_None` to clear it.

`PyObject *``PyException_GetContext(PyObject *ex)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return the context (another exception instance during whose handling `ex` was raised) associated with the exception as a new reference, as accessible from Python through `__context__`. If there is no context associated, this returns `NULL`.

`void` `PyException_SetContext(PyObject *ex, PyObject *ctx)`

*Part of the [Stable ABI](#).*

Set the context associated with the exception to `ctx`. Use `NULL` to clear it. There is no type check to make sure that `ctx` is an exception instance. This steals a reference to `ctx`.

`PyObject *``PyException_GetCause(PyObject *ex)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return the cause (either an exception instance, or `None`, set by `raise ... from ...`) associated with the exception as a new reference, as accessible from Python through `__cause__`.

`void` `PyException_SetCause(PyObject *ex, PyObject *cause)`

Part of the *Stable ABI*.

Set the cause associated with the exception to *cause*. Use `NULL` to clear it. There is no type check to make sure that *cause* is either an exception instance or `None`. This steals a reference to *cause*.

`__suppress_context__` is implicitly set to `True` by this function.

## Unicode Exception Objects

The following functions are used to create and modify Unicode exceptions from C.

`PyObject *PyUnicodeDecodeError_Create(const char *encoding, const char *object, Py_ssize_t length, Py_ssize_t start, Py_ssize_t end, const char *reason)`

*Return value:* New reference. Part of the *Stable ABI*.

Create a `UnicodeDecodeError` object with the attributes *encoding*, *object*, *length*, *start*, *end* and *reason*. *encoding* and *reason* are UTF-8 encoded strings.

`PyObject *PyUnicodeDecodeError_GetEncoding(PyObject *exc)`

`PyObject *PyUnicodeEncodeError_GetEncoding(PyObject *exc)`

*Return value:* New reference. Part of the *Stable ABI*.

Return the *encoding* attribute of the given exception object.

`PyObject *PyUnicodeDecodeError_GetObject(PyObject *exc)`

`PyObject *PyUnicodeEncodeError_GetObject(PyObject *exc)`

`PyObject *PyUnicodeTranslateError_GetObject(PyObject *exc)`

*Return value:* New reference. Part of the *Stable ABI*.

Return the *object* attribute of the given exception object.

`int PyUnicodeDecodeError_GetStart(PyObject *exc, Py_ssize_t *start)`

`int PyUnicodeEncodeError_GetStart(PyObject *exc, Py_ssize_t`

`*start)`

`int PyUnicodeTranslateError_GetStart(PyObject *exc, Py_ssize_t  
*start)`

*Part of the [Stable ABI](#).*

Get the *start* attribute of the given exception object and place it into *\*start*. *start* must not be `NULL`. Return `0` on success, `-1` on failure.

`int PyUnicodeDecodeError_SetStart(PyObject *exc, Py_ssize_t start)`

`int PyUnicodeEncodeError_SetStart(PyObject *exc, Py_ssize_t start)`

`int PyUnicodeTranslateError_SetStart(PyObject *exc, Py_ssize_t  
start)`

*Part of the [Stable ABI](#).*

Set the *start* attribute of the given exception object to *start*. Return `0` on success, `-1` on failure.

`int PyUnicodeDecodeError_GetEnd(PyObject *exc, Py_ssize_t *end)`

`int PyUnicodeEncodeError_GetEnd(PyObject *exc, Py_ssize_t *end)`

`int PyUnicodeTranslateError_GetEnd(PyObject *exc, Py_ssize_t  
*end)`

*Part of the [Stable ABI](#).*

Get the *end* attribute of the given exception object and place it into *\*end*. *end* must not be `NULL`. Return `0` on success, `-1` on failure.

`int PyUnicodeDecodeError_SetEnd(PyObject *exc, Py_ssize_t end)`

`int PyUnicodeEncodeError_SetEnd(PyObject *exc, Py_ssize_t end)`

`int PyUnicodeTranslateError_SetEnd(PyObject *exc, Py_ssize_t end)`

*Part of the [Stable ABI](#).*

Set the *end* attribute of the given exception object to *end*. Return `0` on success, `-1` on failure.

`PyObject *PyUnicodeDecodeError_GetReason(PyObject *exc)`

`PyObject *PyUnicodeEncodeError_GetReason(PyObject *exc)`

`PyObject *PyUnicodeTranslateError_GetReason(PyObject *exc)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return the *reason* attribute of the given exception object.

```
int PyUnicodeDecodeError_SetReason(PyObject *exc, const char  
*reason)
```

```
int PyUnicodeEncodeError_SetReason(PyObject *exc, const char  
*reason)
```

```
int PyUnicodeTranslateError_SetReason(PyObject *exc, const char  
*reason)
```

*Part of the [Stable ABI](#).*

Set the *reason* attribute of the given exception object to *reason*. Return 0 on success, -1 on failure.

## Recursion Control

These two functions provide a way to perform safe recursive calls at the C level, both in the core and in extension modules. They are needed if the recursive code does not necessarily invoke Python code (which tracks its recursion depth automatically). They are also not needed for *tp\_call* implementations because the [call protocol](#) takes care of recursion handling.

```
int Py_EnterRecursiveCall(const char *where)
```

*Part of the [Stable ABI](#) since version 3.9.*

Marks a point where a recursive C-level call is about to be performed.

If **USE\_STACKCHECK** is defined, this function checks if the OS stack overflowed using [PyOS\\_CheckStack\(\)](#). In this is the case, it sets a [MemoryError](#) and returns a nonzero value.

The function then checks if the recursion limit is reached. If this is the case, a [RecursionError](#) is set and a nonzero value is returned. Otherwise, zero is returned.

*where* should be a UTF-8 encoded string such as " in instance check" to be concatenated to the

**RecursionError** message caused by the recursion depth limit.

*Changed in version 3.9:* This function is now also available in the limited API.

void Py\_LeaveRecursiveCall(void)

*Part of the **Stable ABI** since version 3.9.*

Ends a **Py\_EnterRecursiveCall()**. Must be called once for each *successful* invocation of **Py\_EnterRecursiveCall()**.

*Changed in version 3.9:* This function is now also available in the limited API.

Properly implementing **tp\_repr** for container types requires special recursion handling. In addition to protecting the stack, **tp\_repr** also needs to track objects to prevent cycles. The following two functions facilitate this functionality. Effectively, these are the C equivalent to **reprlib.recursive\_repr()**.

int Py\_ReprEnter(PyObject \*object)

*Part of the **Stable ABI**.*

Called at the beginning of the **tp\_repr** implementation to detect cycles.

If the object has already been processed, the function returns a positive integer. In that case the **tp\_repr** implementation should return a string object indicating a cycle. As examples, **dict** objects return `{...}` and **list** objects return `[...]`.

The function will return a negative integer if the recursion limit is reached. In that case the **tp\_repr** implementation should typically return `NULL`.

Otherwise, the function returns zero and the **tp\_repr** implementation can continue normally.

void Py\_ReprLeave(PyObject \*object)

Part of the *Stable ABI*.

Ends a `Py_ReprEnter()`. Must be called once for each invocation of `Py_ReprEnter()` that returns zero.

## Standard Exceptions

All standard Python exceptions are available as global variables whose names are `PyExc_` followed by the Python exception name. These have the type `PyObject*`; they are all class objects. For completeness, here are all the variables:

~~PyModule~~ Name

---

`PyExc_BaseException`

---

`PyExc_Exception`

---

`PyExc_ArithmeticError`

---

`PyExc_AssertionError`

---

`PyExc_AttributeError`

---

`PyExc_BlockingIOError`

---

`PyExc_BrokenPipeError`

---

`PyExc_BufferError`

---

`PyExc_ChildProcessError`

---

`PyExc_ConnectionAbortedError`

---

`PyExc_ConnectionError`

---

`PyExc_ConnectionRefusedError`

---

`PyExc_ConnectionResetError`

---

`PyExc_EOFError`

---

`PyExc_FileExistsError`

---

`PyExc_FileNotFoundError`

---

`PyExc_FloatingPointError`

---

`PyExc_GeneratorExit`

---

`PyExc_ImportError`

---

`PyExc_IndentationError`

---

`PyExc_IndexError`

---

`PyExc_InterruptedError`

---

`PyExc_IsADirectoryError`

---

`PyExc_KeyError`

---

`PyExc_KeyboardInterrupt`

---

`PyExc_LookupError`

---

<code>PyExc_MemoryError</code>
<code>PyExc_ModuleNotFoundError</code>
<code>PyExc_NameError</code>
<code>PyExc_NotADirectoryError</code>
<code>PyExc_NotImplementedError</code>
<code>PyExc_OSError</code>
<code>PyExc_OSError</code>
<code>PyExc_PermissionError</code>
<code>PyExc_ProcessLookupError</code>
<code>PyExc_RecursionError</code>
<code>PyExc_ReferenceError</code>
<code>PyExc_RuntimeError</code>
<code>PyExc_StopAsyncIteration</code>
<code>PyExc_StopIteration</code>
<code>PyExc_SyntaxError</code>
<code>PyExc_SystemError</code>
<code>PyExc_SystemExit</code>
<code>PyExc_TabError</code>
<code>PyExc_TimeoutError</code>
<code>PyExc_TypeError</code>
<code>PyExc_UnboundLocalError</code>
<code>PyExc_UnencodeError</code>
<code>PyExc_UnencodeError</code>
<code>PyExc_UniencodeError</code>
<code>PyExc_UniencodeError</code>
<code>PyExc_UniencodeError</code>
<code>PyExc_ValueError</code>
<code>PyExc_WarningError</code>

New in version 3.3: `PyExc_BlockingIOError`, `PyExc_BrokenPipeError`, `PyExc_ChildProcessError`, `PyExc_ConnectionError`, `PyExc_ConnectionAbortedError`, `PyExc_ConnectionRefusedError`, `PyExc_ConnectionResetError`, `PyExc_FileExistsError`, `PyExc_FileNotFoundError`, `PyExc_InterruptedError`, `PyExc_IsADirectoryError`, `PyExc_NotADirectoryError`, `PyExc_PermissionError`, `PyExc_ProcessLookupError` and `PyExc_TimeoutError` were introduced following [PEP 3151](https://peps.python.org/pep-3151/) [https://peps.python.org/pep-3151/].

New in version 3.5: `PyExc_StopAsyncIteration` and `PyExc_RecursionError`.

New in version 3.6: `PyExc_ModuleNotFoundError`.

These are compatibility aliases to `PyExc_OSError`:

Name
<code>PyExc_EnvironmentError</code>
<code>PyExc_IOError</code>
<code>PyExc_WindowsError</code>

Changed in version 3.3: These aliases used to be separate exception types.

Notes:

1([1](#),[2](#),[3](#),[4](#),[5](#))

This is a base class for other standard exceptions.

2

Only defined on Windows; protect code that uses this by testing that the preprocessor macro `MS_WINDOWS` is defined.

## Standard Warning Categories

All standard Python warning categories are available as global variables whose names are `PyExc_` followed by the Python exception name. These have the type `PyObject*`; they are all class objects. For completeness, here are all the variables:

Name
<code>PyExc_Warning</code>
<code>PyExc_SyntaxWarning</code>
<code>PyExc_DeprecationWarning</code>
<code>PyExc_FutureWarning</code>
<code>PyExc_ImportWarning</code>
<code>PyExc_EndlessDeprecationWarning</code>
<code>PyExc_ResourceWarning</code>
<code>PyExc_RuntimeWarning</code>

~~PyExc\_SyntaxWarning~~

~~PyExc\_UniCodeWarning~~

---

~~PyExc\_UserWarning~~

---

*New in version 3.2:* **PyExc\_ResourceWarning**.

Notes:

3

This is a base class for other standard warning categories.

# Utilities

The functions in this chapter perform various utility tasks, ranging from helping C code be more portable across platforms, using Python modules from C, and parsing function arguments and constructing Python values from C values.

- [Operating System Utilities](#)
- [System Functions](#)
- [Process Control](#)
- [Importing Modules](#)
- [Data marshalling support](#)
- [Parsing arguments and building values](#)
  - [Parsing arguments](#)
    - [Strings and buffers](#)
    - [Numbers](#)
    - [Other objects](#)
    - [API Functions](#)
  - [Building values](#)
- [String conversion and formatting](#)
- [Reflection](#)
- [Codec registry and support functions](#)
  - [Codec lookup API](#)
  - [Registry API for Unicode encoding error handlers](#)

# Operating System Utilities

`PyObject *PyOS_FSPath(PyObject *path)`

*Return value:* New reference. Part of the [Stable ABI](#) since version 3.6.

Return the file system representation for *path*. If the object is a `str` or `bytes` object, then its reference count is incremented. If the object implements the `os.PathLike` interface, then `__fspath__()` is returned as long as it is a `str` or `bytes` object. Otherwise `TypeError` is raised and `NULL` is returned.

*New in version 3.6.*

`int Py_FdIsInteractive(FILE *fp, const char *filename)`

Return true (nonzero) if the standard I/O file *fp* with name *filename* is deemed interactive. This is the case for files for which `isatty(fileno(fp))` is true. If the global flag `Py_InteractiveFlag` is true, this function also returns true if the *filename* pointer is `NULL` or if the name is equal to one of the strings `'<stdin>'` or `'???'`.

`void PyOS_BeforeFork()`

*Part of the [Stable ABI](#) on platforms with `fork()` since version 3.7.* Function to prepare some internal state before a process fork. This should be called before calling `fork()` or any similar function that clones the current process. Only available on systems where `fork()` is defined.

## Warning

The C `fork()` call should only be made from the “[main](#)” [thread](#) (of the “[main](#)” [interpreter](#)). The same is true for `PyOS_BeforeFork()`.

*New in version 3.7.*

`void PyOS_AfterFork_Parent()`

*Part of the [Stable ABI](#) on platforms with `fork()` since version 3.7.*  
Function to update some internal state after a process fork. This should be called from the parent process after calling **`fork()`** or any similar function that clones the current process, regardless of whether process cloning was successful. Only available on systems where **`fork()`** is defined.

### Warning

The C **`fork()`** call should only be made from the “[main](#)” [thread](#) (of the “[main](#)” [interpreter](#)). The same is true for `PyOS_AfterFork_Parent()`.

*New in version 3.7.*

`void PyOS_AfterFork_Child()`

*Part of the [Stable ABI](#) on platforms with `fork()` since version 3.7.*  
Function to update internal interpreter state after a process fork. This must be called from the child process after calling **`fork()`**, or any similar function that clones the current process, if there is any chance the process will call back into the Python interpreter. Only available on systems where **`fork()`** is defined.

### Warning

The C **`fork()`** call should only be made from the “[main](#)” [thread](#) (of the “[main](#)” [interpreter](#)). The same is true for `PyOS_AfterFork_Child()`.

*New in version 3.7.*

### See also

[`os.register\_at\_fork\(\)`](#) allows registering custom Python functions to be called by [`PyOS\_BeforeFork\(\)`](#),

`PyOS_AfterFork_Parent()` and  
`PyOS_AfterFork_Child()`.

`void PyOS_AfterFork()`

*Part of the [Stable ABI](#) on platforms with `fork()`.*

Function to update some internal state after a process fork; this should be called in the new process if the Python interpreter will continue to be used. If a new executable is loaded into the new process, this function does not need to be called.

*Deprecated since version 3.7:* This function is superseded by `PyOS_AfterFork_Child()`.

`int PyOS_CheckStack()`

*Part of the [Stable ABI](#) on platforms with `USE_STACKCHECK` since version 3.7.*

Return true when the interpreter runs out of stack space. This is a reliable check, but is only available when

**USE\_STACKCHECK** is defined (currently on certain versions of Windows using the Microsoft Visual C++ compiler).

**USE\_STACKCHECK** will be defined automatically; you should never change the definition in your own code.

`PyOS_sighandler_t PyOS_getsig(int i)`

*Part of the [Stable ABI](#).*

Return the current signal handler for signal *i*. This is a thin wrapper around either `sigaction()` or `signal()`. Do not call those functions directly! **PyOS\_sighandler\_t** is a typedef alias for `void (*)(int)`.

`PyOS_sighandler_t PyOS_setsig(int i, PyOS_sighandler_t h)`

*Part of the [Stable ABI](#).*

Set the signal handler for signal *i* to be *h*; return the old signal handler. This is a thin wrapper around either `sigaction()` or `signal()`. Do not call those functions directly!

**PyOS\_sighandler\_t** is a typedef alias for `void (*)(int)`.

wchar\_t \*Py\_DecodeLocale(const char \*arg, size\_t \*size)

*Part of the [Stable ABI](#) since version 3.7.*

### Warning

This function should not be called directly: use the [PyConfig](#) API with the [PyConfig\\_SetBytesString\(\)](#) function which ensures that [Python is preinitialized](#).

This function must not be called before [Python is preinitialized](#) and so that the LC\_CTYPE locale is properly configured: see the [Py\\_PreInitialize\(\)](#) function.

Decode a byte string from the [filesystem encoding and error handler](#). If the error handler is [surrogateescape error handler](#), undecodable bytes are decoded as characters in range U +DC80..U +DCFF; and if a byte sequence can be decoded as a surrogate character, the bytes are escaped using the surrogateescape error handler instead of decoding them.

Return a pointer to a newly allocated wide character string, use [PyMem\\_RawFree\(\)](#) to free the memory. If size is not NULL, write the number of wide characters excluding the null character into \*size

Return NULL on decoding error or memory allocation error. If size is not NULL, \*size is set to (size\_t)-1 on memory error or set to (size\_t)-2 on decoding error.

The [filesystem encoding and error handler](#) are selected by [PyConfig\\_Read\(\)](#): see [filesystem\\_encoding](#) and [filesystem\\_errors](#) members of [PyConfig](#).

Decoding errors should never happen, unless there is a bug in the C library.

Use the [Py\\_EncodeLocale\(\)](#) function to encode the character string back to a byte string.

**See also**

The `PyUnicode_DecodeFSDefaultAndSize()` and `PyUnicode_DecodeLocaleAndSize()` functions.

*New in version 3.5.*

*Changed in version 3.7:* The function now uses the UTF-8 encoding in the [Python UTF-8 Mode](#).

*Changed in version 3.8:* The function now uses the UTF-8 encoding on Windows if `Py_LegacyWindowsFSEncodingFlag` is zero;

`char *Py_EncodeLocale(const wchar_t *text, size_t *error_pos)`

*Part of the [Stable ABI](#) since version 3.7.*

Encode a wide character string to the [filesystem encoding and error handler](#). If the error handler is [surrogateescape error handler](#), surrogate characters in the range U+DC80..U+DCFF are converted to bytes 0x80..0xFF.

Return a pointer to a newly allocated byte string, use `PyMem_Free()` to free the memory. Return `NULL` on encoding error or memory allocation error.

If `error_pos` is not `NULL`, `*error_pos` is set to `(size_t)-1` on success, or set to the index of the invalid character on encoding error.

The [filesystem encoding and error handler](#) are selected by `PyConfig_Read()`: see [filesystem\\_encoding](#) and [filesystem\\_errors](#) members of `PyConfig`.

Use the `Py_DecodeLocale()` function to decode the bytes string back to a wide character string.

## Warning

This function must not be called before [Python is preinitialized](#) and so that the `LC_CTYPE` locale is properly configured: see the `Py_PreInitialize()` function.

## See also

The `PyUnicode_EncodeFSDefault()` and `PyUnicode_EncodeLocale()` functions.

*New in version 3.5.*

*Changed in version 3.7:* The function now uses the UTF-8 encoding in the [Python UTF-8 Mode](#).

*Changed in version 3.8:* The function now uses the UTF-8 encoding on Windows if `Py_LegacyWindowsFSEncodingFlag` is zero.

# System Functions

These are utility functions that make functionality from the `sys` module accessible to C code. They all work with the current interpreter thread's `sys` module's dict, which is contained in the internal thread state structure.

`PyObject *``PySys_GetObject`(const char \*name)

*Return value:* Borrowed reference. Part of the [Stable ABI](#).

Return the object *name* from the `sys` module or `NULL` if it does not exist, without setting an exception.

int `PySys_SetObject`(const char \*name, `PyObject *`v)

*Part of the [Stable ABI](#).*

Set *name* in the `sys` module to *v* unless *v* is `NULL`, in which case *name* is deleted from the `sys` module. Returns `0` on success, `-1` on error.

void `PySys_ResetWarnOptions`()

*Part of the [Stable ABI](#).*

Reset `sys.warnoptions` to an empty list. This function may be called prior to `Py_Initialize()`.

`void PySys_AddWarnOption(const wchar_t *s)`

*Part of the [Stable ABI](#).*

This API is kept for backward compatibility: setting [PyConfig.warnoptions](#) should be used instead, see [Python Initialization Configuration](#).

Append *s* to [sys.warnoptions](#). This function must be called prior to [Py\\_Initialize\(\)](#) in order to affect the warnings filter list.

*Deprecated since version 3.11.*

`void PySys_AddWarnOptionUnicode(PyObject *unicode)`

*Part of the [Stable ABI](#).*

This API is kept for backward compatibility: setting [PyConfig.warnoptions](#) should be used instead, see [Python Initialization Configuration](#).

Append *unicode* to [sys.warnoptions](#).

Note: this function is not currently usable from outside the CPython implementation, as it must be called prior to the implicit import of [warnings](#) in [Py\\_Initialize\(\)](#) to be effective, but can't be called until enough of the runtime has been initialized to permit the creation of Unicode objects.

*Deprecated since version 3.11.*

`void PySys_SetPath(const wchar_t *path)`

*Part of the [Stable ABI](#).*

This API is kept for backward compatibility: setting [PyConfig.module\\_search\\_paths](#) and [PyConfig.module\\_search\\_paths\\_set](#) should be used instead, see [Python Initialization Configuration](#).

Set [sys.path](#) to a list object of paths found in *path* which should be a list of paths separated with the platform's search path delimiter (: on Unix, ; on Windows).

*Deprecated since version 3.11.*

`void PySys_WriteStdout(const char *format, ...)`

*Part of the [Stable ABI](#).*

Write the output string described by *format* to `sys.stdout`. No exceptions are raised, even if truncation occurs (see below).

*format* should limit the total size of the formatted output string to 1000 bytes or less – after 1000 bytes, the output string is truncated. In particular, this means that no unrestricted “%s” formats should occur; these should be limited using “%.<N>s” where <N> is a decimal number calculated so that <N> plus the maximum size of other formatted text does not exceed 1000 bytes. Also watch out for “%f”, which can print hundreds of digits for very large numbers.

If a problem occurs, or `sys.stdout` is unset, the formatted message is written to the real (C level) *stdout*.

`void PySys_WriteStderr(const char *format, ...)`

*Part of the [Stable ABI](#).*

As `PySys_WriteStdout()`, but write to `sys.stderr` or *stderr* instead.

`void PySys_FormatStdout(const char *format, ...)`

*Part of the [Stable ABI](#).*

Function similar to `PySys_WriteStdout()` but format the message using `PyUnicode_FromFormatV()` and don't truncate the message to an arbitrary length.

*New in version 3.2.*

`void PySys_FormatStderr(const char *format, ...)`

*Part of the [Stable ABI](#).*

As `PySys_FormatStdout()`, but write to `sys.stderr` or *stderr* instead.

*New in version 3.2.*

`void PySys_AddXOption(const wchar_t *s)`

*Part of the [Stable ABI](#) since version 3.7.*

This API is kept for backward compatibility: setting `PyConfig.xoptions` should be used instead, see [Python Initialization Configuration](#).

Parse *s* as a set of `-X` options and add them to the current options mapping as returned by `PySys_GetXOptions()`. This function may be called prior to `Py_Initialize()`.

*New in version 3.2.*

*Deprecated since version 3.11.*

`PyObject *PySys_GetXOptions()`

*Return value: Borrowed reference. Part of the [Stable ABI](#) since version 3.7.*

Return the current dictionary of `-X` options, similarly to `sys._xoptions`. On error, `NULL` is returned and an exception is set.

*New in version 3.2.*

`int PySys_Audit(const char *event, const char *format, ...)`

Raise an auditing event with any active hooks. Return zero for success and non-zero with an exception set on failure.

If any hooks have been added, *format* and other arguments will be used to construct a tuple to pass. Apart from `N`, the same format characters as used in `Py_BuildValue()` are available. If the built value is not a tuple, it will be added into a single-element tuple. (The `N` format option consumes a reference, but since there is no way to know whether arguments to this function will be consumed, using it may cause reference leaks.)

Note that `#` format characters should always be treated as `Py_ssize_t`, regardless of whether `PY_SSIZE_T_CLEAN` was defined.

`sys.audit()` performs the same function from Python code.

*New in version 3.8.*

*Changed in version 3.8.2:* Require `Py_ssize_t` for `#` format characters. Previously, an unavoidable deprecation warning was raised.

```
int PySys_AddAuditHook(Py_AuditHookFunction hook, void
*userData)
```

Append the callable *hook* to the list of active auditing hooks. Return zero on success and non-zero on failure. If the runtime has been initialized, also set an error on failure. Hooks added through this API are called for all interpreters created by the runtime.

The *userData* pointer is passed into the hook function. Since hook functions may be called from different runtimes, this pointer should not refer directly to Python state.

This function is safe to call before `Py_Initialize()`. When called after runtime initialization, existing audit hooks are notified and may silently abort the operation by raising an error subclassed from `Exception` (other errors will not be silenced).

The hook function is of type `int (*)(const char *event, PyObject *args, void *userData)`, where *args* is guaranteed to be a `PyTupleObject`. The hook function is always called with the GIL held by the Python interpreter that raised the event.

See [PEP 578](https://peps.python.org/pep-0578/) [https://peps.python.org/pep-0578/] for a detailed description of auditing. Functions in the runtime and standard library that raise events are listed in the [audit events table](#). Details are in each function's documentation.

If the interpreter is initialized, this function raises a auditing event `sys.addaudithook` with no arguments. If any existing hooks raise an exception derived from `Exception`,

the new hook will not be added and the exception is cleared. As a result, callers cannot assume that their hook has been added unless they control all existing hooks.

*New in version 3.8.*

## Process Control

`void Py_FatalError(const char *message)`

*Part of the [Stable ABI](#).*

Print a fatal error message and kill the process. No cleanup is performed. This function should only be invoked when a condition is detected that would make it dangerous to continue using the Python interpreter; e.g., when the object administration appears to be corrupted. On Unix, the standard C library function `abort()` is called which will attempt to produce a `core` file.

The `Py_FatalError()` function is replaced with a macro which logs automatically the name of the current function, unless the `PY_LIMITED_API` macro is defined.

*Changed in version 3.9:* Log the function name automatically.

`void Py_Exit(int status)`

*Part of the [Stable ABI](#).*

Exit the current process. This calls `Py_FinalizeEx()` and then calls the standard C library function `exit(status)`. If `Py_FinalizeEx()` indicates an error, the exit status is set to 120.

*Changed in version 3.6:* Errors from finalization no longer ignored.

`int Py_AtExit(void (*func)())`

*Part of the [Stable ABI](#).*

Register a cleanup function to be called by `Py_FinalizeEx()`. The cleanup function will be called with no arguments and should return no value. At most 32 cleanup functions can be registered. When the registration is successful, `Py_AtExit()` returns 0; on failure, it returns -1. The cleanup function registered last is called first. Each cleanup function will be called at most once. Since Python's internal finalization will have completed before the cleanup function, no Python APIs should be called by *func*.

# Importing Modules

**PyObject \***PyImport\_ImportModule(const char \*name)

*Return value:* New reference. Part of the [Stable ABI](#).

This is a simplified interface to

**PyImport\_ImportModuleEx()** below, leaving the *globals* and *locals* arguments set to `NULL` and *level* set to 0. When the *name* argument contains a dot (when it specifies a submodule of a package), the *fromlist* argument is set to the list `['*']` so that the return value is the named module rather than the top-level package containing it as would otherwise be the case. (Unfortunately, this has an additional side effect when *name* in fact specifies a subpackage instead of a submodule: the submodules specified in the package's `__all__` variable are loaded.) Return a new reference to the imported module, or `NULL` with an exception set on failure. A failing import of a module doesn't leave the module in `sys.modules`.

This function always uses absolute imports.

**PyObject \***PyImport\_ImportModuleNoBlock(const char \*name)

*Return value:* New reference. Part of the [Stable ABI](#).

This function is a deprecated alias of

**PyImport\_ImportModule()**.

*Changed in version 3.3:* This function used to fail immediately when the import lock was held by another thread. In Python 3.3 though, the locking scheme switched to per-module locks for most purposes, so this function's special behaviour isn't needed anymore.

**PyObject \***PyImport\_ImportModuleEx(const char \*name, **PyObject** \*globals, **PyObject** \*locals, **PyObject** \*fromlist)

*Return value:* New reference.

Import a module. This is best described by referring to the built-in Python function `__import__()`.

The return value is a new reference to the imported module or top-level package, or `NULL` with an exception set on failure. Like for `__import__()`, the return value when a submodule of a package was requested is normally the top-level package, unless a non-empty *fromlist* was given.

Failing imports remove incomplete module objects, like with `PyImport_ImportModule()`.

`PyObject *``PyImport_ImportModuleLevelObject(PyObject *name, PyObject *globals, PyObject *locals, PyObject *fromlist, int level)`

*Return value:* New reference. Part of the *Stable ABI* since version 3.7.

Import a module. This is best described by referring to the built-in Python function `__import__()`, as the standard `__import__()` function calls this function directly.

The return value is a new reference to the imported module or top-level package, or `NULL` with an exception set on failure. Like for `__import__()`, the return value when a submodule of a package was requested is normally the top-level package, unless a non-empty *fromlist* was given.

*New in version 3.3.*

`PyObject *``PyImport_ImportModuleLevel(const char *name, PyObject *globals, PyObject *locals, PyObject *fromlist, int level)`

*Return value:* New reference. Part of the *Stable ABI*.

Similar to `PyImport_ImportModuleLevelObject()`, but the name is a UTF-8 encoded string instead of a Unicode object.

*Changed in version 3.3:* Negative values for *level* are no longer accepted.

`PyObject *``PyImport_Import(PyObject *name)`

*Return value: New reference. Part of the [Stable ABI](#).*

This is a higher-level interface that calls the current “import hook function” (with an explicit *level* of 0, meaning absolute import). It invokes the `__import__()` function from the `__builtins__` of the current globals. This means that the import is done using whatever import hooks are installed in the current environment.

This function always uses absolute imports.

`PyObject *``PyImport_ReloadModule(PyObject *m)`

*Return value: New reference. Part of the [Stable ABI](#).*

Reload a module. Return a new reference to the reloaded module, or `NULL` with an exception set on failure (the module still exists in this case).

`PyObject *``PyImport_AddModuleObject(PyObject *name)`

*Return value: Borrowed reference. Part of the [Stable ABI](#) since version 3.7.*

Return the module object corresponding to a module name. The *name* argument may be of the form `package.module`. First check the modules dictionary if there’s one there, and if not, create a new one and insert it in the modules dictionary. Return `NULL` with an exception set on failure.

### Note

This function does not load or import the module; if the module wasn’t already loaded, you will get an empty module object. Use `PyImport_ImportModule()` or one of its variants to import a module. Package structures implied by a dotted name for *name* are not created if not already present.

*New in version 3.3.*

`PyObject *``PyImport_AddModule(const char *name)`

*Return value: Borrowed reference. Part of the [Stable ABI](#).*

Similar to `PyImport_AddModuleObject()`, but the name is a UTF-8 encoded string instead of a Unicode object.

`PyObject *PyImport_ExecCodeModule(const char *name, PyObject *co)`

*Return value:* New reference. Part of the [Stable ABI](#).

Given a module name (possibly of the form `package.module`) and a code object read from a Python bytecode file or obtained from the built-in function `compile()`, load the module. Return a new reference to the module object, or `NULL` with an exception set if an error occurred. `name` is removed from `sys.modules` in error cases, even if `name` was already in `sys.modules` on entry to `PyImport_ExecCodeModule()`. Leaving incompletely initialized modules in `sys.modules` is dangerous, as imports of such modules have no way to know that the module object is an unknown (and probably damaged with respect to the module author's intents) state.

The module's `__spec__` and `__loader__` will be set, if not set already, with the appropriate values. The spec's loader will be set to the module's `__loader__` (if set) and to an instance of `SourceFileLoader` otherwise.

The module's `__file__` attribute will be set to the code object's `co_filename`. If applicable, `__cached__` will also be set.

This function will reload the module if it was already imported. See `PyImport_ReloadModule()` for the intended way to reload a module.

If `name` points to a dotted name of the form `package.module`, any package structures not already created will still not be created.

See also `PyImport_ExecCodeModuleEx()` and `PyImport_ExecCodeModuleWithPathnames()`.

`PyObject *PyImport_ExecCodeModuleEx(const char *name,`

`PyObject *co, const char *pathname)`

*Return value:* New reference. Part of the [Stable ABI](#).

Like `PyImport_ExecCodeModule()`, but the `__file__` attribute of the module object is set to *pathname* if it is non-NULL.

See also `PyImport_ExecCodeModuleWithPathnames()`.

`PyObject *PyImport_ExecCodeModuleObject(PyObject *name,  
PyObject *co, PyObject *pathname, PyObject *cpathname)`

*Return value:* New reference. Part of the [Stable ABI](#) since version 3.7.

Like `PyImport_ExecCodeModuleEx()`, but the `__cached__` attribute of the module object is set to *cpathname* if it is non-NULL. Of the three functions, this is the preferred one to use.

*New in version 3.3.*

`PyObject *PyImport_ExecCodeModuleWithPathnames(const char  
*name, PyObject *co, const char *pathname, const char  
*cpathname)`

*Return value:* New reference. Part of the [Stable ABI](#).

Like `PyImport_ExecCodeModuleObject()`, but *name*, *pathname* and *cpathname* are UTF-8 encoded strings. Attempts are also made to figure out what the value for *pathname* should be from *cpathname* if the former is set to NULL.

*New in version 3.2.*

*Changed in version 3.3:* Uses `imp.source_from_cache()` in calculating the source path if only the bytecode path is provided.

`long PyImport_GetMagicNumber()`

*Part of the [Stable ABI](#).*

Return the magic number for Python bytecode files (a.k.a. `.pyc` file). The magic number should be present in the first

four bytes of the bytecode file, in little-endian byte order.  
Returns `-1` on error.

*Changed in version 3.3:* Return value of `-1` upon failure.

`const char *PyImport_GetMagicTag()`

*Part of the [Stable ABI](#).*

Return the magic tag string for [PEP 3147](#) [<https://peps.python.org/pep-3147/>] format Python bytecode file names. Keep in mind that the value at `sys.implementation.cache_tag` is authoritative and should be used instead of this function.

*New in version 3.2.*

`PyObject *PyImport_GetModuleDict()`

*Return value: Borrowed reference. Part of the [Stable ABI](#).*

Return the dictionary used for the module administration (a.k.a. `sys.modules`). Note that this is a per-interpreter variable.

`PyObject *PyImport_GetModule(PyObject *name)`

*Return value: New reference. Part of the [Stable ABI](#) since version 3.8.*

Return the already imported module with the given name. If the module has not been imported yet then returns `NULL` but does not set an error. Returns `NULL` and sets an error if the lookup failed.

*New in version 3.7.*

`PyObject *PyImport_GetImporter(PyObject *path)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return a finder object for a `sys.path/pkg.__path__` item `path`, possibly by fetching it from the `sys.path_importer_cache` dict. If it wasn't yet cached, traverse `sys.path_hooks` until a hook is found that can handle the path item. Return `None` if no hook could; this

tells our caller that the [path based finder](#) could not find a finder for this path item. Cache the result in [sys.path\\_importer\\_cache](#). Return a new reference to the finder object.

`int PyImport_ImportFrozenModuleObject(PyObject *name)`

*Part of the [Stable ABI](#) since version 3.7.*

Load a frozen module named *name*. Return 1 for success, 0 if the module is not found, and -1 with an exception set if the initialization failed. To access the imported module on a successful load, use [PyImport\\_ImportModule\(\)](#). (Note the misnomer — this function would reload the module if it was already imported.)

*New in version 3.3.*

*Changed in version 3.4:* The `__file__` attribute is no longer set on the module.

`int PyImport_ImportFrozenModule(const char *name)`

*Part of the [Stable ABI](#).*

Similar to [PyImport\\_ImportFrozenModuleObject\(\)](#), but the name is a UTF-8 encoded string instead of a Unicode object.

`struct _frozen`

This is the structure type definition for frozen module descriptors, as generated by the **freeze** utility (see `Tools/freeze/` in the Python source distribution). Its definition, found in `Include/import.h`, is:

```
struct _frozen {
    const char *name;
    const unsigned char *code;
    int size;
    bool is_package;
};
```

*Changed in version 3.11:* The new `is_package` field

indicates whether the module is a package or not. This replaces setting the `size` field to a negative value.

`const struct _frozen *PyImport_FrozenModules`

This pointer is initialized to point to an array of `_frozen` records, terminated by one whose members are all `NULL` or zero. When a frozen module is imported, it is searched in this table. Third-party code could play tricks with this to provide a dynamically created collection of frozen modules.

`int PyImport_AppendInittab(const char *name, PyObject  
*(*initfunc)(void))`

*Part of the [Stable ABI](#).*

Add a single module to the existing table of built-in modules. This is a convenience wrapper around

`PyImport_ExtendInittab()`, returning `-1` if the table could not be extended. The new module can be imported by the name *name*, and uses the function *initfunc* as the initialization function called on the first attempted import. This should be called before `Py_Initialize()`.

`struct _inittab`

Structure describing a single entry in the list of built-in modules. Each of these structures gives the name and initialization function for a module built into the interpreter. The name is an ASCII encoded string. Programs which embed Python may use an array of these structures in conjunction with `PyImport_ExtendInittab()` to provide additional built-in modules. The structure is defined in `Include/import.h` as:

```
struct _inittab {  
    const char *name; /* ASCII encoded st  
    PyObject* (*initfunc)(void);  
};
```

`int PyImport_ExtendInittab(struct _inittab *newtab)`

Add a collection of modules to the table of built-in modules.

The *newtab* array must end with a sentinel entry which contains `NULL` for the **name** field; failure to provide the sentinel value can result in a memory fault. Returns `0` on success or `-1` if insufficient memory could be allocated to extend the internal table. In the event of failure, no modules are added to the internal table. This must be called before `Py_Initialize()`.

If Python is initialized multiple times, `PyImport_AppendInittab()` or `PyImport_ExtendInittab()` must be called before each Python initialization.

# Data marshalling support

These routines allow C code to work with serialized objects using the same data format as the `marshal` module. There are functions to write data into the serialization format, and additional functions that can be used to read the data back. Files used to store marshalled data must be opened in binary mode.

Numeric values are stored with the least significant byte first.

The module supports two versions of the data format: version 0 is the historical version, version 1 shares interned strings in the file, and upon unmarshalling. Version 2 uses a binary format for floating point numbers. `Py_MARSHAL_VERSION` indicates the current file format (currently 2).

`void PyMarshal_WriteLongToFile(long value, FILE *file, int version)`

Marshal a long integer, *value*, to *file*. This will only write the least-significant 32 bits of *value*; regardless of the size of the native long type. *version* indicates the file format.

This function can fail, in which case it sets the error indicator. Use `PyErr_Occurred()` to check for that.

`void PyMarshal_WriteObjectToFile(PyObject *value, FILE *file, int version)`

Marshal a Python object, *value*, to *file*. *version* indicates the file format.

This function can fail, in which case it sets the error indicator. Use `PyErr_Occurred()` to check for that.

`PyObject *PyMarshal_WriteObjectToString(PyObject *value, int version)`

*Return value:* New reference.

Return a bytes object containing the marshalled representation of *value*. *version* indicates the file format.

The following functions allow marshalled values to be read back in.

`long PyMarshal_ReadLongFromFile(FILE *file)`

Return a C long from the data stream in a FILE\* opened for reading. Only a 32-bit value can be read in using this function, regardless of the native size of long.

On error, sets the appropriate exception (**EOFError**) and returns `-1`.

`int PyMarshal_ReadShortFromFile(FILE *file)`

Return a C short from the data stream in a FILE\* opened for reading. Only a 16-bit value can be read in using this function, regardless of the native size of short.

On error, sets the appropriate exception (**EOFError**) and returns `-1`.

**PyObject** \*PyMarshal\_ReadObjectFromFile(FILE \*file)

*Return value: New reference.*

Return a Python object from the data stream in a FILE\* opened for reading.

On error, sets the appropriate exception (**EOFError**, **ValueError** or **TypeError**) and returns `NULL`.

**PyObject** \*PyMarshal\_ReadLastObjectFromFile(FILE \*file)

*Return value: New reference.*

Return a Python object from the data stream in a FILE\* opened for reading. Unlike

**PyMarshal\_ReadObjectFromFile()**, this function assumes that no further objects will be read from the file, allowing it to aggressively load file data into memory so that the de-serialization can operate from data in memory rather than reading a byte at a time from the file. Only use these

variant if you are certain that you won't be reading anything else from the file.

On error, sets the appropriate exception (**EOFError**, **ValueError** or **TypeError**) and returns `NULL`.

**PyObject** \*PyMarshal\_ReadObjectFromString(const char \*data,  
**Py\_ssize\_t** len)

*Return value: New reference.*

Return a Python object from the data stream in a byte buffer containing *len* bytes pointed to by *data*.

On error, sets the appropriate exception (**EOFError**, **ValueError** or **TypeError**) and returns `NULL`.

# Parsing arguments and building values

These functions are useful when creating your own extensions functions and methods. Additional information and examples are available in [Extending and Embedding the Python Interpreter](#).

The first three of these functions described, `PyArg_ParseTuple()`, `PyArg_ParseTupleAndKeywords()`, and `PyArg_Parse()`, all use *format strings* which are used to tell the function about the expected arguments. The format strings use the same syntax for each of these functions.

## Parsing arguments

A format string consists of zero or more “format units.” A format unit describes one Python object; it is usually a single character or a parenthesized sequence of format units. With a few exceptions, a format unit that is not a parenthesized sequence normally corresponds to a single address argument to these functions. In the following description, the quoted form is the format unit; the entry in (round) parentheses is the Python object type that matches the format unit; and the entry in [square] brackets is the type of the C variable(s) whose address should be passed.

## Strings and buffers

These formats allow accessing an object as a contiguous chunk of memory. You don’t have to provide raw storage for the returned unicode or bytes area.

Unless otherwise stated, buffers are not NUL-terminated.

There are three ways strings and buffers can be converted to C:

- Formats such as `y*` and `s*` fill a `Py_buffer` structure. This locks the underlying buffer so that the caller can subsequently use the buffer even inside a `Py_BEGIN_ALLOW_THREADS` block without the risk of mutable data being resized or destroyed. As a result, **you have to call `PyBuffer_Release()`** after you have finished processing the data (or in any early abort case).
- The `es`, `es#`, `et` and `et#` formats allocate the result buffer. **You have to call `PyMem_Free()`** after you have finished processing the data (or in any early abort case).
- Other formats take a `str` or a read-only bytes-like object, such as `bytes`, and provide a `const char *` pointer to its buffer. In this case the buffer is “borrowed”: it is managed by the corresponding Python object, and shares the lifetime of this object. You won’t have to release any memory yourself.

To ensure that the underlying buffer may be safely borrowed, the object’s `PyBufferProcs.bf_releasebuffer` field must be `NULL`. This disallows common mutable objects such as `bytearray`, but also some read-only objects such as `memoryview` of `bytes`.

Besides this `bf_releasebuffer` requirement, there is no check to verify whether the input object is immutable (e.g. whether it would honor a request for a writable buffer, or whether another thread can mutate the data).

## Note

For all `#` variants of formats (`s#`, `y#`, etc.), the macro `PY_SSIZE_T_CLEAN` must be defined before including `Python.h`. On Python 3.9 and older, the type of the length argument is `Py_ssize_t` if the `PY_SSIZE_T_CLEAN` macro is defined, or `int` otherwise.

`s (str) [const char *]`

Convert a Unicode object to a C pointer to a character string. A pointer to an existing string is stored in the character

pointer variable whose address you pass. The C string is NUL-terminated. The Python string must not contain embedded null code points; if it does, a `ValueError` exception is raised. Unicode objects are converted to C strings using `'utf-8'` encoding. If this conversion fails, a `UnicodeError` is raised.

### Note

This format does not accept `bytes-like objects`. If you want to accept filesystem paths and convert them to C character strings, it is preferable to use the `o&` format with `PyUnicode_FSConverter()` as *converter*.

*Changed in version 3.5:* Previously, `TypeError` was raised when embedded null code points were encountered in the Python string.

`s*` (`str` or `bytes-like object`) [`Py_buffer`]

This format accepts Unicode objects as well as bytes-like objects. It fills a `Py_buffer` structure provided by the caller. In this case the resulting C string may contain embedded NUL bytes. Unicode objects are converted to C strings using `'utf-8'` encoding.

`s#` (`str`, read-only `bytes-like object`) [`const char *`, `Py_ssize_t`]

Like `s*`, except that it provides a `borrowed buffer`. The result is stored into two C variables, the first one a pointer to a C string, the second one its length. The string may contain embedded null bytes. Unicode objects are converted to C strings using `'utf-8'` encoding.

`z` (`str` or `None`) [`const char *`]

Like `s`, but the Python object may also be `None`, in which case the C pointer is set to `NULL`.

`z*` (`str`, `bytes-like object` or `None`) [`Py_buffer`]

Like `s*`, but the Python object may also be `None`, in which case the `buf` member of the `Py_buffer` structure is set to `NULL`.

z# (**str**, read-only **bytes-like object** or None) [const char \*, **Py\_ssize\_t**]

Like s#, but the Python object may also be None, in which case the C pointer is set to NULL.

y (read-only **bytes-like object**) [const char \*]

This format converts a bytes-like object to a C pointer to a **borrowed** character string; it does not accept Unicode objects. The bytes buffer must not contain embedded null bytes; if it does, a **ValueError** exception is raised.

*Changed in version 3.5:* Previously, **TypeError** was raised when embedded null bytes were encountered in the bytes buffer.

y\* (**bytes-like object**) [Py\_buffer]

This variant on s\* doesn't accept Unicode objects, only bytes-like objects. **This is the recommended way to accept binary data.**

y# (read-only **bytes-like object**) [const char \*, **Py\_ssize\_t**]

This variant on s# doesn't accept Unicode objects, only bytes-like objects.

S (**bytes**) [PyBytesObject \*]

Requires that the Python object is a **bytes** object, without attempting any conversion. Raises **TypeError** if the object is not a bytes object. The C variable may also be declared as **PyObject\***.

Y (**bytearray**) [PyByteArrayObject \*]

Requires that the Python object is a **bytearray** object, without attempting any conversion. Raises **TypeError** if the object is not a **bytearray** object. The C variable may also be declared as **PyObject\***.

u (**str**) [const Py\_UNICODE \*]

Convert a Python Unicode object to a C pointer to a NUL-terminated buffer of Unicode characters. You must pass the address of a **Py\_UNICODE** pointer variable, which will be

filled with the pointer to an existing Unicode buffer. Please note that the width of a `Py_UNICODE` character depends on compilation options (it is either 16 or 32 bits). The Python string must not contain embedded null code points; if it does, a `ValueError` exception is raised.

*Changed in version 3.5:* Previously, `TypeError` was raised when embedded null code points were encountered in the Python string.

*Deprecated since version 3.3, will be removed in version 3.12:* Part of the old-style `Py_UNICODE` API; please migrate to using `PyUnicode_AsWideCharString()`.

`u# (str) [const Py_UNICODE *, Py_ssize_t]`

This variant on `u` stores into two C variables, the first one a pointer to a Unicode data buffer, the second one its length. This variant allows null code points.

*Deprecated since version 3.3, will be removed in version 3.12:* Part of the old-style `Py_UNICODE` API; please migrate to using `PyUnicode_AsWideCharString()`.

`z (str or None) [const Py_UNICODE *]`

Like `u`, but the Python object may also be `None`, in which case the `Py_UNICODE` pointer is set to `NULL`.

*Deprecated since version 3.3, will be removed in version 3.12:* Part of the old-style `Py_UNICODE` API; please migrate to using `PyUnicode_AsWideCharString()`.

`z# (str or None) [const Py_UNICODE *, Py_ssize_t]`

Like `u#`, but the Python object may also be `None`, in which case the `Py_UNICODE` pointer is set to `NULL`.

*Deprecated since version 3.3, will be removed in version 3.12:* Part of the old-style `Py_UNICODE` API; please migrate to using `PyUnicode_AsWideCharString()`.

`U (str) [PyObject *]`

Requires that the Python object is a Unicode object, without

attempting any conversion. Raises `TypeError` if the object is not a Unicode object. The C variable may also be declared as `PyObject*`.

`w*` (read-write `bytes-like object`) [`Py_buffer`]

This format accepts any object which implements the read-write buffer interface. It fills a `Py_buffer` structure provided by the caller. The buffer may contain embedded null bytes. The caller have to call `PyBuffer_Release()` when it is done with the buffer.

`es` (`str`) [`const char *encoding`, `char **buffer`]

This variant on `s` is used for encoding Unicode into a character buffer. It only works for encoded data without embedded NUL bytes.

This format requires two arguments. The first is only used as input, and must be a `const char*` which points to the name of an encoding as a NUL-terminated string, or `NULL`, in which case `'utf-8'` encoding is used. An exception is raised if the named encoding is not known to Python. The second argument must be a `char**`; the value of the pointer it references will be set to a buffer with the contents of the argument text. The text will be encoded in the encoding specified by the first argument.

`PyArg_ParseTuple()` will allocate a buffer of the needed size, copy the encoded data into this buffer and adjust `*buffer` to reference the newly allocated storage. The caller is responsible for calling `PyMem_Free()` to free the allocated buffer after use.

`et` (`str`, `bytes` or `bytearray`) [`const char *encoding`, `char **buffer`]

Same as `es` except that byte string objects are passed through without recoding them. Instead, the implementation assumes that the byte string object uses the encoding passed in as parameter.

`es#` (`str`) [`const char *encoding`, `char **buffer`, `Py_ssize_t`

`*buffer_length]`

This variant on `s#` is used for encoding Unicode into a character buffer. Unlike the `es` format, this variant allows input data which contains NUL characters.

It requires three arguments. The first is only used as input, and must be a `const char*` which points to the name of an encoding as a NUL-terminated string, or `NULL`, in which case `'utf-8'` encoding is used. An exception is raised if the named encoding is not known to Python. The second argument must be a `char**`; the value of the pointer it references will be set to a buffer with the contents of the argument text. The text will be encoded in the encoding specified by the first argument. The third argument must be a pointer to an integer; the referenced integer will be set to the number of bytes in the output buffer.

There are two modes of operation:

If `*buffer` points a `NULL` pointer, the function will allocate a buffer of the needed size, copy the encoded data into this buffer and set `*buffer` to reference the newly allocated storage. The caller is responsible for calling `PyMem_Free()` to free the allocated buffer after usage.

If `*buffer` points to a non-`NULL` pointer (an already allocated buffer), `PyArg_ParseTuple()` will use this location as the buffer and interpret the initial value of `*buffer_length` as the buffer size. It will then copy the encoded data into the buffer and NUL-terminate it. If the buffer is not large enough, a `ValueError` will be set.

In both cases, `*buffer_length` is set to the length of the encoded data without the trailing NUL byte.

`et# (str, bytes or bytearray) [const char *encoding, char **buffer, Py_ssize_t *buffer_length]`

Same as `es#` except that byte string objects are passed through without recoding them. Instead, the implementation assumes that the byte string object uses the encoding passed in as parameter.

## Numbers

b ([int](#)) [unsigned char]

Convert a nonnegative Python integer to an unsigned tiny int, stored in a C unsigned char.

B ([int](#)) [unsigned char]

Convert a Python integer to a tiny int without overflow checking, stored in a C unsigned char.

h ([int](#)) [short int]

Convert a Python integer to a C short int.

H ([int](#)) [unsigned short int]

Convert a Python integer to a C unsigned short int, without overflow checking.

i ([int](#)) [int]

Convert a Python integer to a plain C int.

I ([int](#)) [unsigned int]

Convert a Python integer to a C unsigned int, without overflow checking.

l ([int](#)) [long int]

Convert a Python integer to a C long int.

k ([int](#)) [unsigned long]

Convert a Python integer to a C unsigned long without overflow checking.

L ([int](#)) [long long]

Convert a Python integer to a C long long.

K ([int](#)) [unsigned long long]

Convert a Python integer to a C unsigned long long without overflow checking.

n ([int](#)) [[Py\\_ssize\\_t](#)]

Convert a Python integer to a C `Py_ssize_t`.

c (`bytes` or `bytearray` of length 1) [char]

Convert a Python byte, represented as a `bytes` or `bytearray` object of length 1, to a C char.

*Changed in version 3.3:* Allow `bytearray` objects.

C (`str` of length 1) [int]

Convert a Python character, represented as a `str` object of length 1, to a C int.

f (`float`) [float]

Convert a Python floating point number to a C float.

d (`float`) [double]

Convert a Python floating point number to a C double.

D (`complex`) [Py\_complex]

Convert a Python complex number to a C `Py_complex` structure.

## Other objects

O (object) [PyObject \*]

Store a Python object (without any conversion) in a C object pointer. The C program thus receives the actual object that was passed. The object's reference count is not increased. The pointer stored is not `NULL`.

O! (object) [`PyObject*`, PyObject \*]

Store a Python object in a C object pointer. This is similar to O, but takes two C arguments: the first is the address of a Python type object, the second is the address of the C variable (of type `PyObject*`) into which the object pointer is stored. If the Python object does not have the required type, `TypeError` is raised.

O& (object) [`converter`, *anything*]

Convert a Python object to a C variable through a *converter* function. This takes two arguments: the first is a function, the second is the address of a C variable (of arbitrary type), converted to void\*. The *converter* function in turn is called as follows:

```
status = converter(object, address);
```

where *object* is the Python object to be converted and *address* is the void\* argument that was passed to the `PyArg_Parse*` function. The returned *status* should be 1 for a successful conversion and 0 if the conversion has failed. When the conversion fails, the *converter* function should raise an exception and leave the content of *address* unmodified.

If the *converter* returns `Py_CLEANUP_SUPPORTED`, it may get called a second time if the argument parsing eventually fails, giving the converter a chance to release any memory that it had already allocated. In this second call, the *object* parameter will be `NULL`; *address* will have the same value as in the original call.

*Changed in version 3.1:* `Py_CLEANUP_SUPPORTED` was added.

`p (bool)` [int]

Tests the value passed in for truth (a boolean predicate) and converts the result to its equivalent C true/false integer value. Sets the int to 1 if the expression was true and 0 if it was false. This accepts any valid Python value. See [Truth Value Testing](#) for more information about how Python tests values for truth.

*New in version 3.3.*

`(items) (tuple)` [*matching-items*]

The object must be a Python sequence whose length is the number of format units in *items*. The C arguments must correspond to the individual format units in *items*. Format units for sequences may be nested.

It is possible to pass “long” integers (integers whose value exceeds the platform’s **LONG\_MAX**) however no proper range checking is done — the most significant bits are silently truncated when the receiving field is too small to receive the value (actually, the semantics are inherited from downcasts in C — your mileage may vary).

A few other characters have a meaning in a format string. These may not occur inside nested parentheses. They are:

|

Indicates that the remaining arguments in the Python argument list are optional. The C variables corresponding to optional arguments should be initialized to their default value — when an optional argument is not specified, **PyArg\_ParseTuple()** does not touch the contents of the corresponding C variable(s).

\$

**PyArg\_ParseTupleAndKeywords()** only: Indicates that the remaining arguments in the Python argument list are keyword-only. Currently, all keyword-only arguments must also be optional arguments, so | must always be specified before \$ in the format string.

*New in version 3.3.*

:

The list of format units ends here; the string after the colon is used as the function name in error messages (the “associated value” of the exception that **PyArg\_ParseTuple()** raises).

;

The list of format units ends here; the string after the semicolon is used as the error message *instead* of the default error message. : and ; mutually exclude each other.

Note that any Python object references which are provided to the caller are *borrowed* references; do not decrement their reference count!

Additional arguments passed to these functions must be addresses of variables whose type is determined by the format string; these are used to store values from the input tuple. There are a few cases, as described in the list of format units above, where these parameters are used as input values; they should match what is specified for the corresponding format unit in that case.

For the conversion to succeed, the *arg* object must match the format and the format must be exhausted. On success, the `PyArg_Parse*` functions return true, otherwise they return false and raise an appropriate exception. When the `PyArg_Parse*` functions fail due to conversion failure in one of the format units, the variables at the addresses corresponding to that and the following format units are left untouched.

## API Functions

`int PyArg_ParseTuple(PyObject *args, const char *format, ...)`

*Part of the [Stable ABI](#).*

Parse the parameters of a function that takes only positional parameters into local variables. Returns true on success; on failure, it returns false and raises the appropriate exception.

`int PyArg_VaParse(PyObject *args, const char *format, va_list vargs)`

*Part of the [Stable ABI](#).*

Identical to `PyArg_ParseTuple()`, except that it accepts a *va\_list* rather than a variable number of arguments.

`int PyArg_ParseTupleAndKeywords(PyObject *args, PyObject *kw, const char *format, char *keywords[], ...)`

*Part of the [Stable ABI](#).*

Parse the parameters of a function that takes both positional and keyword parameters into local variables. The *keywords* argument is a NULL-terminated array of keyword parameter names. Empty names denote [positional-only parameters](#). Returns true on success; on failure, it returns false and raises the appropriate exception.

Changed in version 3.6: Added support for [positional-only parameters](#).

```
int PyArg_VaParseTupleAndKeywords(PyObject *args, PyObject  
*kw, const char *format, char *keywords[], va_list vargs)
```

*Part of the [Stable ABI](#).*

Identical to [PyArg\\_ParseTupleAndKeywords\(\)](#), except that it accepts a `va_list` rather than a variable number of arguments.

```
int PyArg_ValidateKeywordArguments(PyObject*)
```

*Part of the [Stable ABI](#).*

Ensure that the keys in the keywords argument dictionary are strings. This is only needed if

[PyArg\\_ParseTupleAndKeywords\(\)](#) is not used, since the latter already does this check.

*New in version 3.2.*

```
int PyArg_Parse(PyObject *args, const char *format, ...)
```

*Part of the [Stable ABI](#).*

Function used to deconstruct the argument lists of “old-style” functions — these are functions which use the **METH\_OLDARGS** parameter parsing method, which has been removed in Python 3. This is not recommended for use in parameter parsing in new code, and most code in the standard interpreter has been modified to no longer use this for that purpose. It does remain a convenient way to decompose other tuples, however, and may continue to be used for that purpose.

```
int PyArg_UnpackTuple(PyObject *args, const char *name,  
Py\_ssize\_t min, Py\_ssize\_t max, ...)
```

*Part of the [Stable ABI](#).*

A simpler form of parameter retrieval which does not use a format string to specify the types of the arguments. Functions which use this method to retrieve their parameters should be

declared as `METH_VARARGS` in function or method tables. The tuple containing the actual parameters should be passed as *args*; it must actually be a tuple. The length of the tuple must be at least *min* and no more than *max*; *min* and *max* may be equal. Additional arguments must be passed to the function, each of which should be a pointer to a `PyObject*` variable; these will be filled in with the values from *args*; they will contain [borrowed references](#). The variables which correspond to optional parameters not given by *args* will not be filled in; these should be initialized by the caller. This function returns true on success and false if *args* is not a tuple or contains the wrong number of elements; an exception will be set if there was a failure.

This is an example of the use of this function, taken from the sources for the `_weakref` helper module for weak references:

```
static PyObject *
weakref_ref(PyObject *self, PyObject *args)
{
    PyObject *object;
    PyObject *callback = NULL;
    PyObject *result = NULL;

    if (PyArg_UnpackTuple(args, "ref", 1, 2, &object,
                          &callback) != 0)
        return result;
    result = PyWeakref_NewRef(object, callback);
    return result;
}
```

The call to `PyArg_UnpackTuple()` in this example is entirely equivalent to this call to `PyArg_ParseTuple()`:

```
PyArg_ParseTuple(args, "O|O:ref", &object, &callback)
```

## Building values

`PyObject*` `Py_BuildValue(const char *format, ...)`

*Return value: New reference. Part of the [Stable ABI](#).*

Create a new value based on a format string similar to those accepted by the `PyArg_Parse*` family of functions and a sequence of values. Returns the value or `NULL` in the case of an error; an exception will be raised if `NULL` is returned.

`Py_BuildValue()` does not always build a tuple. It builds a tuple only if its format string contains two or more format units. If the format string is empty, it returns `None`; if it contains exactly one format unit, it returns whatever object is described by that format unit. To force it to return a tuple of size 0 or one, parenthesize the format string.

When memory buffers are passed as parameters to supply data to build objects, as for the `s` and `s#` formats, the required data is copied. Buffers provided by the caller are never referenced by the objects created by

`Py_BuildValue()`. In other words, if your code invokes `malloc()` and passes the allocated memory to `Py_BuildValue()`, your code is responsible for calling `free()` for that memory once `Py_BuildValue()` returns.

In the following description, the quoted form is the format unit; the entry in (round) parentheses is the Python object type that the format unit will return; and the entry in [square] brackets is the type of the C value(s) to be passed.

The characters space, tab, colon and comma are ignored in format strings (but not within format units such as `s#`). This can be used to make long format strings a tad more readable.

`s` (`str` or `None`) [`const char *`]

Convert a null-terminated C string to a Python `str` object using `'utf-8'` encoding. If the C string pointer is `NULL`, `None` is used.

`s#` (`str` or `None`) [`const char *`, `Py_ssize_t`]

Convert a C string and its length to a Python `str` object using `'utf-8'` encoding. If the C string pointer is `NULL`, the length is ignored and `None` is returned.

y (**bytes**) [const char \*]

This converts a C string to a Python **bytes** object. If the C string pointer is `NULL`, `None` is returned.

y# (**bytes**) [const char \*, **Py\_ssize\_t**]

This converts a C string and its lengths to a Python object. If the C string pointer is `NULL`, `None` is returned.

z (**str** or `None`) [const char \*]

Same as `s`.

z# (**str** or `None`) [const char \*, **Py\_ssize\_t**]

Same as `s#`.

u (**str**) [const wchar\_t \*]

Convert a null-terminated `wchar_t` buffer of Unicode (UTF-16 or UCS-4) data to a Python Unicode object. If the Unicode buffer pointer is `NULL`, `None` is returned.

u# (**str**) [const wchar\_t \*, **Py\_ssize\_t**]

Convert a Unicode (UTF-16 or UCS-4) data buffer and its length to a Python Unicode object. If the Unicode buffer pointer is `NULL`, the length is ignored and `None` is returned.

U (**str** or `None`) [const char \*]

Same as `s`.

U# (**str** or `None`) [const char \*, **Py\_ssize\_t**]

Same as `s#`.

i (**int**) [int]

Convert a plain C int to a Python integer object.

b (**int**) [char]

Convert a plain C char to a Python integer object.

h (**int**) [short int]

Convert a plain C short int to a Python integer object.

l (**int**) [long int]

Convert a C long int to a Python integer object.

B (**int**) [unsigned char]

Convert a C unsigned char to a Python integer object.

H (**int**) [unsigned short int]

Convert a C unsigned short int to a Python integer object.

I (**int**) [unsigned int]

Convert a C unsigned int to a Python integer object.

k (**int**) [unsigned long]

Convert a C unsigned long to a Python integer object.

L (**int**) [long long]

Convert a C long long to a Python integer object.

K (**int**) [unsigned long long]

Convert a C unsigned long long to a Python integer object.

n (**int**) [**Py\_ssize\_t**]

Convert a C **Py\_ssize\_t** to a Python integer.

c (**bytes** of length 1) [char]

Convert a C int representing a byte to a Python **bytes** object of length 1.

C (**str** of length 1) [int]

Convert a C int representing a character to Python **str** object of length 1.

d (**float**) [double]

Convert a C double to a Python floating point number.

f (**float**) [float]

Convert a C float to a Python floating point number.

D (**complex**) [Py\_complex \*]

Convert a C **Py\_complex** structure to a Python complex number.

O (object) [PyObject \*]

Pass a Python object untouched (except for its reference count, which is incremented by one). If the object passed in is a `NULL` pointer, it is assumed that this was caused because the call producing the argument found an error and set an exception. Therefore, `Py_BuildValue()` will return `NULL` but won't raise an exception. If no exception has been raised yet, `SystemError` is set.

S (object) [PyObject \*]

Same as O.

N (object) [PyObject \*]

Same as O, except it doesn't increment the reference count on the object. Useful when the object is created by a call to an object constructor in the argument list.

O& (object) [*converter*, *anything*]

Convert *anything* to a Python object through a *converter* function. The function is called with *anything* (which should be compatible with void\*) as its argument and should return a "new" Python object, or `NULL` if an error occurred.

(items) (`tuple`) [*matching-items*]

Convert a sequence of C values to a Python tuple with the same number of items.

[items] (`list`) [*matching-items*]

Convert a sequence of C values to a Python list with the same number of items.

{items} (`dict`) [*matching-items*]

Convert a sequence of C values to a Python dictionary. Each pair of consecutive C values adds one item to the dictionary, serving as key and value, respectively.

If there is an error in the format string, the `SystemError` exception is set and `NULL` returned.

`PyObject *Py_VaBuildValue(const char *format, va_list vars)`

*Return value: New reference. Part of the [Stable ABI](#).*

Identical to `Py_BuildValue()`, except that it accepts a `va_list` rather than a variable number of arguments.

# String conversion and formatting

Functions for number conversion and formatted string output.

```
int PyOS_snprintf(char *str, size_t size, const char *format, ...)
```

*Part of the [Stable ABI](#).*

Output not more than *size* bytes to *str* according to the format string *format* and the extra arguments. See the Unix man page [snprintf\(3\)](#).

```
int PyOS_vsnprintf(char *str, size_t size, const char *format, va_list  
va)
```

*Part of the [Stable ABI](#).*

Output not more than *size* bytes to *str* according to the format string *format* and the variable argument list *va*. Unix man page [vsnprintf\(3\)](#).

[PyOS\\_snprintf\(\)](#) and [PyOS\\_vsnprintf\(\)](#) wrap the Standard C library functions `snprintf()` and `vsnprintf()`. Their purpose is to guarantee consistent behavior in corner cases, which the Standard C functions do not.

The wrappers ensure that `str[size-1]` is always `'\0'` upon return. They never write more than *size* bytes (including the trailing `'\0'`) into *str*. Both functions require that `str != NULL`, `size > 0`, `format != NULL` and `size < INT_MAX`. Note that this means there is no equivalent to the C99 `n = snprintf(NULL, 0, ...)` which would determine the necessary buffer size.

The return value (*rv*) for these functions should be interpreted as follows:

- When `0 <= rv < size`, the output conversion was

successful and *rv* characters were written to *str* (excluding the trailing `'\0'` byte at `str[rv]`).

- When `rv >= size`, the output conversion was truncated and a buffer with `rv + 1` bytes would have been needed to succeed. `str[size-1]` is `'\0'` in this case.
- When `rv < 0`, “something bad happened.” `str[size-1]` is `'\0'` in this case too, but the rest of *str* is undefined. The exact cause of the error depends on the underlying platform.

The following functions provide locale-independent string to number conversions.

`double PyOS_string_to_double(const char *s, char **endptr, PyObject *overflow_exception)`

*Part of the [Stable ABI](#).*

Convert a string *s* to a double, raising a Python exception on failure. The set of accepted strings corresponds to the set of strings accepted by Python’s `float()` constructor, except that *s* must not have leading or trailing whitespace. The conversion is independent of the current locale.

If *endptr* is `NULL`, convert the whole string. Raise `ValueError` and return `-1.0` if the string is not a valid representation of a floating-point number.

If *endptr* is not `NULL`, convert as much of the string as possible and set *\*endptr* to point to the first unconverted character. If no initial segment of the string is the valid representation of a floating-point number, set *\*endptr* to point to the beginning of the string, raise `ValueError`, and return `-1.0`.

If *s* represents a value that is too large to store in a float (for example, `"1e500"` is such a string on many platforms) then if *overflow\_exception* is `NULL` return `Py_HUGE_VAL` (with an appropriate sign) and don’t set any exception. Otherwise, *overflow\_exception* must point to a Python exception object; raise that exception and return `-1.0`. In both cases, set *\*endptr* to point to the first character after the converted value.

If any other error occurs during the conversion (for example an out-of-memory error), set the appropriate Python exception and return `-1.0`.

*New in version 3.1.*

`char *PyOS_double_to_string(double val, char format_code, int precision, int flags, int *ptype)`

Part of the [Stable ABI](#).

Convert a double *val* to a string using supplied *format\_code*, *precision*, and *flags*.

*format\_code* must be one of `'e'`, `'E'`, `'f'`, `'F'`, `'g'`, `'G'` or `'r'`. For `'r'`, the supplied *precision* must be 0 and is ignored. The `'r'` format code specifies the standard [repr\(\)](#) format.

*flags* can be zero or more of the values `Py_DTST_SIGN`, `Py_DTST_ADD_DOT_0`, or `Py_DTST_ALT`, or-ed together:

- `Py_DTST_SIGN` means to always precede the returned string with a sign character, even if *val* is non-negative.
- `Py_DTST_ADD_DOT_0` means to ensure that the returned string will not look like an integer.
- `Py_DTST_ALT` means to apply “alternate” formatting rules. See the documentation for the [PyOS\\_snprintf\(\)](#) `'#'` specifier for details.

If *ptype* is non-NULL, then the value it points to will be set to one of `Py_DTST_FINITE`, `Py_DTST_INFINITE`, or `Py_DTST_NAN`, signifying that *val* is a finite number, an infinite number, or not a number, respectively.

The return value is a pointer to *buffer* with the converted string or `NULL` if the conversion failed. The caller is responsible for freeing the returned string by calling [PyMem\\_Free\(\)](#).

*New in version 3.1.*

`int PyOS_stricmp(const char *s1, const char *s2)`

Case insensitive comparison of strings. The function works almost identically to **`strcmp()`** except that it ignores the case.

`int PyOS_strnicmp(const char *s1, const char *s2, Py\_ssize\_t size)`

Case insensitive comparison of strings. The function works almost identically to **`strncmp()`** except that it ignores the case.

# Reflection

**PyObject** \*PyEval\_GetBuiltins(void)

*Return value: Borrowed reference. Part of the [Stable ABI](#).*

Return a dictionary of the builtins in the current execution frame, or the interpreter of the thread state if no frame is currently executing.

**PyObject** \*PyEval\_GetLocals(void)

*Return value: Borrowed reference. Part of the [Stable ABI](#).*

Return a dictionary of the local variables in the current execution frame, or `NULL` if no frame is currently executing.

**PyObject** \*PyEval\_GetGlobals(void)

*Return value: Borrowed reference. Part of the [Stable ABI](#).*

Return a dictionary of the global variables in the current execution frame, or `NULL` if no frame is currently executing.

**PyFrameObject** \*PyEval\_GetFrame(void)

*Return value: Borrowed reference. Part of the [Stable ABI](#).*

Return the current thread state's frame, which is `NULL` if no frame is currently executing.

See also [PyThreadState\\_GetFrame\(\)](#).

const char \*PyEval\_GetFuncName(**PyObject** \*func)

*Part of the [Stable ABI](#).*

Return the name of *func* if it is a function, class or instance object, else the name of *funcs* type.

const char \*PyEval\_GetFuncDesc(**PyObject** \*func)

*Part of the [Stable ABI](#).*

Return a description string, depending on the type of *func*.

Return values include “()” for functions and methods, “ constructor”, “ instance”, and “ object”. Concatenated with the result of `PyEval_GetFuncName()`, the result will be a description of *func*.

# Codec registry and support functions

`int PyCodec_Register(PyObject *search_function)`

*Part of the [Stable ABI](#).*

Register a new codec search function.

As side effect, this tries to load the **encodings** package, if not yet done, to make sure that it is always first in the list of search functions.

`int PyCodec_Unregister(PyObject *search_function)`

*Part of the [Stable ABI](#) since version 3.10.*

Unregister a codec search function and clear the registry's cache. If the search function is not registered, do nothing. Return 0 on success. Raise an exception and return -1 on error.

*New in version 3.10.*

`int PyCodec_KnownEncoding(const char *encoding)`

*Part of the [Stable ABI](#).*

Return 1 or 0 depending on whether there is a registered codec for the given *encoding*. This function always succeeds.

`PyObject *PyCodec_Encode(PyObject *object, const char *encoding, const char *errors)`

*Return value: New reference. Part of the [Stable ABI](#).*

Generic codec based encoding API.

*object* is passed through the encoder function found for the given *encoding* using the error handling method defined by *errors*. *errors* may be `NULL` to use the default method defined

for the codec. Raises a **LookupError** if no encoder can be found.

**PyObject** \*PyCodec\_Decode(PyObject \*object, const char \*encoding, const char \*errors)

*Return value: New reference. Part of the [Stable ABI](#).*

Generic codec based decoding API.

*object* is passed through the decoder function found for the given *encoding* using the error handling method defined by *errors*. *errors* may be `NULL` to use the default method defined for the codec. Raises a **LookupError** if no encoder can be found.

## Codec lookup API

In the following functions, the *encoding* string is looked up converted to all lower-case characters, which makes encodings looked up through this mechanism effectively case-insensitive. If no codec is found, a **KeyError** is set and `NULL` returned.

**PyObject** \*PyCodec\_Encoder(const char \*encoding)

*Return value: New reference. Part of the [Stable ABI](#).*

Get an encoder function for the given *encoding*.

**PyObject** \*PyCodec\_Decoder(const char \*encoding)

*Return value: New reference. Part of the [Stable ABI](#).*

Get a decoder function for the given *encoding*.

**PyObject** \*PyCodec\_IncrementalEncoder(const char \*encoding, const char \*errors)

*Return value: New reference. Part of the [Stable ABI](#).*

Get an **IncrementalEncoder** object for the given *encoding*.

**PyObject** \*PyCodec\_IncrementalDecoder(const char \*encoding, const char \*errors)

*Return value: New reference. Part of the [Stable ABI](#).*

Get an [IncrementalDecoder](#) object for the given *encoding*.

[PyObject](#) \*PyCodec\_StreamReader(const char \*encoding, [PyObject](#) \*stream, const char \*errors)

*Return value: New reference. Part of the [Stable ABI](#).*

Get a [StreamReader](#) factory function for the given *encoding*.

[PyObject](#) \*PyCodec\_StreamWriter(const char \*encoding, [PyObject](#) \*stream, const char \*errors)

*Return value: New reference. Part of the [Stable ABI](#).*

Get a [StreamWriter](#) factory function for the given *encoding*.

## Registry API for Unicode encoding error handlers

int PyCodec\_RegisterError(const char \*name, [PyObject](#) \*error)

*Part of the [Stable ABI](#).*

Register the error handling callback function *error* under the given *name*. This callback function will be called by a codec when it encounters unencodable characters/undecodable bytes and *name* is specified as the error parameter in the call to the encode/decode function.

The callback gets a single argument, an instance of [UnicodeEncodeError](#), [UnicodeDecodeError](#) or [UnicodeTranslateError](#) that holds information about the problematic sequence of characters or bytes and their offset in the original string (see [Unicode Exception Objects](#) for functions to extract this information). The callback must either raise the given exception, or return a two-item tuple containing the replacement for the problematic sequence, and an integer giving the offset in the original string at which encoding/decoding should be resumed.

Return 0 on success, -1 on error.

**PyObject \***PyCodec\_LookupError(const char \*name)

*Return value:* New reference. Part of the [Stable ABI](#).

Lookup the error handling callback function registered under *name*. As a special case NULL can be passed, in which case the error handling callback for “strict” will be returned.

**PyObject \***PyCodec\_StrictErrors(**PyObject \***exc)

*Return value:* Always NULL. Part of the [Stable ABI](#).

Raise *exc* as an exception.

**PyObject \***PyCodec\_IgnoreErrors(**PyObject \***exc)

*Return value:* New reference. Part of the [Stable ABI](#).

Ignore the unicode error, skipping the faulty input.

**PyObject \***PyCodec\_ReplaceErrors(**PyObject \***exc)

*Return value:* New reference. Part of the [Stable ABI](#).

Replace the unicode encode error with ? or U+FFFD.

**PyObject \***PyCodec\_XMLCharRefReplaceErrors(**PyObject \***exc)

*Return value:* New reference. Part of the [Stable ABI](#).

Replace the unicode encode error with XML character references.

**PyObject \***PyCodec\_BackslashReplaceErrors(**PyObject \***exc)

*Return value:* New reference. Part of the [Stable ABI](#).

Replace the unicode encode error with backslash escapes (\x, \u and \U).

**PyObject \***PyCodec\_NameReplaceErrors(**PyObject \***exc)

*Return value:* New reference. Part of the [Stable ABI](#) since version 3.7.

Replace the unicode encode error with \N{...} escapes.

*New in version 3.5.*

# Abstract Objects Layer

The functions in this chapter interact with Python objects regardless of their type, or with wide classes of object types (e.g. all numerical types, or all sequence types). When used on object types for which they do not apply, they will raise a Python exception.

It is not possible to use these functions on objects that are not properly initialized, such as a list object that has been created by `PyList_New()`, but whose items have not been set to some non-NULL value yet.

# Object Protocol

`PyObject *Py_NotImplemented`

The `NotImplemented` singleton, used to signal that an operation is not implemented for the given type combination.

`Py_RETURN_NOTIMPLEMENTED`

Properly handle returning `Py_NotImplemented` from within a C function (that is, increment the reference count of `NotImplemented` and return it).

`int PyObject_Print(PyObject *o, FILE *fp, int flags)`

Print an object `o`, on file `fp`. Returns `-1` on error. The flags argument is used to enable certain printing options. The only option currently supported is `Py_PRINT_RAW`; if given, the `str()` of the object is written instead of the `repr()`.

`int PyObject_HasAttr(PyObject *o, PyObject *attr_name)`

*Part of the [Stable ABI](#).*

Returns `1` if `o` has the attribute `attr_name`, and `0` otherwise. This is equivalent to the Python expression `hasattr(o, attr_name)`. This function always succeeds.

## Note

Exceptions that occur when this calls `__getattr__()` and `__getattribute__()` methods are silently ignored. For proper error handling, use `PyObject_GetAttr()` instead.

`int PyObject_HasAttrString(PyObject *o, const char *attr_name)`

*Part of the [Stable ABI](#).*

Returns 1 if *o* has the attribute *attr\_name*, and 0 otherwise. This is equivalent to the Python expression `hasattr(o, attr_name)`. This function always succeeds.

## Note

Exceptions that occur when this calls `__getattr__()` and `__getattribute__()` methods or while creating the temporary `str` object are silently ignored. For proper error handling, use `PyObject_GetAttrString()` instead.

`PyObject *PyObject_GetAttr(PyObject *o, PyObject *attr_name)`

*Return value:* New reference. Part of the [Stable ABI](#).

Retrieve an attribute named *attr\_name* from object *o*. Returns the attribute value on success, or `NULL` on failure. This is the equivalent of the Python expression `o.attr_name`.

`PyObject *PyObject_GetAttrString(PyObject *o, const char *attr_name)`

*Return value:* New reference. Part of the [Stable ABI](#).

Retrieve an attribute named *attr\_name* from object *o*. Returns the attribute value on success, or `NULL` on failure. This is the equivalent of the Python expression `o.attr_name`.

`PyObject *PyObject_GenericGetAttr(PyObject *o, PyObject *name)`

*Return value:* New reference. Part of the [Stable ABI](#).

Generic attribute getter function that is meant to be put into a type object's `tp_getattro` slot. It looks for a descriptor in the dictionary of classes in the object's MRO as well as an attribute in the object's `__dict__` (if present). As outlined in [Implementing Descriptors](#), data descriptors take preference over instance attributes, while non-data descriptors don't. Otherwise, an `AttributeError` is raised.

`int PyObject_SetAttr(PyObject *o, PyObject *attr_name, PyObject`

\*v)

*Part of the [Stable ABI](#).*

Set the value of the attribute named *attr\_name*, for object *o*, to the value *v*. Raise an exception and return `-1` on failure; return `0` on success. This is the equivalent of the Python statement `o.attr_name = v`.

If *v* is `NULL`, the attribute is deleted. This behaviour is deprecated in favour of using [PyObject\\_DelAttr\(\)](#), but there are currently no plans to remove it.

int PyObject\_SetAttrString(PyObject \*o, const char \*attr\_name,  
PyObject \*v)

*Part of the [Stable ABI](#).*

Set the value of the attribute named *attr\_name*, for object *o*, to the value *v*. Raise an exception and return `-1` on failure; return `0` on success. This is the equivalent of the Python statement `o.attr_name = v`.

If *v* is `NULL`, the attribute is deleted, but this feature is deprecated in favour of using [PyObject\\_DelAttrString\(\)](#).

int PyObject\_GenericSetAttr(PyObject \*o, PyObject \*name,  
PyObject \*value)

*Part of the [Stable ABI](#).*

Generic attribute setter and deleter function that is meant to be put into a type object's `tp_setattro` slot. It looks for a data descriptor in the dictionary of classes in the object's MRO, and if found it takes preference over setting or deleting the attribute in the instance dictionary. Otherwise, the attribute is set or deleted in the object's `__dict__` (if present). On success, `0` is returned, otherwise an [AttributeError](#) is raised and `-1` is returned.

int PyObject\_DelAttr(PyObject \*o, PyObject \*attr\_name)

Delete attribute named *attr\_name*, for object *o*. Returns `-1` on failure. This is the equivalent of the Python statement `del`

`o.attr_name.`

`int PyObject_DelAttrString(PyObject *o, const char *attr_name)`

Delete attribute named *attr\_name*, for object *o*. Returns `-1` on failure. This is the equivalent of the Python statement `del o.attr_name.`

`PyObject *PyObject_GenericGetDict(PyObject *o, void *context)`

*Return value:* New reference. Part of the [Stable ABI](#) since version 3.10.

A generic implementation for the getter of a `__dict__` descriptor. It creates the dictionary if necessary.

This function may also be called to get the `__dict__` of the object *o*. Pass `NULL` for *context* when calling it. Since this function may need to allocate memory for the dictionary, it may be more efficient to call `PyObject_GetAttr()` when accessing an attribute on the object.

On failure, returns `NULL` with an exception set.

*New in version 3.3.*

`int PyObject_GenericSetDict(PyObject *o, PyObject *value, void *context)`

*Part of the [Stable ABI](#) since version 3.7.*

A generic implementation for the setter of a `__dict__` descriptor. This implementation does not allow the dictionary to be deleted.

*New in version 3.3.*

`PyObject **_PyObject_GetDictPtr(PyObject *obj)`

Return a pointer to `__dict__` of the object *obj*. If there is no `__dict__`, return `NULL` without setting an exception.

This function may need to allocate memory for the dictionary, so it may be more efficient to call

**PyObject\_GetAttr()** when accessing an attribute on the object.

**PyObject \***PyObject\_RichCompare(**PyObject \***o1, **PyObject \***o2, int opid)

*Return value:* New reference. Part of the [Stable ABI](#).

Compare the values of *o1* and *o2* using the operation specified by *opid*, which must be one of **Py\_LT**, **Py\_LE**, **Py\_EQ**, **Py\_NE**, **Py\_GT**, or **Py\_GE**, corresponding to <, <=, ==, !=, >, or >= respectively. This is the equivalent of the Python expression *o1 op o2*, where *op* is the operator corresponding to *opid*. Returns the value of the comparison on success, or **NULL** on failure.

int PyObject\_RichCompareBool(**PyObject \***o1, **PyObject \***o2, int opid)

*Part of the [Stable ABI](#).*

Compare the values of *o1* and *o2* using the operation specified by *opid*, which must be one of **Py\_LT**, **Py\_LE**, **Py\_EQ**, **Py\_NE**, **Py\_GT**, or **Py\_GE**, corresponding to <, <=, ==, !=, >, or >= respectively. Returns -1 on error, 0 if the result is false, 1 otherwise. This is the equivalent of the Python expression *o1 op o2*, where *op* is the operator corresponding to *opid*.

## Note

If *o1* and *o2* are the same object,

**PyObject\_RichCompareBool()** will always return 1 for **Py\_EQ** and 0 for **Py\_NE**.

**PyObject \***PyObject\_Format(**PyObject \***obj, **PyObject \***format\_spec)

*Part of the [Stable ABI](#).*

Format *obj* using *format\_spec*. This is equivalent to the Python expression `format(obj, format_spec)`.

*format\_spec* may be **NULL**. In this case the call is equivalent to

`format(obj)`. Returns the formatted string on success, NULL on failure.

**PyObject \***`PyObject_Repr(PyObject *o)`

*Return value:* New reference. Part of the [Stable ABI](#).

Compute a string representation of object `o`. Returns the string representation on success, NULL on failure. This is the equivalent of the Python expression `repr(o)`. Called by the [repr\(\)](#) built-in function.

*Changed in version 3.4:* This function now includes a debug assertion to help ensure that it does not silently discard an active exception.

**PyObject \***`PyObject_ASCII(PyObject *o)`

*Return value:* New reference. Part of the [Stable ABI](#).

As [PyObject\\_Repr\(\)](#), compute a string representation of object `o`, but escape the non-ASCII characters in the string returned by [PyObject\\_Repr\(\)](#) with `\x`, `\u` or `\U` escapes. This generates a string similar to that returned by [PyObject\\_Repr\(\)](#) in Python 2. Called by the [ascii\(\)](#) built-in function.

**PyObject \***`PyObject_Str(PyObject *o)`

*Return value:* New reference. Part of the [Stable ABI](#).

Compute a string representation of object `o`. Returns the string representation on success, NULL on failure. This is the equivalent of the Python expression `str(o)`. Called by the [str\(\)](#) built-in function and, therefore, by the [print\(\)](#) function.

*Changed in version 3.4:* This function now includes a debug assertion to help ensure that it does not silently discard an active exception.

**PyObject \***`PyObject_Bytes(PyObject *o)`

*Return value:* New reference. Part of the [Stable ABI](#).

Compute a bytes representation of object *o*. `NULL` is returned on failure and a bytes object on success. This is equivalent to the Python expression `bytes(o)`, when *o* is not an integer. Unlike `bytes(o)`, a `TypeError` is raised when *o* is an integer instead of a zero-initialized bytes object.

`int PyObject_IsSubclass(PyObject *derived, PyObject *cls)`

*Part of the [Stable ABI](#).*

Return `1` if the class *derived* is identical to or derived from the class *cls*, otherwise return `0`. In case of an error, return `-1`.

If *cls* is a tuple, the check will be done against every entry in *cls*. The result will be `1` when at least one of the checks returns `1`, otherwise it will be `0`.

If *cls* has a `__subclasscheck__()` method, it will be called to determine the subclass status as described in [PEP 3119](#) [<https://peps.python.org/pep-3119/>]. Otherwise, *derived* is a subclass of *cls* if it is a direct or indirect subclass, i.e. contained in `cls.__mro__`.

Normally only class objects, i.e. instances of `type` or a derived class, are considered classes. However, objects can override this by having a `__bases__` attribute (which must be a tuple of base classes).

`int PyObject_IsInstance(PyObject *inst, PyObject *cls)`

*Part of the [Stable ABI](#).*

Return `1` if *inst* is an instance of the class *cls* or a subclass of *cls*, or `0` if not. On error, returns `-1` and sets an exception.

If *cls* is a tuple, the check will be done against every entry in *cls*. The result will be `1` when at least one of the checks returns `1`, otherwise it will be `0`.

If *cls* has a `__instancecheck__()` method, it will be called to determine the subclass status as described in [PEP 3119](#) [<https://peps.python.org/pep-3119/>]. Otherwise, *inst* is an

instance of *cls* if its class is a subclass of *cls*.

An instance *inst* can override what is considered its class by having a `__class__` attribute.

An object *cls* can override if it is considered a class, and what its base classes are, by having a `__bases__` attribute (which must be a tuple of base classes).

`Py_hash_t PyObject_Hash(PyObject *o)`

*Part of the [Stable ABI](#).*

Compute and return the hash value of an object *o*. On failure, return `-1`. This is the equivalent of the Python expression `hash(o)`.

*Changed in version 3.2:* The return type is now `Py_hash_t`. This is a signed integer the same size as `Py_ssize_t`.

`Py_hash_t PyObject_HashNotImplemented(PyObject *o)`

*Part of the [Stable ABI](#).*

Set a `TypeError` indicating that `type(o)` is not [hashable](#) and return `-1`. This function receives special treatment when stored in a `tp_hash` slot, allowing a type to explicitly indicate to the interpreter that it is not hashable.

`int PyObject_IsTrue(PyObject *o)`

*Part of the [Stable ABI](#).*

Returns `1` if the object *o* is considered to be true, and `0` otherwise. This is equivalent to the Python expression `not not o`. On failure, return `-1`.

`int PyObject_Not(PyObject *o)`

*Part of the [Stable ABI](#).*

Returns `0` if the object *o* is considered to be true, and `1` otherwise. This is equivalent to the Python expression `not o`. On failure, return `-1`.

`PyObject *PyObject_Type(PyObject *o)`

*Return value: New reference. Part of the [Stable ABI](#).*

When *o* is non-NULL, returns a type object corresponding to the object type of object *o*. On failure, raises [SystemError](#) and returns NULL. This is equivalent to the Python expression `type(o)`. This function increments the reference count of the return value. There's really no reason to use this function instead of the [Py\\_TYPE\(\)](#) function, which returns a pointer of type [PyObject\\*](#), except when the incremented reference count is needed.

`int PyObject_TypeCheck(PyObject *o, PyTypeObject *type)`

Return non-zero if the object *o* is of type *type* or a subtype of *type*, and 0 otherwise. Both parameters must be non-NULL.

`Py\_ssize\_t PyObject_Size(PyObject *o)`

`Py\_ssize\_t PyObject_Length(PyObject *o)`

*Part of the [Stable ABI](#).*

Return the length of object *o*. If the object *o* provides either the sequence and mapping protocols, the sequence length is returned. On error, -1 is returned. This is the equivalent to the Python expression `len(o)`.

`Py\_ssize\_t PyObject_LengthHint(PyObject *o, Py\_ssize\_t defaultvalue)`

Return an estimated length for the object *o*. First try to return its actual length, then an estimate using [\\_\\_length\\_hint\\_\\_\(\)](#), and finally return the default value. On error return -1. This is the equivalent to the Python expression `operator.length_hint(o, defaultvalue)`.

*New in version 3.4.*

`PyObject *PyObject_GetItem(PyObject *o, PyObject *key)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return element of *o* corresponding to the object *key* or NULL on failure. This is the equivalent of the Python expression

`o[key]`.

`int PyObject_SetItem(PyObject *o, PyObject *key, PyObject *v)`

*Part of the [Stable ABI](#).*

Map the object `key` to the value `v`. Raise an exception and return `-1` on failure; return `0` on success. This is the equivalent of the Python statement `o[key] = v`. This function *does not* steal a reference to `v`.

`int PyObject_DelItem(PyObject *o, PyObject *key)`

*Part of the [Stable ABI](#).*

Remove the mapping for the object `key` from the object `o`. Return `-1` on failure. This is equivalent to the Python statement `del o[key]`.

`PyObject *PyObject_Dir(PyObject *o)`

*Return value: New reference. Part of the [Stable ABI](#).*

This is equivalent to the Python expression `dir(o)`, returning a (possibly empty) list of strings appropriate for the object argument, or `NULL` if there was an error. If the argument is `NULL`, this is like the Python `dir()`, returning the names of the current locals; in this case, if no execution frame is active then `NULL` is returned but `PyErr_Occurred()` will return false.

`PyObject *PyObject_GetIter(PyObject *o)`

*Return value: New reference. Part of the [Stable ABI](#).*

This is equivalent to the Python expression `iter(o)`. It returns a new iterator for the object argument, or the object itself if the object is already an iterator. Raises `TypeError` and returns `NULL` if the object cannot be iterated.

`PyObject *PyObject_GetAIter(PyObject *o)`

*Return value: New reference. Part of the [Stable ABI](#) since version 3.10.*

This is the equivalent to the Python expression `aiter(o)`. Takes an `AsyncIterable` object and returns an

**AsyncIterator** for it. This is typically a new iterator but if the argument is an **AsyncIterator**, this returns itself. Raises **TypeError** and returns `NULL` if the object cannot be iterated.

*New in version 3.10.*

# Call Protocol

CPython supports two different calling protocols: *tp\_call* and *vectorcall*.

## The *tp\_call* Protocol

Instances of classes that set `tp_call` are callable. The signature of the slot is:

```
PyObject *tp_call(PyObject *callable, PyObject *args, PyObject *
```

A call is made using a tuple for the positional arguments and a dict for the keyword arguments, similarly to `callable(*args, **kwargs)` in Python code. *args* must be non-NULL (use an empty tuple if there are no arguments) but *kwargs* may be *NULL* if there are no keyword arguments.

This convention is not only used by *tp\_call*: `tp_new` and `tp_init` also pass arguments this way.

To call an object, use `PyObject_Call()` or another [call API](#).

## The Vectorcall Protocol

*New in version 3.9.*

The vectorcall protocol was introduced in [PEP 590](#) [<https://peps.python.org/pep-0590/>] as an additional protocol for making calls more efficient.

As rule of thumb, CPython will prefer the vectorcall for internal calls if the callable supports it. However, this is not a hard rule. Additionally, some third-party extensions use *tp\_call* directly (rather than using `PyObject_Call()`). Therefore, a class supporting vectorcall must also implement `tp_call`. Moreover, the callable

must behave the same regardless of which protocol is used. The recommended way to achieve this is by setting `tp_call` to `PyVectorcall_Call()`. This bears repeating:

## Warning

A class supporting vectorcall **must** also implement `tp_call` with the same semantics.

A class should not implement vectorcall if that would be slower than `tp_call`. For example, if the callee needs to convert the arguments to an args tuple and kwargs dict anyway, then there is no point in implementing vectorcall.

Classes can implement the vectorcall protocol by enabling the `Py_TPFLAGS_HAVE_VECTORCALL` flag and setting `tp_vectorcall_offset` to the offset inside the object structure where a `vectorcallfunc` appears. This is a pointer to a function with the following signature:

```
typedef PyObject *(*vectorcallfunc)(PyObject *callable, PyObject
*const *args, size_t nargsf, PyObject *kwnames)
```

- *callable* is the object being called.
- *args* is a C array consisting of the positional arguments followed by the values of the keyword arguments. This can be `NULL` if there are no arguments.
- *nargsf* is the number of positional arguments plus possibly the `PY_VECTORCALL_ARGUMENTS_OFFSET` flag. To get the actual number of positional arguments from *nargsf*, use `PyVectorcall_NARGS()`.
- *kwnames* is a tuple containing the names of the keyword arguments;  
in other words, the keys of the kwargs dict. These names must be strings (instances of `str` or a subclass)

and they must be unique. If there are no keyword arguments, then *kwnames* can instead be *NULL*.

## PY\_VECTORCALL\_ARGUMENTS\_OFFSET

If this flag is set in a vectorcall *nargsf* argument, the callee is allowed to temporarily change `args[-1]`. In other words, *args* points to argument 1 (not 0) in the allocated vector. The callee must restore the value of `args[-1]` before returning.

For `PyObject_VectorcallMethod()`, this flag means instead that `args[0]` may be changed.

Whenever they can do so cheaply (without additional allocation), callers are encouraged to use **PY\_VECTORCALL\_ARGUMENTS\_OFFSET**. Doing so will allow callables such as bound methods to make their onward calls (which include a prepended *self* argument) very efficiently.

To call an object that implements vectorcall, use a [call API](#) function as with any other callable. `PyObject_Vectorcall()` will usually be most efficient.

### Note

In CPython 3.8, the vectorcall API and related functions were available provisionally under names with a leading underscore:

```
_PyObject_Vectorcall,  
_Py_TPFLAGS_HAVE_VECTORCALL,  
_PyObject_VectorcallMethod,  
_PyVectorcall_Function, _PyObject_CallOneArg,  
_PyObject_CallMethodNoArgs,  
_PyObject_CallMethodOneArg. Additionally,  
PyObject_VectorcallDict was available as  
_PyObject_FastCallDict. The old names are still defined as  
aliases of the new, non-underscored names.
```

## Recursion Control

When using *tp\_call*, callees do not need to worry about [recursion](#):

CPython uses `Py_EnterRecursiveCall()` and `Py_LeaveRecursiveCall()` for calls made using `tp_call`.

For efficiency, this is not the case for calls done using vectorcall: the callee should use `Py_EnterRecursiveCall` and `Py_LeaveRecursiveCall` if needed.

## Vectorcall Support API

`Py_ssize_t` `PyVectorcall_NARGS(size_t nargsf)`

Given a vectorcall *nargsf* argument, return the actual number of arguments. Currently equivalent to:

```
(Py_ssize_t)(nargsf & ~PY_VECTORCALL_ARGUMENTS_OFFSET)
```

However, the function `PyVectorcall_NARGS` should be used to allow for future extensions.

*New in version 3.8.*

`vectorcallfunc` `PyVectorcall_Function(PyObject *op)`

If *op* does not support the vectorcall protocol (either because the type does not or because the specific instance does not), return `NULL`. Otherwise, return the vectorcall function pointer stored in *op*. This function never raises an exception.

This is mostly useful to check whether or not *op* supports vectorcall, which can be done by checking `PyVectorcall_Function(op) != NULL`.

*New in version 3.8.*

`PyObject *``PyVectorcall_Call(PyObject *callable, PyObject *tuple, PyObject *dict)`

Call *callable*'s `vectorcallfunc` with positional and keyword arguments given in a tuple and dict, respectively.

This is a specialized function, intended to be put in the `tp_call` slot or be used in an implementation of `tp_call`.

It does not check the `Py_TPFLAGS_HAVE_VECTORCALL` flag and it does not fall back to `tp_call`.

*New in version 3.8.*

## Object Calling API

Various functions are available for calling a Python object. Each converts its arguments to a convention supported by the called object – either *tp\_call* or *vectorcall*. In order to do as little conversion as possible, pick one that best fits the format of data you have available.

The following table summarizes the available functions; please see individual documentation for details.

Function
<code>PyObject_Call()</code>
<code>PyObject_CallNoArgs()</code>
<code>PyObject_CallOneArg()</code>
<code>PyObject_CallObject()</code>
<code>PyObject_CallFunction()</code>
<code>PyObject_CallMethod()</code>
<code>PyObject_CallFunctionObjArgs()</code>
<code>PyObject_CallMethodObjArgs()</code>
<code>PyObject_CallMethodNoArgs()</code>
<code>PyObject_CallMethodOneArg()</code>
<code>PyObject_Vectorcall()</code>
<code>PyObject_VectorcallDict()</code>
<code>PyObject_VectorcallMethod()</code>

`PyObject *PyObject_Call(PyObject *callable, PyObject *args, PyObject *kwargs)`

*Return value:* New reference. Part of the [Stable ABI](#).

Call a callable Python object *callable*, with arguments given by the tuple *args*, and named arguments given by the dictionary *kwargs*.

*args* must not be *NULL*; use an empty tuple if no arguments

are needed. If no named arguments are needed, *kwargs* can be *NULL*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

This is the equivalent of the Python expression:  
`callable(*args, **kwargs)`.

**PyObject \***PyObject\_CallNoArgs(**PyObject \***callable)

*Part of the [Stable ABI](#) since version 3.10.*

Call a callable Python object *callable* without any arguments. It is the most efficient way to call a callable Python object without any argument.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

*New in version 3.9.*

**PyObject \***PyObject\_CallOneArg(**PyObject \***callable, **PyObject \***arg)

Call a callable Python object *callable* with exactly 1 positional argument *arg* and no keyword arguments.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

*New in version 3.9.*

**PyObject \***PyObject\_CallObject(**PyObject \***callable, **PyObject \***args)

*Return value: New reference. Part of the [Stable ABI](#).*

Call a callable Python object *callable*, with arguments given by the tuple *args*. If no arguments are needed, then *args* can be *NULL*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

This is the equivalent of the Python expression:  
`callable(*args)`.

**PyObject** \*PyObject\_CallFunction(**PyObject** \*callable, const char \*format, ...)

*Return value:* New reference. Part of the [Stable ABI](#).

Call a callable Python object *callable*, with a variable number of C arguments. The C arguments are described using a **Py\_BuildValue()** style format string. The format can be *NULL*, indicating that no arguments are provided.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

This is the equivalent of the Python expression:  
`callable(*args)`.

Note that if you only pass **PyObject\*** args, **PyObject\_CallFunctionObjArgs()** is a faster alternative.

*Changed in version 3.4:* The type of *format* was changed from `char *`.

**PyObject** \*PyObject\_CallMethod(**PyObject** \*obj, const char \*name, const char \*format, ...)

*Return value:* New reference. Part of the [Stable ABI](#).

Call the method named *name* of object *obj* with a variable number of C arguments. The C arguments are described by a **Py\_BuildValue()** format string that should produce a tuple.

The format can be *NULL*, indicating that no arguments are provided.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

This is the equivalent of the Python expression:  
`obj.name(arg1, arg2, ...)`.

Note that if you only pass **PyObject\*** args, **PyObject\_CallMethodObjArgs()** is a faster alternative.

*Changed in version 3.4:* The types of *name* and *format* were changed from `char *`.

**PyObject \***PyObject\_CallFunctionObjArgs(PyObject \*callable, ...)

*Return value:* New reference. Part of the [Stable ABI](#).

Call a callable Python object *callable*, with a variable number of **PyObject\*** arguments. The arguments are provided as a variable number of parameters followed by *NULL*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

This is the equivalent of the Python expression:  
`callable(arg1, arg2, ...)`.

**PyObject \***PyObject\_CallMethodObjArgs(PyObject \*obj, PyObject \*name, ...)

*Return value:* New reference. Part of the [Stable ABI](#).

Call a method of the Python object *obj*, where the name of the method is given as a Python string object in *name*. It is called with a variable number of **PyObject\*** arguments. The arguments are provided as a variable number of parameters followed by *NULL*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

**PyObject \***PyObject\_CallMethodNoArgs(PyObject \*obj, PyObject \*name)

Call a method of the Python object *obj* without arguments, where the name of the method is given as a Python string object in *name*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

*New in version 3.9.*

**PyObject** \*PyObject\_CallMethodOneArg(**PyObject** \*obj, **PyObject** \*name, **PyObject** \*arg)

Call a method of the Python object *obj* with a single positional argument *arg*, where the name of the method is given as a Python string object in *name*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

*New in version 3.9.*

**PyObject** \*PyObject\_Vectorcall(**PyObject** \*callable, **PyObject** \*const \*args, size\_t nargsf, **PyObject** \*kwnames)

Call a callable Python object *callable*. The arguments are the same as for **vectorcallfunc**. If *callable* supports **vectorcall**, this directly calls the vectorcall function stored in *callable*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

*New in version 3.9.*

**PyObject** \*PyObject\_VectorcallDict(**PyObject** \*callable, **PyObject** \*const \*args, size\_t nargsf, **PyObject** \*kwdict)

Call *callable* with positional arguments passed exactly as in the **vectorcall** protocol, but with keyword arguments passed as a dictionary *kwdict*. The *args* array contains only the positional arguments.

Regardless of which protocol is used internally, a conversion of arguments needs to be done. Therefore, this function should only be used if the caller already has a dictionary ready to use for the keyword arguments, but not a tuple for the positional arguments.

*New in version 3.9.*

`PyObject *PyObject_VectorcallMethod(PyObject *name, PyObject *const *args, size_t nargsf, PyObject *kwnames)`

Call a method using the vectorcall calling convention. The name of the method is given as a Python string *name*. The object whose method is called is *args[0]*, and the *args* array starting at *args[1]* represents the arguments of the call. There must be at least one positional argument. *nargsf* is the number of positional arguments including *args[0]*, plus

**PY\_VECTORCALL\_ARGUMENTS\_OFFSET** if the value of *args[0]* may temporarily be changed. Keyword arguments can be passed just like in `PyObject_Vectorcall()`.

If the object has the **Py\_TPFLAGS\_METHOD\_DESCRIPTOR** feature, this will call the unbound method object with the full *args* vector as arguments.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

*New in version 3.9.*

## Call Support API

`int PyCcallable_Check(PyObject *o)`

*Part of the [Stable ABI](#).*

Determine if the object *o* is callable. Return `1` if the object is callable and `0` otherwise. This function always succeeds.

# Number Protocol

`int PyNumber_Check(PyObject *o)`

*Part of the [Stable ABI](#).*

Returns 1 if the object *o* provides numeric protocols, and false otherwise. This function always succeeds.

*Changed in version 3.8:* Returns 1 if *o* is an index integer.

`PyObject *PyNumber_Add(PyObject *o1, PyObject *o2)`

*Return value: New reference. Part of the [Stable ABI](#).*

Returns the result of adding *o1* and *o2*, or `NULL` on failure. This is the equivalent of the Python expression `o1 + o2`.

`PyObject *PyNumber_Subtract(PyObject *o1, PyObject *o2)`

*Return value: New reference. Part of the [Stable ABI](#).*

Returns the result of subtracting *o2* from *o1*, or `NULL` on failure. This is the equivalent of the Python expression `o1 - o2`.

`PyObject *PyNumber_Multiply(PyObject *o1, PyObject *o2)`

*Return value: New reference. Part of the [Stable ABI](#).*

Returns the result of multiplying *o1* and *o2*, or `NULL` on failure. This is the equivalent of the Python expression `o1 * o2`.

`PyObject *PyNumber_MatrixMultiply(PyObject *o1, PyObject *o2)`

*Return value: New reference. Part of the [Stable ABI](#) since version 3.7.*

Returns the result of matrix multiplication on *o1* and *o2*, or `NULL` on failure. This is the equivalent of the Python expression `o1 @ o2`.

*New in version 3.5.*

**PyObject \***PyNumber\_FloorDivide(**PyObject \***o1, **PyObject \***o2)

*Return value: New reference. Part of the [Stable ABI](#).*

Return the floor of *o1* divided by *o2*, or `NULL` on failure. This is the equivalent of the Python expression `o1 // o2`.

**PyObject \***PyNumber\_TrueDivide(**PyObject \***o1, **PyObject \***o2)

*Return value: New reference. Part of the [Stable ABI](#).*

Return a reasonable approximation for the mathematical value of *o1* divided by *o2*, or `NULL` on failure. The return value is “approximate” because binary floating point numbers are approximate; it is not possible to represent all real numbers in base two. This function can return a floating point value when passed two integers. This is the equivalent of the Python expression `o1 / o2`.

**PyObject \***PyNumber\_Remainder(**PyObject \***o1, **PyObject \***o2)

*Return value: New reference. Part of the [Stable ABI](#).*

Returns the remainder of dividing *o1* by *o2*, or `NULL` on failure. This is the equivalent of the Python expression `o1 % o2`.

**PyObject \***PyNumber\_Divmod(**PyObject \***o1, **PyObject \***o2)

*Return value: New reference. Part of the [Stable ABI](#).*

See the built-in function `divmod()`. Returns `NULL` on failure. This is the equivalent of the Python expression `divmod(o1, o2)`.

**PyObject \***PyNumber\_Power(**PyObject \***o1, **PyObject \***o2, **PyObject \***o3)

*Return value: New reference. Part of the [Stable ABI](#).*

See the built-in function `pow()`. Returns `NULL` on failure. This is the equivalent of the Python expression `pow(o1, o2, o3)`, where *o3* is optional. If *o3* is to be ignored, pass `Py_None` in its place (passing `NULL` for *o3* would cause an illegal memory access).

**PyObject \***PyNumber\_Negative(**PyObject \***o)

*Return value: New reference. Part of the [Stable ABI](#).*

Returns the negation of `o` on success, or `NULL` on failure. This is the equivalent of the Python expression `-o`.

**PyObject \***PyNumber\_Positive(PyObject \*o)

*Return value: New reference. Part of the [Stable ABI](#).*

Returns `o` on success, or `NULL` on failure. This is the equivalent of the Python expression `+o`.

**PyObject \***PyNumber\_Absolute(PyObject \*o)

*Return value: New reference. Part of the [Stable ABI](#).*

Returns the absolute value of `o`, or `NULL` on failure. This is the equivalent of the Python expression `abs(o)`.

**PyObject \***PyNumber\_Invert(PyObject \*o)

*Return value: New reference. Part of the [Stable ABI](#).*

Returns the bitwise negation of `o` on success, or `NULL` on failure. This is the equivalent of the Python expression `~o`.

**PyObject \***PyNumber\_Lshift(PyObject \*o1, PyObject \*o2)

*Return value: New reference. Part of the [Stable ABI](#).*

Returns the result of left shifting `o1` by `o2` on success, or `NULL` on failure. This is the equivalent of the Python expression `o1 << o2`.

**PyObject \***PyNumber\_Rshift(PyObject \*o1, PyObject \*o2)

*Return value: New reference. Part of the [Stable ABI](#).*

Returns the result of right shifting `o1` by `o2` on success, or `NULL` on failure. This is the equivalent of the Python expression `o1 >> o2`.

**PyObject \***PyNumber\_And(PyObject \*o1, PyObject \*o2)

*Return value: New reference. Part of the [Stable ABI](#).*

Returns the “bitwise and” of `o1` and `o2` on success and `NULL` on failure. This is the equivalent of the Python expression `o1 & o2`.

**PyObject \***PyNumber\_Xor(**PyObject \***o1, **PyObject \***o2)

*Return value:* New reference. Part of the [Stable ABI](#).

Returns the “bitwise exclusive or” of *o1* by *o2* on success, or `NULL` on failure. This is the equivalent of the Python expression `o1 ^ o2`.

**PyObject \***PyNumber\_Or(**PyObject \***o1, **PyObject \***o2)

*Return value:* New reference. Part of the [Stable ABI](#).

Returns the “bitwise or” of *o1* and *o2* on success, or `NULL` on failure. This is the equivalent of the Python expression `o1 | o2`.

**PyObject \***PyNumber\_InPlaceAdd(**PyObject \***o1, **PyObject \***o2)

*Return value:* New reference. Part of the [Stable ABI](#).

Returns the result of adding *o1* and *o2*, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 += o2`.

**PyObject \***PyNumber\_InPlaceSubtract(**PyObject \***o1, **PyObject \***o2)

*Return value:* New reference. Part of the [Stable ABI](#).

Returns the result of subtracting *o2* from *o1*, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 -= o2`.

**PyObject \***PyNumber\_InPlaceMultiply(**PyObject \***o1, **PyObject \***o2)

*Return value:* New reference. Part of the [Stable ABI](#).

Returns the result of multiplying *o1* and *o2*, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 *= o2`.

**PyObject \***PyNumber\_InPlaceMatrixMultiply(**PyObject \***o1,  
**PyObject \***o2)

*Return value:* New reference. Part of the [Stable ABI](#) since version 3.7.

Returns the result of matrix multiplication on *o1* and *o2*, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1`

`@= o2.`

*New in version 3.5.*

**PyObject** \*PyNumber\_InPlaceFloorDivide(PyObject \*o1, PyObject \*o2)

*Return value: New reference. Part of the [Stable ABI](#).*

Returns the mathematical floor of dividing *o1* by *o2*, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 //= o2`.

**PyObject** \*PyNumber\_InPlaceTrueDivide(PyObject \*o1, PyObject \*o2)

*Return value: New reference. Part of the [Stable ABI](#).*

Return a reasonable approximation for the mathematical value of *o1* divided by *o2*, or `NULL` on failure. The return value is “approximate” because binary floating point numbers are approximate; it is not possible to represent all real numbers in base two. This function can return a floating point value when passed two integers. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 /= o2`.

**PyObject** \*PyNumber\_InPlaceRemainder(PyObject \*o1, PyObject \*o2)

*Return value: New reference. Part of the [Stable ABI](#).*

Returns the remainder of dividing *o1* by *o2*, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 %= o2`.

**PyObject** \*PyNumber\_InPlacePower(PyObject \*o1, PyObject \*o2, PyObject \*o3)

*Return value: New reference. Part of the [Stable ABI](#).*

See the built-in function `pow()`. Returns `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 **= o2` when *o3* is `Py_None`, or an in-place variant of `pow(o1, o2, o3)`

otherwise. If `o3` is to be ignored, pass `Py_None` in its place (passing `NULL` for `o3` would cause an illegal memory access).

`PyObject *PyNumber_InPlaceLshift(PyObject *o1, PyObject *o2)`

*Return value:* New reference. Part of the [Stable ABI](#).

Returns the result of left shifting `o1` by `o2` on success, or `NULL` on failure. The operation is done *in-place* when `o1` supports it. This is the equivalent of the Python statement `o1 <<= o2`.

`PyObject *PyNumber_InPlaceRshift(PyObject *o1, PyObject *o2)`

*Return value:* New reference. Part of the [Stable ABI](#).

Returns the result of right shifting `o1` by `o2` on success, or `NULL` on failure. The operation is done *in-place* when `o1` supports it. This is the equivalent of the Python statement `o1 >>= o2`.

`PyObject *PyNumber_InPlaceAnd(PyObject *o1, PyObject *o2)`

*Return value:* New reference. Part of the [Stable ABI](#).

Returns the “bitwise and” of `o1` and `o2` on success and `NULL` on failure. The operation is done *in-place* when `o1` supports it. This is the equivalent of the Python statement `o1 &= o2`.

`PyObject *PyNumber_InPlaceXor(PyObject *o1, PyObject *o2)`

*Return value:* New reference. Part of the [Stable ABI](#).

Returns the “bitwise exclusive or” of `o1` by `o2` on success, or `NULL` on failure. The operation is done *in-place* when `o1` supports it. This is the equivalent of the Python statement `o1 ^= o2`.

`PyObject *PyNumber_InPlaceOr(PyObject *o1, PyObject *o2)`

*Return value:* New reference. Part of the [Stable ABI](#).

Returns the “bitwise or” of `o1` and `o2` on success, or `NULL` on failure. The operation is done *in-place* when `o1` supports it. This is the equivalent of the Python statement `o1 |= o2`.

`PyObject *PyNumber_Long(PyObject *o)`

*Return value:* New reference. Part of the [Stable ABI](#).

Returns the *o* converted to an integer object on success, or `NULL` on failure. This is the equivalent of the Python expression `int(o)`.

[PyObject](#) \*PyNumber\_Float([PyObject](#) \*o)

*Return value:* New reference. Part of the [Stable ABI](#).

Returns the *o* converted to a float object on success, or `NULL` on failure. This is the equivalent of the Python expression `float(o)`.

[PyObject](#) \*PyNumber\_Index([PyObject](#) \*o)

*Return value:* New reference. Part of the [Stable ABI](#).

Returns the *o* converted to a Python int on success or `NULL` with a [TypeError](#) exception raised on failure.

*Changed in version 3.10:* The result always has exact type [int](#). Previously, the result could have been an instance of a subclass of `int`.

[PyObject](#) \*PyNumber\_ToBase([PyObject](#) \*n, int base)

*Return value:* New reference. Part of the [Stable ABI](#).

Returns the integer *n* converted to base *base* as a string. The *base* argument must be one of 2, 8, 10, or 16. For base 2, 8, or 16, the returned string is prefixed with a base marker of `'0b'`, `'0o'`, or `'0x'`, respectively. If *n* is not a Python int, it is converted with [PyNumber\\_Index\(\)](#) first.

[Py\\_ssize\\_t](#) PyNumber\_AsSsize\_t([PyObject](#) \*o, [PyObject](#) \*exc)

*Part of the [Stable ABI](#).*

Returns *o* converted to a [Py\\_ssize\\_t](#) value if *o* can be interpreted as an integer. If the call fails, an exception is raised and `-1` is returned.

If *o* can be converted to a Python int but the attempt to convert to a [Py\\_ssize\\_t](#) value would raise an [OverflowError](#), then the *exc* argument is the type of exception that will be raised (usually [IndexError](#) or

**OverflowError**). If `exc` is `NULL`, then the exception is cleared and the value is clipped to `PY_SSIZE_T_MIN` for a negative integer or `PY_SSIZE_T_MAX` for a positive integer.

`int PyIndex_Check(PyObject *o)`

*Part of the [Stable ABI](#) since version 3.8.*

Returns `1` if `o` is an index integer (has the `nb_index` slot of the `tp_as_number` structure filled in), and `0` otherwise.

This function always succeeds.

# Sequence Protocol

`int PySequence_Check(PyObject *o)`

*Part of the [Stable ABI](#).*

Return 1 if the object provides the sequence protocol, and 0 otherwise. Note that it returns 1 for Python classes with a `__getitem__()` method, unless they are `dict` subclasses, since in general it is impossible to determine what type of keys the class supports. This function always succeeds.

`Py_ssize_t PySequence_Size(PyObject *o)`

`Py_ssize_t PySequence_Length(PyObject *o)`

*Part of the [Stable ABI](#).*

Returns the number of objects in sequence `o` on success, and `-1` on failure. This is equivalent to the Python expression `len(o)`.

`PyObject *PySequence_Concat(PyObject *o1, PyObject *o2)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return the concatenation of `o1` and `o2` on success, and `NULL` on failure. This is the equivalent of the Python expression `o1 + o2`.

`PyObject *PySequence_Repeat(PyObject *o, Py_ssize_t count)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return the result of repeating sequence object `o` `count` times, or `NULL` on failure. This is the equivalent of the Python expression `o * count`.

`PyObject *PySequence_InPlaceConcat(PyObject *o1, PyObject *o2)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return the concatenation of `o1` and `o2` on success, and `NULL` on failure. The operation is done *in-place* when `o1` supports it.

This is the equivalent of the Python expression `o1 += o2`.

**PyObject \***PySequence\_InPlaceRepeat(**PyObject \****o*, **Py\_ssize\_t** *count*)

*Return value:* New reference. Part of the [Stable ABI](#).

Return the result of repeating sequence object *o* *count* times, or `NULL` on failure. The operation is done *in-place* when *o* supports it. This is the equivalent of the Python expression `o *= count`.

**PyObject \***PySequence\_GetItem(**PyObject \****o*, **Py\_ssize\_t** *i*)

*Return value:* New reference. Part of the [Stable ABI](#).

Return the *i*th element of *o*, or `NULL` on failure. This is the equivalent of the Python expression `o[i]`.

**PyObject \***PySequence\_GetSlice(**PyObject \****o*, **Py\_ssize\_t** *i1*, **Py\_ssize\_t** *i2*)

*Return value:* New reference. Part of the [Stable ABI](#).

Return the slice of sequence object *o* between *i1* and *i2*, or `NULL` on failure. This is the equivalent of the Python expression `o[i1:i2]`.

**int** PySequence\_SetItem(**PyObject \****o*, **Py\_ssize\_t** *i*, **PyObject \****v*)

*Part of the [Stable ABI](#).*

Assign object *v* to the *i*th element of *o*. Raise an exception and return `-1` on failure; return `0` on success. This is the equivalent of the Python statement `o[i] = v`. This function *does not* steal a reference to *v*.

If *v* is `NULL`, the element is deleted, but this feature is deprecated in favour of using [PySequence\\_DelItem\(\)](#).

**int** PySequence\_DelItem(**PyObject \****o*, **Py\_ssize\_t** *i*)

*Part of the [Stable ABI](#).*

Delete the *i*th element of object *o*. Returns `-1` on failure. This is the equivalent of the Python statement `del o[i]`.

`int PySequence_SetSlice(PyObject *o, Py_ssize_t i1, Py_ssize_t i2, PyObject *v)`

*Part of the [Stable ABI](#).*

Assign the sequence object *v* to the slice in sequence object *o* from *i1* to *i2*. This is the equivalent of the Python statement `o[i1:i2] = v`.

`int PySequence_DelSlice(PyObject *o, Py_ssize_t i1, Py_ssize_t i2)`

*Part of the [Stable ABI](#).*

Delete the slice in sequence object *o* from *i1* to *i2*. Returns `-1` on failure. This is the equivalent of the Python statement `del o[i1:i2]`.

`Py_ssize_t PySequence_Count(PyObject *o, PyObject *value)`

*Part of the [Stable ABI](#).*

Return the number of occurrences of *value* in *o*, that is, return the number of keys for which `o[key] == value`. On failure, return `-1`. This is equivalent to the Python expression `o.count(value)`.

`int PySequence_Contains(PyObject *o, PyObject *value)`

*Part of the [Stable ABI](#).*

Determine if *o* contains *value*. If an item in *o* is equal to *value*, return `1`, otherwise return `0`. On error, return `-1`. This is equivalent to the Python expression `value in o`.

`Py_ssize_t PySequence_Index(PyObject *o, PyObject *value)`

*Part of the [Stable ABI](#).*

Return the first index *i* for which `o[i] == value`. On error, return `-1`. This is equivalent to the Python expression `o.index(value)`.

`PyObject *PySequence_List(PyObject *o)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return a list object with the same contents as the sequence or iterable *o*, or `NULL` on failure. The returned list is guaranteed to be new. This is equivalent to the Python expression

`list(o)`.

**PyObject** \*PySequence\_Tuple(PyObject \*o)

*Return value:* New reference. Part of the [Stable ABI](#).

Return a tuple object with the same contents as the sequence or iterable `o`, or `NULL` on failure. If `o` is a tuple, a new reference will be returned, otherwise a tuple will be constructed with the appropriate contents. This is equivalent to the Python expression `tuple(o)`.

**PyObject** \*PySequence\_Fast(PyObject \*o, const char \*m)

*Return value:* New reference. Part of the [Stable ABI](#).

Return the sequence or iterable `o` as an object usable by the other `PySequence_Fast*` family of functions. If the object is not a sequence or iterable, raises **TypeError** with `m` as the message text. Returns `NULL` on failure.

The `PySequence_Fast*` functions are thus named because they assume `o` is a **PyTupleObject** or a **PyListObject** and access the data fields of `o` directly.

As a CPython implementation detail, if `o` is already a sequence or list, it will be returned.

**Py\_ssize\_t** PySequence\_Fast\_GET\_SIZE(PyObject \*o)

Returns the length of `o`, assuming that `o` was returned by **PySequence\_Fast()** and that `o` is not `NULL`. The size can also be retrieved by calling **PySequence\_Size()** on `o`, but **PySequence\_Fast\_GET\_SIZE()** is faster because it can assume `o` is a list or tuple.

**PyObject** \*PySequence\_Fast\_GET\_ITEM(PyObject \*o, Py\_ssize\_t i)

*Return value:* Borrowed reference.

Return the `i`th element of `o`, assuming that `o` was returned by **PySequence\_Fast()**, `o` is not `NULL`, and that `i` is within bounds.

**PyObject** \*\*PySequence\_Fast\_ITEMS(PyObject \*o)

Return the underlying array of PyObject pointers. Assumes that *o* was returned by `PySequence_Fast()` and *o* is not NULL.

Note, if a list gets resized, the reallocation may relocate the items array. So, only use the underlying array pointer in contexts where the sequence cannot change.

`PyObject *PySequence_ITEM(PyObject *o, Py_ssize_t i)`

*Return value:* New reference.

Return the *i*th element of *o* or NULL on failure. Faster form of `PySequence_GetItem()` but without checking that `PySequence_Check()` on *o* is true and without adjustment for negative indices.

# Mapping Protocol

See also [PyObject\\_GetItem\(\)](#), [PyObject\\_SetItem\(\)](#) and [PyObject\\_DelItem\(\)](#).

int PyMapping\_Check([PyObject](#) \*o)

*Part of the [Stable ABI](#).*

Return 1 if the object provides the mapping protocol or supports slicing, and 0 otherwise. Note that it returns 1 for Python classes with a `__getitem__()` method, since in general it is impossible to determine what type of keys the class supports. This function always succeeds.

[Py\\_ssize\\_t](#) PyMapping\_Size([PyObject](#) \*o)

[Py\\_ssize\\_t](#) PyMapping\_Length([PyObject](#) \*o)

*Part of the [Stable ABI](#).*

Returns the number of keys in object *o* on success, and -1 on failure. This is equivalent to the Python expression `len(o)`.

[PyObject](#) \*PyMapping\_GetItemString([PyObject](#) \*o, const char \*key)

*Return value: New reference. Part of the [Stable ABI](#).*

Return element of *o* corresponding to the string *key* or NULL on failure. This is the equivalent of the Python expression `o[key]`. See also [PyObject\\_GetItem\(\)](#).

int PyMapping\_SetItemString([PyObject](#) \*o, const char \*key,  
[PyObject](#) \*v)

*Part of the [Stable ABI](#).*

Map the string *key* to the value *v* in object *o*. Returns -1 on failure. This is the equivalent of the Python statement `o[key] = v`. See also [PyObject\\_SetItem\(\)](#). This function *does not* steal a reference to *v*.

`int PyMapping_DelItem(PyObject *o, PyObject *key)`

Remove the mapping for the object *key* from the object *o*.  
Return `-1` on failure. This is equivalent to the Python statement `del o[key]`. This is an alias of `PyObject_DelItem()`.

`int PyMapping_DelItemString(PyObject *o, const char *key)`

Remove the mapping for the string *key* from the object *o*.  
Return `-1` on failure. This is equivalent to the Python statement `del o[key]`.

`int PyMapping_HasKey(PyObject *o, PyObject *key)`

*Part of the [Stable ABI](#).*

Return `1` if the mapping object has the key *key* and `0` otherwise. This is equivalent to the Python expression `key in o`. This function always succeeds.

Note that exceptions which occur while calling the `__getitem__()` method will get suppressed. To get error reporting use `PyObject_GetItem()` instead.

`int PyMapping_HasKeyString(PyObject *o, const char *key)`

*Part of the [Stable ABI](#).*

Return `1` if the mapping object has the key *key* and `0` otherwise. This is equivalent to the Python expression `key in o`. This function always succeeds.

Note that exceptions which occur while calling the `__getitem__()` method and creating a temporary string object will get suppressed. To get error reporting use `PyMapping_GetItemString()` instead.

`PyObject *PyMapping_Keys(PyObject *o)`

*Return value: New reference. Part of the [Stable ABI](#).*

On success, return a list of the keys in object *o*. On failure, return `NULL`.

*Changed in version 3.7:* Previously, the function returned a list

or a tuple.

**PyObject \***PyMapping\_Values(**PyObject \***o)

*Return value:* New reference. Part of the [Stable ABI](#).

On success, return a list of the values in object *o*. On failure, return `NULL`.

*Changed in version 3.7:* Previously, the function returned a list or a tuple.

**PyObject \***PyMapping\_Items(**PyObject \***o)

*Return value:* New reference. Part of the [Stable ABI](#).

On success, return a list of the items in object *o*, where each item is a tuple containing a key-value pair. On failure, return `NULL`.

*Changed in version 3.7:* Previously, the function returned a list or a tuple.

# Iterator Protocol

There are two functions specifically for working with iterators.

`int PyIter_Check(PyObject *o)`

*Part of the [Stable ABI](#) since version 3.8.*

Return non-zero if the object *o* can be safely passed to [PyIter\\_Next\(\)](#), and 0 otherwise. This function always succeeds.

`int PyAlter_Check(PyObject *o)`

*Part of the [Stable ABI](#) since version 3.10.*

Return non-zero if the object *o* provides the **AsyncIterator** protocol, and 0 otherwise. This function always succeeds.

*New in version 3.10.*

`PyObject *PyIter_Next(PyObject *o)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return the next value from the iterator *o*. The object must be an iterator according to [PyIter\\_Check\(\)](#) (it is up to the caller to check this). If there are no remaining values, returns NULL with no exception set. If an error occurs while retrieving the item, returns NULL and passes along the exception.

To write a loop which iterates over an iterator, the C code should look something like this:

```
PyObject *iterator = PyObject_GetIter(obj);
PyObject *item;

if (iterator == NULL) {
```

```

        /* propagate error */
    }

    while ((item = PyIter_Next(iterator))) {
        /* do something with item */
        ...
        /* release reference when done */
        Py_DECREF(item);
    }

    Py_DECREF(iterator);

    if (PyErr_Occurred()) {
        /* propagate error */
    }
    else {
        /* continue doing useful work */
    }

```

type PySendResult

The enum value used to represent different results of [PyIter\\_Send\(\)](#).

*New in version 3.10.*

[PySendResult](#) PyIter\_Send([PyObject](#) \*iter, [PyObject](#) \*arg, [PyObject](#) \*\*presult)

*Part of the [Stable ABI](#) since version 3.10.*

Sends the *arg* value into the iterator *iter*. Returns:

- PYGEN\_RETURN if iterator returns. Return value is returned via *presult*.
- PYGEN\_NEXT if iterator yields. Yielded value is returned via *presult*.
- PYGEN\_ERROR if iterator has raised an exception. *presult* is set to NULL.

*New in version 3.10.*

# Buffer Protocol

Certain objects available in Python wrap access to an underlying memory array or *buffer*. Such objects include the built-in `bytes` and `bytearray`, and some extension types like `array.array`. Third-party libraries may define their own types for special purposes, such as image processing or numeric analysis.

While each of these types have their own semantics, they share the common characteristic of being backed by a possibly large memory buffer. It is then desirable, in some situations, to access that buffer directly and without intermediate copying.

Python provides such a facility at the C level in the form of the `buffer protocol`. This protocol has two sides:

- on the producer side, a type can export a “buffer interface” which allows objects of that type to expose information about their underlying buffer. This interface is described in the section `Buffer Object Structures`;
- on the consumer side, several means are available to obtain a pointer to the raw underlying data of an object (for example a method parameter).

Simple objects such as `bytes` and `bytearray` expose their underlying buffer in byte-oriented form. Other forms are possible; for example, the elements exposed by an `array.array` can be multi-byte values.

An example consumer of the buffer interface is the `write()` method of file objects: any object that can export a series of bytes through the buffer interface can be written to a file. While `write()` only needs read-only access to the internal contents of the object passed to it, other methods such as `readinto()` need write access to the contents of their argument. The buffer interface allows objects to selectively allow or reject exporting of read-write and read-only buffers.

There are two ways for a consumer of the buffer interface to acquire a buffer over a target object:

- call `PyObject_GetBuffer()` with the right parameters;
- call `PyArg_ParseTuple()` (or one of its siblings) with one of the `y*`, `w*` or `s*` [format codes](#).

In both cases, `PyBuffer_Release()` must be called when the buffer isn't needed anymore. Failure to do so could lead to various issues such as resource leaks.

## Buffer structure

Buffer structures (or simply “buffers”) are useful as a way to expose the binary data from another object to the Python programmer. They can also be used as a zero-copy slicing mechanism. Using their ability to reference a block of memory, it is possible to expose any data to the Python programmer quite easily. The memory could be a large, constant array in a C extension, it could be a raw block of memory for manipulation before passing to an operating system library, or it could be used to pass around structured data in its native, in-memory format.

Contrary to most data types exposed by the Python interpreter, buffers are not `PyObject` pointers but rather simple C structures. This allows them to be created and copied very simply. When a generic wrapper around a buffer is needed, a [memoryview](#) object can be created.

For short instructions how to write an exporting object, see [Buffer Object Structures](#). For obtaining a buffer, see `PyObject_GetBuffer()`.

type `Py_buffer`

*Part of the [Stable ABI](#) (including all members) since version 3.11.*

`void *buf`

A pointer to the start of the logical structure described by the buffer fields. This can be any location within the underlying physical memory block of the exporter. For

example, with negative **strides** the value may point to the end of the memory block.

For **contiguous** arrays, the value points to the beginning of the memory block.

### **PyObject \***obj

A new reference to the exporting object. The reference is owned by the consumer and automatically decremented and set to `NULL` by **PyBuffer\_Release()**. The field is the equivalent of the return value of any standard C-API function.

As a special case, for *temporary* buffers that are wrapped by **PyMemoryView\_FromBuffer()** or **PyBuffer\_FillInfo()** this field is `NULL`. In general, exporting objects **MUST NOT** use this scheme.

### **Py\_ssize\_t** len

`product(shape) * itemsize`. For contiguous arrays, this is the length of the underlying memory block. For non-contiguous arrays, it is the length that the logical structure would have if it were copied to a contiguous representation.

Accessing `((char *)buf)[0]` up to `((char *)buf)[len-1]` is only valid if the buffer has been obtained by a request that guarantees contiguity. In most cases such a request will be **PyBUF\_SIMPLE** or **PyBUF\_WRITABLE**.

### **int** readonly

An indicator of whether the buffer is read-only. This field is controlled by the **PyBUF\_WRITABLE** flag.

### **Py\_ssize\_t** itemsize

Item size in bytes of a single element. Same as the value of **struct.calcsize()** called on non-NULL **format** values.

Important exception: If a consumer requests a buffer without the `PyBUF_FORMAT` flag, `format` will be set to `NULL`, but `itemsize` still has the value for the original format.

If `shape` is present, the equality `product(shape) * itemsize == len` still holds and the consumer can use `itemsize` to navigate the buffer.

If `shape` is `NULL` as a result of a `PyBUF_SIMPLE` or a `PyBUF_WRITABLE` request, the consumer must disregard `itemsize` and assume `itemsize == 1`.

`const char *format`

A `NUL` terminated string in `struct` module style syntax describing the contents of a single item. If this is `NULL`, `"B"` (unsigned bytes) is assumed.

This field is controlled by the `PyBUF_FORMAT` flag.

`int ndim`

The number of dimensions the memory represents as an n-dimensional array. If it is `0`, `buf` points to a single item representing a scalar. In this case, `shape`, `strides` and `suboffsets` MUST be `NULL`.

The macro `PyBUF_MAX_NDIM` limits the maximum number of dimensions to 64. Exporters MUST respect this limit, consumers of multi-dimensional buffers SHOULD be able to handle up to `PyBUF_MAX_NDIM` dimensions.

`Py_ssize_t *shape`

An array of `Py_ssize_t` of length `ndim` indicating the shape of the memory as an n-dimensional array. Note that `shape[0] * ... * shape[ndim-1] * itemsize` MUST be equal to `len`.

Shape values are restricted to `shape[n] >= 0`. The case `shape[n] == 0` requires special attention. See

[complex arrays](#) for further information.

The shape array is read-only for the consumer.

#### `Py_ssize_t *strides`

An array of `Py_ssize_t` of length `ndim` giving the number of bytes to skip to get to a new element in each dimension.

Stride values can be any integer. For regular arrays, strides are usually positive, but a consumer **MUST** be able to handle the case `strides[n] <= 0`. See [complex arrays](#) for further information.

The strides array is read-only for the consumer.

#### `Py_ssize_t *suboffsets`

An array of `Py_ssize_t` of length `ndim`. If `suboffsets[n] >= 0`, the values stored along the `n`th dimension are pointers and the suboffset value dictates how many bytes to add to each pointer after de-referencing. A suboffset value that is negative indicates that no de-referencing should occur (striding in a contiguous memory block).

If all suboffsets are negative (i.e. no de-referencing is needed), then this field must be `NULL` (the default value).

This type of array representation is used by the Python Imaging Library (PIL). See [complex arrays](#) for further information how to access elements of such an array.

The suboffsets array is read-only for the consumer.

#### `void *internal`

This is for use internally by the exporting object. For example, this might be re-cast as an integer by the exporter and used to store flags about whether or not the shape, strides, and suboffsets arrays must be freed

when the buffer is released. The consumer **MUST NOT** alter this value.

## Buffer request types

Buffers are usually obtained by sending a buffer request to an exporting object via `PyObject_GetBuffer()`. Since the complexity of the logical structure of the memory can vary drastically, the consumer uses the *flags* argument to specify the exact buffer type it can handle.

All `Py_buffer` fields are unambiguously defined by the request type.

### request-independent fields

The following fields are not influenced by *flags* and must always be filled in with the correct values: `obj`, `buf`, `len`, `itemsizes`, `ndim`.

### readonly, format

#### PyBUF\_WRITABLE

Controls the `readonly` field. If set, the exporter **MUST** provide a writable buffer or else report failure. Otherwise, the exporter **MAY** provide either a read-only or writable buffer, but the choice **MUST** be consistent for all consumers.

#### PyBUF\_FORMAT

Controls the `format` field. If set, this field **MUST** be filled in correctly. Otherwise, this field **MUST** be `NULL`.

`PyBUF_WRITABLE` can be |'d to any of the flags in the next section. Since `PyBUF_SIMPLE` is defined as 0, `PyBUF_WRITABLE` can be used as a stand-alone flag to request a simple writable buffer.

`PyBUF_FORMAT` can be |'d to any of the flags except `PyBUF_SIMPLE`. The latter already implies format `B` (unsigned bytes).

## shape, strides, suboffsets

The flags that control the logical structure of the memory are listed in decreasing order of complexity. Note that each flag contains all bits of the flags below it.

### Suboffsets

<code>PyBUF_DIRECT</code>
<code>PyBUF_STRIDES</code>
<code>PyBUF_ND</code>
<code>PyBUF_SIMPLE</code>

## contiguity requests

C or Fortran [contiguity](#) can be explicitly requested, with and without stride information. Without stride information, the buffer must be C-contiguous.

### Suboffsets

<code>PyBUF_C_CONTIGUOUS</code>
<code>PyBUF_F_CONTIGUOUS</code>
<code>PyBUF_ANY_CONTIGUOUS</code>
<code>PyBUF_ND</code>

## compound requests

All possible requests are fully defined by some combination of the flags in the previous section. For convenience, the buffer protocol provides frequently used combinations as single flags.

In the following table *U* stands for undefined contiguity. The consumer would have to call `PyBuffer_IsContiguous()` to determine contiguity.

### Suboffsets

<code>PyBUF_NULL</code>
-------------------------

<del>PyObject</del>	<del>NULL</del>
<del>PyObject</del>	<del>NULL</del>
<del>PyObject</del>	<del>NULL</del>
<del>PyObject</del>	<del>NULL</del>
<del>PyObject</del>	<del>NULL</del>
<del>PyObject</del>	<del>NULL</del>
<del>PyObject</del>	<del>NULL</del>
<del>PyObject</del>	<del>NULL</del>

## Complex arrays

### NumPy-style: shape and strides

The logical structure of NumPy-style arrays is defined by **itemsizes**, **ndim**, **shape** and **strides**.

If `ndim == 0`, the memory location pointed to by **buf** is interpreted as a scalar of size **itemsizes**. In that case, both **shape** and **strides** are `NULL`.

If **strides** is `NULL`, the array is interpreted as a standard n-dimensional C-array. Otherwise, the consumer must access an n-dimensional array as follows:

```
ptr = (char *)buf + indices[0] * strides[0] + ... + indices[ndim-1] * strides[ndim-1]
item = *((typeof(item) *)ptr);
```

As noted above, **buf** can point to any location within the actual memory block. An exporter can check the validity of a buffer with this function:

```
def verify_structure(memlen, itemsizes, ndim, shape, strides):
    """Verify that the parameters represent a valid array
    the bounds of the allocated memory:
        char *mem: start of the physical memory block
        memlen: length of the physical memory block
        offset: (char *)buf - mem
    """
    if offset % itemsizes:
        return False
    if offset < 0 or offset+itemsizes > memlen:
```

```

        return False
    if any(v % itemsize for v in strides):
        return False

    if ndim <= 0:
        return ndim == 0 and not shape and not strides
    if 0 in shape:
        return True

    imin = sum(strides[j]*(shape[j]-1) for j in range(ndim)
               if strides[j] <= 0)
    imax = sum(strides[j]*(shape[j]-1) for j in range(ndim)
               if strides[j] > 0)

    return 0 <= offset+imin and offset+imax+itemsize <=

```

## PIL-style: shape, strides and suboffsets

In addition to the regular items, PIL-style arrays can contain pointers that must be followed in order to get to the next element in a dimension. For example, the regular three-dimensional C-array `char v[2][2][3]` can also be viewed as an array of 2 pointers to 2 two-dimensional arrays: `char (*v[2])[2][3]`. In suboffsets representation, those two pointers can be embedded at the start of **buf**, pointing to two `char x[2][3]` arrays that can be located anywhere in memory.

Here is a function that returns a pointer to the element in an N-D array pointed to by an N-dimensional index when there are both non-NULL strides and suboffsets:

```

void *get_item_pointer(int ndim, void *buf, Py_ssize_t *
                      Py_ssize_t *suboffsets, Py_ssize_t
    char *pointer = (char*)buf;
    int i;
    for (i = 0; i < ndim; i++) {
        pointer += strides[i] * indices[i];
        if (suboffsets[i] >= 0 ) {
            pointer = *((char**)pointer) + suboffsets[i]

```

```

    }
}
return (void*)pointer;
}

```

## Buffer-related functions

`int PyObject_CheckBuffer(PyObject *obj)`

*Part of the [Stable ABI](#) since version 3.11.*

Return 1 if *obj* supports the buffer interface otherwise 0.

When 1 is returned, it doesn't guarantee that

[PyObject\\_GetBuffer\(\)](#) will succeed. This function always succeeds.

`int PyObject_GetBuffer(PyObject *exporter, Py_buffer *view, int flags)`

*Part of the [Stable ABI](#) since version 3.11.*

Send a request to *exporter* to fill in *view* as specified by *flags*. If the exporter cannot provide a buffer of the exact type, it MUST raise **PyExc\_BufferError**, set `view->obj` to NULL and return -1.

On success, fill in *view*, set `view->obj` to a new reference to *exporter* and return 0. In the case of chained buffer providers that redirect requests to a single object, `view->obj` MAY refer to this object instead of *exporter* (See [Buffer Object Structures](#)).

Successful calls to [PyObject\\_GetBuffer\(\)](#) must be paired with calls to [PyBuffer\\_Release\(\)](#), similar to **malloc()** and **free()**. Thus, after the consumer is done with the buffer, [PyBuffer\\_Release\(\)](#) must be called exactly once.

`void PyBuffer_Release(Py_buffer *view)`

*Part of the [Stable ABI](#) since version 3.11.*

Release the buffer *view* and decrement the reference count for `view->obj`. This function MUST be called when the buffer is no longer being used, otherwise reference leaks may occur.

It is an error to call this function on a buffer that was not obtained via `PyObject_GetBuffer()`.

`Py_ssize_t PyBuffer_SizeFromFormat(const char *format)`

*Part of the [Stable ABI](#) since version 3.11.*

Return the implied `itemsizes` from `format`. On error, raise an exception and return -1.

*New in version 3.9.*

`int PyBuffer_IsContiguous(const Py\_buffer *view, char order)`

*Part of the [Stable ABI](#) since version 3.11.*

Return 1 if the memory defined by the `view` is C-style (`order` is 'C') or Fortran-style (`order` is 'F') `contiguous` or either one (`order` is 'A'). Return 0 otherwise. This function always succeeds.

`void *PyBuffer_GetPointer(const Py\_buffer *view, const Py\_ssize\_t *indices)`

*Part of the [Stable ABI](#) since version 3.11.*

Get the memory area pointed to by the `indices` inside the given `view`. `indices` must point to an array of `view->ndim` indices.

`int PyBuffer_FromContiguous(const Py\_buffer *view, const void *buf, Py\_ssize\_t len, char fort)`

*Part of the [Stable ABI](#) since version 3.11.*

Copy contiguous `len` bytes from `buf` to `view`. `fort` can be 'C' or 'F' (for C-style or Fortran-style ordering). 0 is returned on success, -1 on error.

`int PyBuffer_ToContiguous(void *buf, const Py\_buffer *src, Py\_ssize\_t len, char order)`

*Part of the [Stable ABI](#) since version 3.11.*

Copy `len` bytes from `src` to its contiguous representation in `buf`. `order` can be 'C' or 'F' or 'A' (for C-style or Fortran-style ordering or either one). 0 is returned on success, -1 on

error.

This function fails if *len* != *src->len*.

int PyObject\_CopyData(PyObject \*dest, PyObject \*src)

Part of the *Stable ABI* since version 3.11.

Copy data from *src* to *dest* buffer. Can convert between C-style and or Fortran-style buffers.

0 is returned on success, -1 on error.

void PyBuffer\_FillContiguousStrides(int ndims, Py\_ssize\_t \*shape, Py\_ssize\_t \*strides, int itemsize, char order)

Part of the *Stable ABI* since version 3.11.

Fill the *strides* array with byte-strides of a *contiguous* (C-style if *order* is 'C' or Fortran-style if *order* is 'F') array of the given shape with the given number of bytes per element.

int PyBuffer\_FillInfo(Py\_buffer \*view, PyObject \*exporter, void \*buf, Py\_ssize\_t len, int readonly, int flags)

Part of the *Stable ABI* since version 3.11.

Handle buffer requests for an exporter that wants to expose *buf* of size *len* with writability set according to *readonly*. *buf* is interpreted as a sequence of unsigned bytes.

The *flags* argument indicates the request type. This function always fills in *view* as specified by flags, unless *buf* has been designated as read-only and **PyBUF\_WRITABLE** is set in *flags*.

On success, set *view->obj* to a new reference to *exporter* and return 0. Otherwise, raise **PyExc\_BufferError**, set *view->obj* to NULL and return -1;

If this function is used as part of a *getbufferproc*, *exporter* MUST be set to the exporting object and *flags* must be passed unmodified. Otherwise, *exporter* MUST be NULL.

# Old Buffer Protocol

*Deprecated since version 3.0.*

These functions were part of the “old buffer protocol” API in Python 2. In Python 3, this protocol doesn’t exist anymore but the functions are still exposed to ease porting 2.x code. They act as a compatibility wrapper around the [new buffer protocol](#), but they don’t give you control over the lifetime of the resources acquired when a buffer is exported.

Therefore, it is recommended that you call [PyObject\\_GetBuffer\(\)](#) (or the `y*` or `w*` [format codes](#) with the [PyArg\\_ParseTuple\(\)](#) family of functions) to get a buffer view over an object, and [PyBuffer\\_Release\(\)](#) when the buffer view can be released.

```
int PyObject_AsCharBuffer(PyObject *obj, const char **buffer,  
Py\_ssize\_t *buffer_len)
```

*Part of the [Stable ABI](#).*

Returns a pointer to a read-only memory location usable as character-based input. The *obj* argument must support the single-segment character buffer interface. On success, returns 0, sets *buffer* to the memory location and *buffer\_len* to the buffer length. Returns -1 and sets a [TypeError](#) on error.

```
int PyObject_AsReadBuffer(PyObject *obj, const void **buffer,  
Py\_ssize\_t *buffer_len)
```

*Part of the [Stable ABI](#).*

Returns a pointer to a read-only memory location containing arbitrary data. The *obj* argument must support the single-segment readable buffer interface. On success, returns 0, sets *buffer* to the memory location and *buffer\_len* to the buffer length. Returns -1 and sets a [TypeError](#) on error.

int PyObject\_CheckReadBuffer(PyObject \*o)

*Part of the [Stable ABI](#).*

Returns 1 if *o* supports the single-segment readable buffer interface. Otherwise returns 0. This function always succeeds.

Note that this function tries to get and release a buffer, and exceptions which occur while calling corresponding functions will get suppressed. To get error reporting use [PyObject\\_GetBuffer\(\)](#) instead.

int PyObject\_AsWriteBuffer(PyObject \*obj, void \*\*buffer, Py\_ssize\_t \*buffer\_len)

*Part of the [Stable ABI](#).*

Returns a pointer to a writable memory location. The *obj* argument must support the single-segment, character buffer interface. On success, returns 0, sets *buffer* to the memory location and *buffer\_len* to the buffer length. Returns -1 and sets a [TypeError](#) on error.

# Concrete Objects Layer

The functions in this chapter are specific to certain Python object types. Passing them an object of the wrong type is not a good idea; if you receive an object from a Python program and you are not sure that it has the right type, you must perform a type check first; for example, to check that an object is a dictionary, use `PyDict_Check()`. The chapter is structured like the “family tree” of Python object types.

## Warning

While the functions described in this chapter carefully check the type of the objects which are passed in, many of them do not check for `NULL` being passed instead of a valid object. Allowing `NULL` to be passed in can cause memory access violations and immediate termination of the interpreter.

## Fundamental Objects

This section describes Python type objects and the singleton object `None`.

# Type Objects

type PyObject

*Part of the [Limited API](#) (as an opaque struct).*

The C structure of the objects used to describe built-in types.

[PyObject](#) PyType\_Type

*Part of the [Stable ABI](#).*

This is the type object for type objects; it is the same object as [type](#) in the Python layer.

int PyType\_Check([PyObject](#) \*o)

Return non-zero if the object *o* is a type object, including instances of types derived from the standard type object. Return 0 in all other cases. This function always succeeds.

int PyType\_CheckExact([PyObject](#) \*o)

Return non-zero if the object *o* is a type object, but not a subtype of the standard type object. Return 0 in all other cases. This function always succeeds.

unsigned int PyType\_ClearCache()

*Part of the [Stable ABI](#).*

Clear the internal lookup cache. Return the current version tag.

unsigned long PyType\_GetFlags([PyObject](#) \*type)

*Part of the [Stable ABI](#).*

Return the [tp\\_flags](#) member of *type*. This function is primarily meant for use with `Py_LIMITED_API`; the individual flag bits are guaranteed to be stable across Python releases, but access to [tp\\_flags](#) itself is not part of the limited API.

*New in version 3.2.*

*Changed in version 3.4:* The return type is now `unsigned long` rather than `long`.

`void PyType_Modified(PyTypeObject *type)`

*Part of the [Stable ABI](#).*

Invalidate the internal lookup cache for the type and all of its subtypes. This function must be called after any manual modification of the attributes or base classes of the type.

`int PyType_HasFeature(PyTypeObject *o, int feature)`

Return non-zero if the type object *o* sets the feature *feature*. Type features are denoted by single bit flags.

`int PyType_IS_GC(PyTypeObject *o)`

Return true if the type object includes support for the cycle detector; this tests the type flag `Py_TPFLAGS_HAVE_GC`.

`int PyType_IsSubtype(PyTypeObject *a, PyTypeObject *b)`

*Part of the [Stable ABI](#).*

Return true if *a* is a subtype of *b*.

This function only checks for actual subtypes, which means that `__subclasscheck__()` is not called on *b*. Call `PyObject_IsSubclass()` to do the same check that `issubclass()` would do.

`PyObject *PyType_GenericAlloc(PyTypeObject *type, Py_ssize_t nitems)`

*Return value:* New reference. *Part of the [Stable ABI](#).*

Generic handler for the `tp_alloc` slot of a type object. Use Python's default memory allocation mechanism to allocate a new instance and initialize all its contents to `NULL`.

`PyObject *PyType_GenericNew(PyTypeObject *type, PyObject *args, PyObject *kwargs)`

*Return value: New reference. Part of the [Stable ABI](#).*

Generic handler for the `tp_new` slot of a type object. Create a new instance using the type's `tp_alloc` slot.

`int PyType_Ready(PyTypeObject *type)`

*Part of the [Stable ABI](#).*

Finalize a type object. This should be called on all type objects to finish their initialization. This function is responsible for adding inherited slots from a type's base class. Return 0 on success, or return -1 and sets an exception on error.

### Note

If some of the base classes implements the GC protocol and the provided type does not include the `Py_TPFLAGS_HAVE_GC` in its flags, then the GC protocol will be automatically implemented from its parents. On the contrary, if the type being created does include `Py_TPFLAGS_HAVE_GC` in its flags then it **must** implement the GC protocol itself by at least implementing the `tp_traverse` handle.

`PyObject *PyType_GetName(PyTypeObject *type)`

*Return value: New reference. Part of the [Stable ABI](#) since version 3.11.*

Return the type's name. Equivalent to getting the type's `__name__` attribute.

*New in version 3.11.*

`PyObject *PyType_GetQualName(PyTypeObject *type)`

*Return value: New reference. Part of the [Stable ABI](#) since version 3.11.*

Return the type's qualified name. Equivalent to getting the type's `__qualname__` attribute.

*New in version 3.11.*

`void *PyType_GetSlot(PyTypeObject *type, int slot)`

*Part of the [Stable ABI](#) since version 3.4.*

Return the function pointer stored in the given slot. If the result is `NULL`, this indicates that either the slot is `NULL`, or that the function was called with invalid parameters. Callers will typically cast the result pointer into the appropriate function type.

See `PyType_Slot.slot` for possible values of the *slot* argument.

*New in version 3.4.*

*Changed in version 3.10:* `PyType_GetSlot()` can now accept all types. Previously, it was limited to [heap types](#).

`PyObject *PyType_GetModule(PyTypeObject *type)`

*Part of the [Stable ABI](#) since version 3.10.*

Return the module object associated with the given type when the type was created using

`PyType_FromModuleAndSpec()`.

If no module is associated with the given type, sets `TypeError` and returns `NULL`.

This function is usually used to get the module in which a method is defined. Note that in such a method,

`PyType_GetModule(Py_TYPE(self))` may not return the intended result. `Py_TYPE(self)` may be a *subclass* of the intended class, and subclasses are not necessarily defined in the same module as their superclass. See [PyCMethod](#) to get the class that defines the method. See

`PyType_GetModuleByDef()` for cases when `PyCMethod` cannot be used.

*New in version 3.9.*

`void *PyType_GetModuleState(PyTypeObject *type)`

*Part of the [Stable ABI](#) since version 3.10.*

Return the state of the module object associated with the given type. This is a shortcut for calling `PyModule_GetState()` on the result of `PyType_GetModule()`.

If no module is associated with the given type, sets `TypeError` and returns `NULL`.

If the `type` has an associated module but its state is `NULL`, returns `NULL` without setting an exception.

*New in version 3.9.*

`PyObject *PyType_GetModuleByDef(PyTypeObject *type, struct PyModuleDef *def)`

Find the first superclass whose module was created from the given `PyModuleDef` `def`, and return that module.

If no module is found, raises a `TypeError` and returns `NULL`.

This function is intended to be used together with `PyModule_GetState()` to get module state from slot methods (such as `tp_init` or `nb_add`) and other places where a method's defining class cannot be passed using the `PyCMethod` calling convention.

*New in version 3.11.*

## Creating Heap-Allocated Types

The following functions and structs are used to create [heap types](#).

`PyObject *PyType_FromModuleAndSpec(PyObject *module, PyType_Spec *spec, PyObject *bases)`

*Return value: New reference. Part of the [Stable ABI](#) since version 3.10.*

Creates and returns a [heap type](#) from the *spec* (`Py_TPFLAGS_HEAPTYPE`).

The *bases* argument can be used to specify base classes; it can either be only one class or a tuple of classes. If *bases* is `NULL`, the `Py_tp_bases` slot is used instead. If that also is `NULL`, the `Py_tp_base` slot is used instead. If that also is `NULL`, the new type derives from `object`.

The *module* argument can be used to record the module in which the new class is defined. It must be a module object or `NULL`. If not `NULL`, the module is associated with the new type and can later be retrieved with `PyType_GetModule()`. The associated module is not inherited by subclasses; it must be specified for each class individually.

This function calls `PyType_Ready()` on the new type.

*New in version 3.9.*

*Changed in version 3.10:* The function now accepts a single class as the *bases* argument and `NULL` as the `tp_doc` slot.

`PyObject *``PyType_FromSpecWithBases(PyType_Spec *spec, PyObject *bases)`

*Return value:* New reference. Part of the [Stable ABI](#) since version 3.3.

Equivalent to `PyType_FromModuleAndSpec(NULL, spec, bases)`.

*New in version 3.3.*

`PyObject *``PyType_FromSpec(PyType_Spec *spec)`

*Return value:* New reference. Part of the [Stable ABI](#).

Equivalent to `PyType_FromSpecWithBases(spec, NULL)`.

`type` `PyType_Spec`

*Part of the [Stable ABI](#) (including all members).*

Structure defining a type's behavior.

const char \*PyType\_Spec.name

Name of the type, used to set  
`PyTypeObject.tp_name`.

int PyType\_Spec.basicsize

int PyType\_Spec.itemsize

Size of the instance in bytes, used to set  
`PyTypeObject.tp_basicsize` and  
`PyTypeObject.tp_itemsize`.

int PyType\_Spec.flags

Type flags, used to set `PyTypeObject.tp_flags`.

If the `Py_TPFLAGS_HEAPTYPE` flag is not set,  
`PyType_FromSpecWithBases()` sets it  
automatically.

`PyType_Slot` \*PyType\_Spec.slots

Array of `PyType_Slot` structures. Terminated by the  
special slot value `{0, NULL}`.

type PyType\_Slot

*Part of the [Stable ABI](#) (including all members).*

Structure defining optional functionality of a type, containing  
a slot ID and a value pointer.

int PyType\_Slot.slot

A slot ID.

Slot IDs are named like the field names  
of the structures `PyTypeObject`,  
`PyNumberMethods`,  
`PySequenceMethods`,  
`PyMappingMethods` and  
`PyAsyncMethods` with an added `Py_`

prefix. For example, use:

- `Py_tp_dealloc` to set `PyTypeObject.tp_dealloc`
- `Py_nb_add` to set `PyNumberMethods.nb_add`
- `Py_sq_length` to set `PySequenceMethods.sq_length`

The following fields cannot be set at all using `PyType_Spec` and `PyType_Slot`:

- `tp_dict`
- `tp_mro`
- `tp_cache`
- `tp_subclasses`
- `tp_weaklist`
- `tp_vectorcall`
- `tp_weaklistoffset` (see `PyMemberDef`)
- `tp_dictoffset` (see `PyMemberDef`)
- `tp_vectorcall_offset` (see `PyMemberDef`)

Setting `Py_tp_bases` or `Py_tp_base` may be problematic on some platforms. To avoid issues, use the *bases* argument of `PyType_FromSpecWithBases()` instead.

*Changed in version 3.9:* Slots in `PyBufferProcs` may be set in the unlimited API.

*Changed in version 3.11:* `bf_getbuffer` and `bf_releasebuffer` are now available under the limited API.

`void *PyType_Slot.pfunc`

The desired value of the slot. In most cases, this is a pointer to a function.

Slots other than `Py_tp_doc` may not be `NULL`.

# The None Object

Note that the `PyTypeObject` for `None` is not directly exposed in the Python/C API. Since `None` is a singleton, testing for object identity (using `==` in C) is sufficient. There is no `PyNone_Check()` function for the same reason.

## `PyObject *``Py_None`

The Python `None` object, denoting lack of value. This object has no methods. It needs to be treated just like any other object with respect to reference counts.

## `Py_RETURN_NONE`

Properly handle returning `Py_None` from within a C function (that is, increment the reference count of `None` and return it.)

# Integer Objects

All integers are implemented as “long” integer objects of arbitrary size.

On error, most `PyLong_As*` APIs return `(return type)-1` which cannot be distinguished from a number. Use `PyErr_Occurred()` to disambiguate.

type `PyLongObject`

*Part of the [Limited API](#) (as an opaque struct).*

This subtype of `PyObject` represents a Python integer object.

`PyTypeObject` `PyLong_Type`

*Part of the [Stable ABI](#).*

This instance of `PyTypeObject` represents the Python integer type. This is the same object as `int` in the Python layer.

int `PyLong_Check(PyObject *p)`

Return true if its argument is a `PyLongObject` or a subtype of `PyLongObject`. This function always succeeds.

int `PyLong_CheckExact(PyObject *p)`

Return true if its argument is a `PyLongObject`, but not a subtype of `PyLongObject`. This function always succeeds.

`PyObject *``PyLong_FromLong(long v)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return a new `PyLongObject` object from `v`, or `NULL` on failure.

The current implementation keeps an array of integer objects

for all integers between `-5` and `256`. When you create an int in that range you actually just get back a reference to the existing object.

**PyObject \***PyLong\_FromUnsignedLong(unsigned long v)

*Return value:* New reference. Part of the [Stable ABI](#).

Return a new **PyLongObject** object from a C unsigned long, or `NULL` on failure.

**PyObject \***PyLong\_FromSize\_t(Py\_ssize\_t v)

*Return value:* New reference. Part of the [Stable ABI](#).

Return a new **PyLongObject** object from a C **Py\_ssize\_t**, or `NULL` on failure.

**PyObject \***PyLong\_FromSize\_t(size\_t v)

*Return value:* New reference. Part of the [Stable ABI](#).

Return a new **PyLongObject** object from a C **size\_t**, or `NULL` on failure.

**PyObject \***PyLong\_FromLongLong(long long v)

*Return value:* New reference. Part of the [Stable ABI](#).

Return a new **PyLongObject** object from a C long long, or `NULL` on failure.

**PyObject \***PyLong\_FromUnsignedLongLong(unsigned long long v)

*Return value:* New reference. Part of the [Stable ABI](#).

Return a new **PyLongObject** object from a C unsigned long long, or `NULL` on failure.

**PyObject \***PyLong\_FromDouble(double v)

*Return value:* New reference. Part of the [Stable ABI](#).

Return a new **PyLongObject** object from the integer part of v, or `NULL` on failure.

**PyObject \***PyLong\_FromString(const char \*str, char \*\*pend, int base)

*Return value: New reference. Part of the [Stable ABI](#).*

Return a new [PyLongObject](#) based on the string value in *str*, which is interpreted according to the radix in *base*. If *pend* is non-NULL, *\*pend* will point to the first character in *str* which follows the representation of the number. If *base* is 0, *str* is interpreted using the [Integer literals](#) definition; in this case, leading zeros in a non-zero decimal number raises a [ValueError](#). If *base* is not 0, it must be between 2 and 36, inclusive. Leading spaces and single underscores after a base specifier and between digits are ignored. If there are no digits, [ValueError](#) will be raised.

### See also

Python methods [int.to\\_bytes\(\)](#) and [int.from\\_bytes\(\)](#) to convert a [PyLongObject](#) to/from an array of bytes in base 256. You can call those from C using [PyObject\\_CallMethod\(\)](#).

[PyObject](#) \*PyLong\_FromUnicodeObject([PyObject](#) \*u, int base)

*Return value: New reference.*

Convert a sequence of Unicode digits in the string *u* to a Python integer value.

*New in version 3.3.*

[PyObject](#) \*PyLong\_FromVoidPtr(void \*p)

*Return value: New reference. Part of the [Stable ABI](#).*

Create a Python integer from the pointer *p*. The pointer value can be retrieved from the resulting value using [PyLong\\_AsVoidPtr\(\)](#).

long PyLong\_AsLong([PyObject](#) \*obj)

*Part of the [Stable ABI](#).*

Return a C long representation of *obj*. If *obj* is not an instance of [PyLongObject](#), first call its [\\_\\_index\\_\\_\(\)](#) method (if present) to convert it to a [PyLongObject](#).

Raise **OverflowError** if the value of *obj* is out of range for a long.

Returns `-1` on error. Use **PyErr\_Occurred()** to disambiguate.

*Changed in version 3.8:* Use **\_\_index\_\_()** if available.

*Changed in version 3.10:* This function will no longer use **\_\_int\_\_()**.

`long PyLong_AsLongAndOverflow(PyObject *obj, int *overflow)`

*Part of the **Stable ABI**.*

Return a C long representation of *obj*. If *obj* is not an instance of **PyLongObject**, first call its **\_\_index\_\_()** method (if present) to convert it to a **PyLongObject**.

If the value of *obj* is greater than **LONG\_MAX** or less than **LONG\_MIN**, set *\*overflow* to `1` or `-1`, respectively, and return `-1`; otherwise, set *\*overflow* to `0`. If any other exception occurs set *\*overflow* to `0` and return `-1` as usual.

Returns `-1` on error. Use **PyErr\_Occurred()** to disambiguate.

*Changed in version 3.8:* Use **\_\_index\_\_()** if available.

*Changed in version 3.10:* This function will no longer use **\_\_int\_\_()**.

`long long PyLong_AsLongLong(PyObject *obj)`

*Part of the **Stable ABI**.*

Return a C long long representation of *obj*. If *obj* is not an instance of **PyLongObject**, first call its **\_\_index\_\_()** method (if present) to convert it to a **PyLongObject**.

Raise **OverflowError** if the value of *obj* is out of range for a long long.

Returns `-1` on error. Use **PyErr\_Occurred()** to

disambiguate.

*Changed in version 3.8:* Use `__index__()` if available.

*Changed in version 3.10:* This function will no longer use `__int__()`.

`long long PyLong_AsLongLongAndOverflow(PyObject *obj, int *overflow)`

*Part of the [Stable ABI](#).*

Return a C long long representation of *obj*. If *obj* is not an instance of `PyLongObject`, first call its `__index__()` method (if present) to convert it to a `PyLongObject`.

If the value of *obj* is greater than `LLONG_MAX` or less than `LLONG_MIN`, set *\*overflow* to 1 or -1, respectively, and return -1; otherwise, set *\*overflow* to 0. If any other exception occurs set *\*overflow* to 0 and return -1 as usual.

Returns -1 on error. Use `PyErr_Occurred()` to disambiguate.

*New in version 3.2.*

*Changed in version 3.8:* Use `__index__()` if available.

*Changed in version 3.10:* This function will no longer use `__int__()`.

`Py_ssize_t PyLong_AsSsize_t(PyObject *pylong)`

*Part of the [Stable ABI](#).*

Return a C `Py_ssize_t` representation of *pylong*. *pylong* must be an instance of `PyLongObject`.

Raise `OverflowError` if the value of *pylong* is out of range for a `Py_ssize_t`.

Returns -1 on error. Use `PyErr_Occurred()` to disambiguate.

unsigned long PyLong\_AsUnsignedLong(PyObject \*pylong)

*Part of the [Stable ABI](#).*

Return a C unsigned long representation of *pylong*. *pylong* must be an instance of [PyLongObject](#).

Raise [OverflowError](#) if the value of *pylong* is out of range for a unsigned long.

Returns (unsigned long)-1 on error. Use [PyErr\\_Occurred\(\)](#) to disambiguate.

size\_t PyLong\_AsSize\_t(PyObject \*pylong)

*Part of the [Stable ABI](#).*

Return a C **size\_t** representation of *pylong*. *pylong* must be an instance of [PyLongObject](#).

Raise [OverflowError](#) if the value of *pylong* is out of range for a **size\_t**.

Returns (size\_t)-1 on error. Use [PyErr\\_Occurred\(\)](#) to disambiguate.

unsigned long long PyLong\_AsUnsignedLongLong(PyObject \*pylong)

*Part of the [Stable ABI](#).*

Return a C unsigned long long representation of *pylong*. *pylong* must be an instance of [PyLongObject](#).

Raise [OverflowError](#) if the value of *pylong* is out of range for an unsigned long long.

Returns (unsigned long long)-1 on error. Use [PyErr\\_Occurred\(\)](#) to disambiguate.

*Changed in version 3.1:* A negative *pylong* now raises [OverflowError](#), not [TypeError](#).

unsigned long PyLong\_AsUnsignedLongMask(PyObject \*obj)

*Part of the [Stable ABI](#).*

Return a C unsigned long representation of *obj*. If *obj* is not an instance of `PyLongObject`, first call its `__index__()` method (if present) to convert it to a `PyLongObject`.

If the value of *obj* is out of range for an unsigned long, return the reduction of that value modulo `ULONG_MAX + 1`.

Returns (unsigned long)-1 on error. Use `PyErr_Occurred()` to disambiguate.

*Changed in version 3.8:* Use `__index__()` if available.

*Changed in version 3.10:* This function will no longer use `__int__()`.

unsigned long long PyLong\_AsUnsignedLongLongMask(`PyObject` \*obj)

*Part of the [Stable ABI](#).*

Return a C unsigned long long representation of *obj*. If *obj* is not an instance of `PyLongObject`, first call its `__index__()` method (if present) to convert it to a `PyLongObject`.

If the value of *obj* is out of range for an unsigned long long, return the reduction of that value modulo `ULLONG_MAX + 1`.

Returns (unsigned long long)-1 on error. Use `PyErr_Occurred()` to disambiguate.

*Changed in version 3.8:* Use `__index__()` if available.

*Changed in version 3.10:* This function will no longer use `__int__()`.

double PyLong\_AsDouble(`PyObject` \*pylong)

*Part of the [Stable ABI](#).*

Return a C double representation of *pylong*. *pylong* must be an instance of `PyLongObject`.

Raise `OverflowError` if the value of *pylong* is out of range for a double.

Returns `-1.0` on error. Use `PyErr_Occurred()` to disambiguate.

`void *PyLong_AsVoidPtr(PyObject *pylong)`

*Part of the [Stable ABI](#).*

Convert a Python integer *pylong* to a C void pointer. If *pylong* cannot be converted, an `OverflowError` will be raised. This is only assured to produce a usable void pointer for values created with `PyLong_FromVoidPtr()`.

Returns `NULL` on error. Use `PyErr_Occurred()` to disambiguate.

# Boolean Objects

Booleans in Python are implemented as a subclass of integers. There are only two booleans, **Py\_False** and **Py\_True**. As such, the normal creation and deletion functions don't apply to booleans. The following macros are available, however.

`int PyBool_Check(PyObject *o)`

Return true if *o* is of type **PyBool\_Type**. This function always succeeds.

`PyObject *Py_False`

The Python `False` object. This object has no methods. It needs to be treated just like any other object with respect to reference counts.

`PyObject *Py_True`

The Python `True` object. This object has no methods. It needs to be treated just like any other object with respect to reference counts.

`Py_RETURN_FALSE`

Return **Py\_False** from a function, properly incrementing its reference count.

`Py_RETURN_TRUE`

Return **Py\_True** from a function, properly incrementing its reference count.

`PyObject *PyBool_FromLong(long v)`

*Return value:* New reference. Part of the [Stable ABI](#).

Return a new reference to **Py\_True** or **Py\_False** depending on the truth value of *v*.

# Floating Point Objects

type PyFloatObject

This subtype of **PyObject** represents a Python floating point object.

**PyTypeObject** PyFloat\_Type

*Part of the **Stable ABI**.*

This instance of **PyTypeObject** represents the Python floating point type. This is the same object as **float** in the Python layer.

int PyFloat\_Check(**PyObject** \*p)

Return true if its argument is a **PyFloatObject** or a subtype of **PyFloatObject**. This function always succeeds.

int PyFloat\_CheckExact(**PyObject** \*p)

Return true if its argument is a **PyFloatObject**, but not a subtype of **PyFloatObject**. This function always succeeds.

**PyObject** \*PyFloat\_FromString(**PyObject** \*str)

*Return value: New reference. Part of the **Stable ABI**.*

Create a **PyFloatObject** object based on the string value in *str*, or **NULL** on failure.

**PyObject** \*PyFloat\_FromDouble(double v)

*Return value: New reference. Part of the **Stable ABI**.*

Create a **PyFloatObject** object from *v*, or **NULL** on failure.

double PyFloat\_AsDouble(**PyObject** \*pyfloat)

*Part of the **Stable ABI**.*

Return a C double representation of the contents of *pyfloat*. If

`pyfloat` is not a Python floating point object but has a `__float__()` method, this method will first be called to convert `pyfloat` into a float. If `__float__()` is not defined then it falls back to `__index__()`. This method returns `-1.0` upon failure, so one should call `PyErr_Occurred()` to check for errors.

*Changed in version 3.8:* Use `__index__()` if available.

`double PyFloat_AS_DOUBLE(PyObject *pyfloat)`

Return a C double representation of the contents of `pyfloat`, but without error checking.

`PyObject *PyFloat_GetInfo(void)`

*Return value:* New reference. Part of the [Stable ABI](#).

Return a structseq instance which contains information about the precision, minimum and maximum values of a float. It's a thin wrapper around the header file `float.h`.

`double PyFloat_GetMax()`

*Part of the [Stable ABI](#).*

Return the maximum representable finite float `DBL_MAX` as C double.

`double PyFloat_GetMin()`

*Part of the [Stable ABI](#).*

Return the minimum normalized positive float `DBL_MIN` as C double.

## Pack and Unpack functions

The pack and unpack functions provide an efficient platform-independent way to store floating-point values as byte strings. The Pack routines produce a bytes string from a C double, and the Unpack routines produce a C double from such a bytes string. The suffix (2, 4 or 8) specifies the number of bytes in the bytes string.

On platforms that appear to use IEEE 754 formats these functions work by copying bits. On other platforms, the 2-byte format is identical to the IEEE 754 binary16 half-precision format, the 4-byte format (32-bit) is identical to the IEEE 754 binary32 single precision format, and the 8-byte format to the IEEE 754 binary64 double precision format, although the packing of INFs and NaNs (if such things exist on the platform) isn't handled correctly, and attempting to unpack a bytes string containing an IEEE INF or NaN will raise an exception.

On non-IEEE platforms with more precision, or larger dynamic range, than IEEE 754 supports, not all values can be packed; on non-IEEE platforms with less precision, or smaller dynamic range, not all values can be unpacked. What happens in such cases is partly accidental (alas).

*New in version 3.11.*

## Pack functions

The pack routines write 2, 4 or 8 bytes, starting at *p*. *le* is an int argument, non-zero if you want the bytes string in little-endian format (exponent last, at *p*+1, *p*+3, or *p*+6 *p*+7), zero if you want big-endian format (exponent first, at *p*). The **PY\_BIG\_ENDIAN** constant can be used to use the native endian: it is equal to 1 on big endian processor, or 0 on little endian processor.

Return value: 0 if all is OK, -1 if error (and an exception is set, most likely **OverflowError**).

There are two problems on non-IEEE platforms:

- What this does is undefined if *x* is a NaN or infinity.
- `-0.0` and `+0.0` produce the same bytes string.

`int PyFloat_Pack2(double x, unsigned char *p, int le)`

Pack a C double as the IEEE 754 binary16 half-precision format.

`int PyFloat_Pack4(double x, unsigned char *p, int le)`

Pack a C double as the IEEE 754 binary32 single precision format.

`int PyFloat_Pack8(double x, unsigned char *p, int le)`

Pack a C double as the IEEE 754 binary64 double precision format.

## Unpack functions

The unpack routines read 2, 4 or 8 bytes, starting at *p*. *le* is an int argument, non-zero if the bytes string is in little-endian format (exponent last, at *p*+1, *p*+3 or *p*+6 and *p*+7), zero if big-endian (exponent first, at *p*). The **PY\_BIG\_ENDIAN** constant can be used to use the native endian: it is equal to 1 on big endian processor, or 0 on little endian processor.

Return value: The unpacked double. On error, this is `-1.0` and **PyErr\_Occurred()** is true (and an exception is set, most likely **OverflowError**).

Note that on a non-IEEE platform this will refuse to unpack a bytes string that represents a NaN or infinity.

`double PyFloat_Unpack2(const unsigned char *p, int le)`

Unpack the IEEE 754 binary16 half-precision format as a C double.

`double PyFloat_Unpack4(const unsigned char *p, int le)`

Unpack the IEEE 754 binary32 single precision format as a C double.

`double PyFloat_Unpack8(const unsigned char *p, int le)`

Unpack the IEEE 754 binary64 double precision format as a C double.

# Complex Number Objects

Python's complex number objects are implemented as two distinct types when viewed from the C API: one is the Python object exposed to Python programs, and the other is a C structure which represents the actual complex number value. The API provides functions for working with both.

## Complex Numbers as C Structures

Note that the functions which accept these structures as parameters and return them as results do so *by value* rather than dereferencing them through pointers. This is consistent throughout the API.

type `Py_complex`

The C structure which corresponds to the value portion of a Python complex number object. Most of the functions for dealing with complex number objects use structures of this type as input or output values, as appropriate. It is defined as:

```
typedef struct {  
    double real;  
    double imag;  
} Py_complex;
```

`Py_complex_Py_c_sum(Py_complex left, Py_complex right)`

Return the sum of two complex numbers, using the C `Py_complex` representation.

`Py_complex_Py_c_diff(Py_complex left, Py_complex right)`

Return the difference between two complex numbers, using the C `Py_complex` representation.

`Py_complex_Py_c_neg(Py_complex num)`

Return the negation of the complex number *num*, using the C **Py\_complex** representation.

**Py\_complex** \_Py\_c\_prod(**Py\_complex** left, **Py\_complex** right)  
Return the product of two complex numbers, using the C **Py\_complex** representation.

**Py\_complex** \_Py\_c\_quot(**Py\_complex** dividend, **Py\_complex** divisor)  
Return the quotient of two complex numbers, using the C **Py\_complex** representation.

If *divisor* is null, this method returns zero and sets **errno** to **EDOM**.

**Py\_complex** \_Py\_c\_pow(**Py\_complex** num, **Py\_complex** exp)  
Return the exponentiation of *num* by *exp*, using the C **Py\_complex** representation.

If *num* is null and *exp* is not a positive real number, this method returns zero and sets **errno** to **EDOM**.

## Complex Numbers as Python Objects

type PyComplexObject

This subtype of **PyObject** represents a Python complex number object.

**PyTypeObject** PyComplex\_Type

*Part of the [Stable ABI](#).*

This instance of **PyTypeObject** represents the Python complex number type. It is the same object as **complex** in the Python layer.

int PyComplex\_Check(**PyObject** \*p)

Return true if its argument is a **PyComplexObject** or a subtype of **PyComplexObject**. This function always succeeds.

int PyComplex\_CheckExact(PyObject \*p)

Return true if its argument is a `PyComplexObject`, but not a subtype of `PyComplexObject`. This function always succeeds.

`PyObject *`PyComplex\_FromCComplex(`Py_complex` v)

*Return value:* New reference.

Create a new Python complex number object from a C `Py_complex` value.

`PyObject *`PyComplex\_FromDoubles(double real, double imag)

*Return value:* New reference. Part of the *Stable ABI*.

Return a new `PyComplexObject` object from *real* and *imag*.

double PyComplex\_RealAsDouble(PyObject \*op)

*Part of the Stable ABI.*

Return the real part of *op* as a C double.

double PyComplex\_ImagAsDouble(PyObject \*op)

*Part of the Stable ABI.*

Return the imaginary part of *op* as a C double.

`Py_complex` PyComplex\_AsCComplex(PyObject \*op)

Return the `Py_complex` value of the complex number *op*.

If *op* is not a Python complex number object but has a `__complex__()` method, this method will first be called to convert *op* to a Python complex number object. If `__complex__()` is not defined then it falls back to `__float__()`. If `__float__()` is not defined then it falls back to `__index__()`. Upon failure, this method returns `-1.0` as a real value.

*Changed in version 3.8:* Use `__index__()` if available.

# Bytes Objects

These functions raise **TypeError** when expecting a bytes parameter and called with a non-bytes parameter.

type PyBytesObject

This subtype of **PyObject** represents a Python bytes object.

**PyTypeObject** PyBytes\_Type

*Part of the **Stable ABI**.*

This instance of **PyTypeObject** represents the Python bytes type; it is the same object as **bytes** in the Python layer.

int PyBytes\_Check(**PyObject** \*o)

Return true if the object *o* is a bytes object or an instance of a subtype of the bytes type. This function always succeeds.

int PyBytes\_CheckExact(**PyObject** \*o)

Return true if the object *o* is a bytes object, but not an instance of a subtype of the bytes type. This function always succeeds.

**PyObject** \*PyBytes\_FromString(const char \*v)

*Return value: New reference. Part of the **Stable ABI**.*

Return a new bytes object with a copy of the string *v* as value on success, and **NULL** on failure. The parameter *v* must not be **NULL**; it will not be checked.

**PyObject** \*PyBytes\_FromStringAndSize(const char \*v, **Py\_ssize\_t** len)

*Return value: New reference. Part of the **Stable ABI**.*

Return a new bytes object with a copy of the string *v* as value and length *len* on success, and **NULL** on failure. If *v* is **NULL**, the contents of the bytes object are uninitialized.

**PyObject** \*PyBytes\_FromFormat(const char \*format, ...)

*Return value: New reference. Part of the [Stable ABI](#).*

Take a C **printf()**-style *format* string and a variable number of arguments, calculate the size of the resulting Python bytes object and return a bytes object with the values formatted into it. The variable arguments must be C types and must correspond exactly to the format characters in the *format* string. The following format characters are allowed:

### **Format Characters**

---

~~The~~ literal % character.

---

~~A~~ single byte, represented as a C int.

---

~~E~~quivalent to `printf("%d").` [1](#)

---

~~E~~quivalent to `printf("%u").` [1](#)

---

~~E~~quivalent to `printf("%ld").` [1](#)

---

~~E~~quivalent to `printf("%lu").` [1](#)

---

~~E~~quivalent to `printf("%zd").` [1](#)

---

~~E~~quivalent to `printf("%zu").` [1](#)

---

~~E~~quivalent to `printf("%i").` [1](#)

---

~~E~~quivalent to `printf("%x").` [1](#)

---

~~A~~ null-terminated C character array.

---

~~E~~quivalent representation of a C pointer. Mostly equivalent to `printf("%p")` except that it is guaranteed to start with the literal `0x` regardless of what the platform's `printf` yields.

---

An unrecognized format character causes all the rest of the format string to be copied as-is to the result object, and any extra arguments discarded.

1([1](#),[2](#),[3](#),[4](#),[5](#),[6](#),[7](#),[8](#))

For integer specifiers (d, u, ld, lu, zd, zu, i, x): the 0-conversion flag has effect even when a precision is given.

**PyObject** \*PyBytes\_FromFormatV(const char \*format, va\_list vargs)

*Return value: New reference. Part of the [Stable ABI](#).*

Identical to **PyBytes\_FromFormat()** except that it takes exactly two arguments.

`PyObject *PyBytes_FromObject(PyObject *o)`

*Return value:* New reference. Part of the [Stable ABI](#).

Return the bytes representation of object *o* that implements the buffer protocol.

`Py_ssize_t PyBytes_Size(PyObject *o)`

*Part of the [Stable ABI](#).*

Return the length of the bytes in bytes object *o*.

`Py_ssize_t PyBytes_GET_SIZE(PyObject *o)`

Similar to [PyBytes\\_Size\(\)](#), but without error checking.

`char *PyBytes_AsString(PyObject *o)`

*Part of the [Stable ABI](#).*

Return a pointer to the contents of *o*. The pointer refers to the internal buffer of *o*, which consists of `len(o) + 1` bytes.

The last byte in the buffer is always null, regardless of whether there are any other null bytes. The data must not be modified in any way, unless the object was just created using `PyBytes_FromStringAndSize(NULL, size)`. It must not be deallocated. If *o* is not a bytes object at all,

[PyBytes\\_AsString\(\)](#) returns `NULL` and raises [TypeError](#).

`char *PyBytes_AS_STRING(PyObject *string)`

Similar to [PyBytes\\_AsString\(\)](#), but without error checking.

`int PyBytes_AsStringAndSize(PyObject *obj, char **buffer, Py_ssize_t *length)`

*Part of the [Stable ABI](#).*

Return the null-terminated contents of the object *obj* through the output variables *buffer* and *length*.

If *length* is `NULL`, the bytes object may not contain embedded null bytes; if it does, the function returns `-1` and a [ValueError](#) is raised.

The buffer refers to an internal buffer of *obj*, which includes an additional null byte at the end (not counted in *length*). The data must not be modified in any way, unless the object was just created using `PyBytes_FromStringAndSize(NULL, size)`. It must not be deallocated. If *obj* is not a bytes object at all, `PyBytes_AsStringAndSize()` returns `-1` and raises `TypeError`.

*Changed in version 3.5:* Previously, `TypeError` was raised when embedded null bytes were encountered in the bytes object.

`void PyBytes_Concat(PyObject **bytes, PyObject *newpart)`

*Part of the [Stable ABI](#).*

Create a new bytes object in *\*bytes* containing the contents of *newpart* appended to *bytes*; the caller will own the new reference. The reference to the old value of *bytes* will be stolen. If the new object cannot be created, the old reference to *bytes* will still be discarded and the value of *\*bytes* will be set to `NULL`; the appropriate exception will be set.

`void PyBytes_ConcatAndDel(PyObject **bytes, PyObject *newpart)`

*Part of the [Stable ABI](#).*

Create a new bytes object in *\*bytes* containing the contents of *newpart* appended to *bytes*. This version decrements the reference count of *newpart*.

`int _PyBytes_Resize(PyObject **bytes, Py_ssize_t newsize)`

A way to resize a bytes object even though it is “immutable”. Only use this to build up a brand new bytes object; don’t use this if the bytes may already be known in other parts of the code. It is an error to call this function if the refcount on the input bytes object is not one. Pass the address of an existing bytes object as an lvalue (it may be written into), and the new size desired. On success, *\*bytes* holds the resized bytes object and `0` is returned; the address in *\*bytes* may differ from its input value. If the reallocation fails, the original bytes object at *\*bytes* is deallocated, *\*bytes* is set to `NULL`,

`MemoryError` is set, and `-1` is returned.

# Byte Array Objects

type PyByteArrayObject

This subtype of [PyObject](#) represents a Python bytearray object.

[PyTypeObject](#) PyByteArray\_Type

*Part of the [Stable ABI](#).*

This instance of [PyTypeObject](#) represents the Python bytearray type; it is the same object as [bytearray](#) in the Python layer.

## Type check macros

int PyByteArray\_Check([PyObject](#) \*o)

Return true if the object *o* is a bytearray object or an instance of a subtype of the bytearray type. This function always succeeds.

int PyByteArray\_CheckExact([PyObject](#) \*o)

Return true if the object *o* is a bytearray object, but not an instance of a subtype of the bytearray type. This function always succeeds.

## Direct API functions

[PyObject](#) \*PyByteArray\_FromObject([PyObject](#) \*o)

*Return value: New reference. Part of the [Stable ABI](#).*

Return a new bytearray object from any object, *o*, that implements the [buffer protocol](#).

[PyObject](#) \*PyByteArray\_FromStringAndSize(const char \*string,

`Py_ssize_t len)`

*Return value:* New reference. Part of the [Stable ABI](#).

Create a new bytearray object from *string* and its length, *len*.  
On failure, `NULL` is returned.

`PyObject *PyByteArray_Concat(PyObject *a, PyObject *b)`

*Return value:* New reference. Part of the [Stable ABI](#).

Concat bytearrays *a* and *b* and return a new bytearray with the result.

`Py_ssize_t PyByteArray_Size(PyObject *bytearray)`

*Part of the [Stable ABI](#).*

Return the size of *bytearray* after checking for a `NULL` pointer.

`char *PyByteArray_AsString(PyObject *bytearray)`

*Part of the [Stable ABI](#).*

Return the contents of *bytearray* as a char array after checking for a `NULL` pointer. The returned array always has an extra null byte appended.

`int PyByteArray_Resize(PyObject *bytearray, Py_ssize_t len)`

*Part of the [Stable ABI](#).*

Resize the internal buffer of *bytearray* to *len*.

## Macros

These macros trade safety for speed and they don't check pointers.

`char *PyByteArray_AS_STRING(PyObject *bytearray)`

Similar to [PyByteArray\\_AsString\(\)](#), but without error checking.

`Py_ssize_t PyByteArray_GET_SIZE(PyObject *bytearray)`

Similar to [PyByteArray\\_Size\(\)](#), but without error checking.

# Unicode Objects and Codecs

## Unicode Objects

Since the implementation of [PEP 393](https://peps.python.org/pep-0393/) [https://peps.python.org/pep-0393/] in Python 3.3, Unicode objects internally use a variety of representations, in order to allow handling the complete range of Unicode characters while staying memory efficient. There are special cases for strings where all code points are below 128, 256, or 65536; otherwise, code points must be below 1114112 (which is the full Unicode range).

`Py_UNICODE*` and UTF-8 representations are created on demand and cached in the Unicode object. The `Py_UNICODE*` representation is deprecated and inefficient.

Due to the transition between the old APIs and the new APIs, Unicode objects can internally be in two states depending on how they were created:

- “canonical” Unicode objects are all objects created by a non-deprecated Unicode API. They use the most efficient representation allowed by the implementation.
- “legacy” Unicode objects have been created through one of the deprecated APIs (typically `PyUnicode_FromUnicode()`) and only bear the `Py_UNICODE*` representation; you will have to call `PyUnicode_READY()` on them before calling any other API.

### Note

The “legacy” Unicode object will be removed in Python 3.12 with deprecated APIs. All Unicode objects will be “canonical” since then. See [PEP 623](https://peps.python.org/pep-0623/) [https://peps.python.org/pep-0623/] for more information.

## Unicode Type

These are the basic Unicode object types used for the Unicode implementation in Python:

type Py\_UCS4

type Py\_UCS2

type Py\_UCS1

*Part of the [Stable ABI](#).*

These types are typedefs for unsigned integer types wide enough to contain characters of 32 bits, 16 bits and 8 bits, respectively. When dealing with single Unicode characters, use [Py\\_UCS4](#).

*New in version 3.3.*

type Py\_UNICODE

This is a typedef of `wchar_t`, which is a 16-bit type or 32-bit type depending on the platform.

*Changed in version 3.3:* In previous versions, this was a 16-bit type or a 32-bit type depending on whether you selected a “narrow” or “wide” Unicode version of Python at build time.

type PyASCIIObject

type PyCompactUnicodeObject

type PyUnicodeObject

These subtypes of [PyObject](#) represent a Python Unicode object. In almost all cases, they shouldn’t be used directly, since all API functions that deal with Unicode objects take and return [PyObject](#) pointers.

*New in version 3.3.*

[PyTypeObject](#) PyUnicode\_Type

*Part of the [Stable ABI](#).*

This instance of [PyTypeObject](#) represents the Python Unicode type. It is exposed to Python code as `str`.

The following APIs are C macros and static inlined functions for fast checks and access to internal read-only data of Unicode objects:

`int PyUnicode_Check(PyObject *o)`

Return true if the object *o* is a Unicode object or an instance of a Unicode subtype. This function always succeeds.

`int PyUnicode_CheckExact(PyObject *o)`

Return true if the object *o* is a Unicode object, but not an instance of a subtype. This function always succeeds.

`int PyUnicode_READY(PyObject *o)`

Ensure the string object *o* is in the “canonical” representation. This is required before using any of the access macros described below.

Returns 0 on success and -1 with an exception set on failure, which in particular happens if memory allocation fails.

*New in version 3.3.*

*Deprecated since version 3.10, will be removed in version 3.12:*

This API will be removed with

`PyUnicode_FromUnicode()`.

`Py_ssize_t PyUnicode_GET_LENGTH(PyObject *o)`

Return the length of the Unicode string, in code points. *o* has to be a Unicode object in the “canonical” representation (not checked).

*New in version 3.3.*

`Py_UCS1 *PyUnicode_1BYTE_DATA(PyObject *o)`

`Py_UCS2 *PyUnicode_2BYTE_DATA(PyObject *o)`

`Py_UCS4 *PyUnicode_4BYTE_DATA(PyObject *o)`

Return a pointer to the canonical representation cast to UCS1, UCS2 or UCS4 integer types for direct character access. No

checks are performed if the canonical representation has the correct character size; use `PyUnicode_KIND()` to select the right macro. Make sure `PyUnicode_READY()` has been called before accessing this.

*New in version 3.3.*

`PyUnicode_WCHAR_KIND`

`PyUnicode_1BYTE_KIND`

`PyUnicode_2BYTE_KIND`

`PyUnicode_4BYTE_KIND`

Return values of the `PyUnicode_KIND()` macro.

*New in version 3.3.*

*Deprecated since version 3.10, will be removed in version 3.12:*

`PyUnicode_WCHAR_KIND` is deprecated.

`int PyUnicode_KIND(PyObject *o)`

Return one of the `PyUnicode` kind constants (see above) that indicate how many bytes per character this Unicode object uses to store its data. *o* has to be a Unicode object in the “canonical” representation (not checked).

*New in version 3.3.*

`void *PyUnicode_DATA(PyObject *o)`

Return a void pointer to the raw Unicode buffer. *o* has to be a Unicode object in the “canonical” representation (not checked).

*New in version 3.3.*

`void PyUnicode_WRITE(int kind, void *data, Py_ssize_t index, Py_UCS4 value)`

Write into a canonical representation *data* (as obtained with `PyUnicode_DATA()`). This function performs no sanity checks, and is intended for usage in loops. The caller should cache the *kind* value and *data* pointer as obtained from other

calls. *index* is the index in the string (starts at 0) and *value* is the new code point value which should be written to that location.

*New in version 3.3.*

**Py\_UCS4** PyUnicode\_READ(int kind, void \*data, **Py\_ssize\_t** index)

Read a code point from a canonical representation *data* (as obtained with **PyUnicode\_DATA()**). No checks or ready calls are performed.

*New in version 3.3.*

**Py\_UCS4** PyUnicode\_READ\_CHAR(PyObject \*o, **Py\_ssize\_t** index)

Read a character from a Unicode object *o*, which must be in the “canonical” representation. This is less efficient than **PyUnicode\_READ()** if you do multiple consecutive reads.

*New in version 3.3.*

**Py\_UCS4** PyUnicode\_MAX\_CHAR\_VALUE(PyObject \*o)

Return the maximum code point that is suitable for creating another string based on *o*, which must be in the “canonical” representation. This is always an approximation but more efficient than iterating over the string.

*New in version 3.3.*

**Py\_ssize\_t** PyUnicode\_GET\_SIZE(PyObject \*o)

Return the size of the deprecated **Py\_UNICODE** representation, in code units (this includes surrogate pairs as 2 units). *o* has to be a Unicode object (not checked).

*Deprecated since version 3.3, will be removed in version 3.12:*  
Part of the old-style Unicode API, please migrate to using **PyUnicode\_GET\_LENGTH()**.

**Py\_ssize\_t** PyUnicode\_GET\_DATA\_SIZE(PyObject \*o)

Return the size of the deprecated `Py_UNICODE` representation in bytes. `o` has to be a Unicode object (not checked).

*Deprecated since version 3.3, will be removed in version 3.12:*  
Part of the old-style Unicode API, please migrate to using `PyUnicode_GET_LENGTH()`.

```
Py_UNICODE *PyUnicode_AS_UNICODE(PyObject *o)
const char *PyUnicode_AS_DATA(PyObject *o)
```

Return a pointer to a `Py_UNICODE` representation of the object. The returned buffer is always terminated with an extra null code point. It may also contain embedded null code points, which would cause the string to be truncated when used in most C functions. The `AS_DATA` form casts the pointer to `const char*`. The `o` argument has to be a Unicode object (not checked).

*Changed in version 3.3:* This function is now inefficient – because in many cases the `Py_UNICODE` representation does not exist and needs to be created – and can fail (return `NULL` with an exception set). Try to port the code to use the new `PyUnicode_nBYTE_DATA()` macros or use `PyUnicode_WRITE()` or `PyUnicode_READ()`.

*Deprecated since version 3.3, will be removed in version 3.12:*  
Part of the old-style Unicode API, please migrate to using the `PyUnicode_nBYTE_DATA()` family of macros.

```
int PyUnicode_IsIdentifier(PyObject *o)
```

Part of the *Stable ABI*.

Return 1 if the string is a valid identifier according to the language definition, section [Identifiers and keywords](#). Return 0 otherwise.

*Changed in version 3.9:* The function does not call `Py_FatalError()` anymore if the string is not ready.

## Unicode Character Properties

Unicode provides many different character properties. The most often needed ones are available through these macros which are mapped to C functions depending on the Python configuration.

`int Py_UNICODE_ISSPACE(Py_UCS4 ch)`

Return 1 or 0 depending on whether *ch* is a whitespace character.

`int Py_UNICODE_ISLOWER(Py_UCS4 ch)`

Return 1 or 0 depending on whether *ch* is a lowercase character.

`int Py_UNICODE_ISUPPER(Py_UCS4 ch)`

Return 1 or 0 depending on whether *ch* is an uppercase character.

`int Py_UNICODE_ISTITLE(Py_UCS4 ch)`

Return 1 or 0 depending on whether *ch* is a titlecase character.

`int Py_UNICODE_ISLINEBREAK(Py_UCS4 ch)`

Return 1 or 0 depending on whether *ch* is a linebreak character.

`int Py_UNICODE_ISDECIMAL(Py_UCS4 ch)`

Return 1 or 0 depending on whether *ch* is a decimal character.

`int Py_UNICODE_ISDIGIT(Py_UCS4 ch)`

Return 1 or 0 depending on whether *ch* is a digit character.

`int Py_UNICODE_ISNUMERIC(Py_UCS4 ch)`

Return 1 or 0 depending on whether *ch* is a numeric character.

`int Py_UNICODE_ISALPHA(Py_UCS4 ch)`

Return 1 or 0 depending on whether *ch* is an alphabetic character.

`int Py_UNICODE_ISALNUM(Py_UCS4 ch)`

Return 1 or 0 depending on whether *ch* is an alphanumeric character.

`int Py_UNICODE_ISPRINTABLE(Py_UCS4 ch)`

Return 1 or 0 depending on whether *ch* is a printable character. Nonprintable characters are those characters defined in the Unicode character database as “Other” or “Separator”, excepting the ASCII space (0x20) which is considered printable. (Note that printable characters in this context are those which should not be escaped when `repr()` is invoked on a string. It has no bearing on the handling of strings written to `sys.stdout` or `sys.stderr`.)

These APIs can be used for fast direct character conversions:

`Py_UCS4 Py_UNICODE_TOLOWER(Py_UCS4 ch)`

Return the character *ch* converted to lower case.

*Deprecated since version 3.3:* This function uses simple case mappings.

`Py_UCS4 Py_UNICODE_Toupper(Py_UCS4 ch)`

Return the character *ch* converted to upper case.

*Deprecated since version 3.3:* This function uses simple case mappings.

`Py_UCS4 Py_UNICODE_TOTITLE(Py_UCS4 ch)`

Return the character *ch* converted to title case.

*Deprecated since version 3.3:* This function uses simple case mappings.

`int Py_UNICODE_TODECIMAL(Py_UCS4 ch)`

Return the character *ch* converted to a decimal positive integer. Return `-1` if this is not possible. This macro does not raise exceptions.

`int Py_UNICODE_TODIGIT(Py_UCS4 ch)`

Return the character *ch* converted to a single digit integer. Return `-1` if this is not possible. This macro does not raise exceptions.

`double Py_UNICODE_TONUMERIC(Py_UCS4 ch)`

Return the character *ch* converted to a double. Return `-1.0` if this is not possible. This macro does not raise exceptions.

These APIs can be used to work with surrogates:

`Py_UNICODE_IS_SURROGATE(ch)`

Check if *ch* is a surrogate (`0xD800 <= ch <= 0xDFFF`).

`Py_UNICODE_IS_HIGH_SURROGATE(ch)`

Check if *ch* is a high surrogate (`0xD800 <= ch <= 0xDBFF`).

`Py_UNICODE_IS_LOW_SURROGATE(ch)`

Check if *ch* is a low surrogate (`0xDC00 <= ch <= 0xDFFF`).

`Py_UNICODE_JOIN_SURROGATES(high, low)`

Join two surrogate characters and return a single `Py_UCS4` value. *high* and *low* are respectively the leading and trailing surrogates in a surrogate pair.

## Creating and accessing Unicode strings

To create Unicode objects and access their basic sequence properties, use these APIs:

**PyObject** \*PyUnicode\_New(Py\_ssize\_t size, Py\_UCS4 maxchar)

*Return value:* New reference.

Create a new Unicode object. *maxchar* should be the true maximum code point to be placed in the string. As an approximation, it can be rounded up to the nearest value in the sequence 127, 255, 65535, 1114111.

This is the recommended way to allocate a new Unicode object. Objects created using this function are not resizable.

*New in version 3.3.*

**PyObject** \*PyUnicode\_FromKindAndData(int kind, const void \*buffer, Py\_ssize\_t size)

*Return value:* New reference.

Create a new Unicode object with the given *kind* (possible values are **PyUnicode\_1BYTE\_KIND** etc., as returned by **PyUnicode\_KIND()**). The *buffer* must point to an array of size units of 1, 2 or 4 bytes per character, as given by the *kind*.

If necessary, the input *buffer* is copied and transformed into the canonical representation. For example, if the *buffer* is a UCS4 string (**PyUnicode\_4BYTE\_KIND**) and it consists only of codepoints in the UCS1 range, it will be transformed into UCS1 (**PyUnicode\_1BYTE\_KIND**).

*New in version 3.3.*

**PyObject** \*PyUnicode\_FromStringAndSize(const char \*u, Py\_ssize\_t size)

*Return value:* New reference. Part of the [Stable ABI](#).

Create a Unicode object from the char buffer *u*. The bytes will be interpreted as being UTF-8 encoded. The buffer is copied into the new object. If the buffer is not `NULL`, the return value might be a shared object, i.e. modification of the data is not allowed.

If *u* is `NULL`, this function behaves like

`PyUnicode_FromUnicode()` with the buffer set to `NULL`. This usage is deprecated in favor of `PyUnicode_New()`, and will be removed in Python 3.12.

`PyObject *``PyUnicode_FromString(const char *u)`

*Return value:* New reference. Part of the [Stable ABI](#).

Create a Unicode object from a UTF-8 encoded null-terminated char buffer *u*.

`PyObject *``PyUnicode_FromFormat(const char *format, ...)`

*Return value:* New reference. Part of the [Stable ABI](#).

Take a C `printf()`-style *format* string and a variable number of arguments, calculate the size of the resulting Python Unicode string and return a string with the values formatted into it. The variable arguments must be C types and must correspond exactly to the format characters in the *format* ASCII-encoded string. The following format characters are allowed:

### Format Characters

The literal % character.

A single character, represented as a C int.

Equivalent to `printf("%d")`. [1](#)

Equivalent to `printf("%u")`. [1](#)

Equivalent to `printf("%ld")`. [1](#)

Equivalent to `printf("%li")`. [1](#)

Equivalent to `printf("%lu")`. [1](#)

Equivalent to `printf("%lld")`. [1](#)

Equivalent to `printf("%lli")`. [1](#)

Equivalent to `printf("%llu")`. [1](#)

Equivalent to `printf("%zd")`. [1](#)

Equivalent to `printf("%zi")`. [1](#)

Equivalent to `printf("%zu")`. [1](#)

Equivalent to `printf("%i")`. [1](#)

Equivalent to `printf("%x")`. [1](#)

A null-terminated C character array.

The void representation of a C pointer. Mostly equivalent to `printf("%p")` except that it is guaranteed to start with the literal `0x` regardless of what the platform's `printf`

yields.

**The result** of calling `ascii()`.

---

**PyObject** object.

---

**PyObject**, object (which may be `NULL`) and a null-terminated C character array as a second parameter (which will be used, if the first parameter is `NULL`).

---

**The result** of calling `PyObject_Str()`.

---

**The result** of calling `PyObject_Repr()`.

---

An unrecognized format character causes all the rest of the format string to be copied as-is to the result string, and any extra arguments discarded.

### Note

The width formatter unit is number of characters rather than bytes. The precision formatter unit is number of bytes for `"%s"` and `"%V"` (if the `PyObject*` argument is `NULL`), and a number of characters for `"%A"`, `"%U"`, `"%S"`, `"%R"` and `"%V"` (if the `PyObject*` argument is not `NULL`).

1([1](#),[2](#),[3](#),[4](#),[5](#),[6](#),[7](#),[8](#),[9](#),[10](#),[11](#),[12](#),[13](#))

For integer specifiers (`d`, `u`, `ld`, `li`, `lu`, `lld`, `lli`, `llu`, `zd`, `zi`, `zu`, `i`, `x`): the 0-conversion flag has effect even when a precision is given.

*Changed in version 3.2:* Support for `"%lld"` and `"%llu"` added.

*Changed in version 3.3:* Support for `"%li"`, `"%lli"` and `"%zi"` added.

*Changed in version 3.4:* Support width and precision formatter for `"%s"`, `"%A"`, `"%U"`, `"%V"`, `"%S"`, `"%R"` added.

`PyObject *``PyUnicode_FromFormatV(const char *format, va_list  
vargs)`

*Return value:* New reference. Part of the [Stable ABI](#).

Identical to `PyUnicode_FromFormat()` except that it takes exactly two arguments.

`PyObject *PyUnicode_FromObject(PyObject *obj)`

*Return value:* New reference. Part of the [Stable ABI](#).

Copy an instance of a Unicode subtype to a new true Unicode object if necessary. If *obj* is already a true Unicode object (not a subtype), return the reference with incremented refcount.

Objects other than Unicode or its subtypes will cause a **`TypeError`**.

`PyObject *PyUnicode_FromEncodedObject(PyObject *obj, const char *encoding, const char *errors)`

*Return value:* New reference. Part of the [Stable ABI](#).

Decode an encoded object *obj* to a Unicode object.

**`bytes`**, **`bytearray`** and other **bytes-like objects** are decoded according to the given *encoding* and using the error handling defined by *errors*. Both can be `NULL` to have the interface use the default values (see [Built-in Codecs](#) for details).

All other objects, including Unicode objects, cause a **`TypeError`** to be set.

The API returns `NULL` if there was an error. The caller is responsible for decref'ing the returned objects.

`Py_ssize_t PyUnicode_GetLength(PyObject *unicode)`

*Part of the [Stable ABI](#) since version 3.7.*

Return the length of the Unicode object, in code points.

*New in version 3.3.*

`Py_ssize_t PyUnicode_CopyCharacters(PyObject *to, Py_ssize_t to_start, PyObject *from, Py_ssize_t from_start, Py_ssize_t how_many)`

Copy characters from one Unicode object into another. This function performs character conversion when necessary and

falls back to `memcpy()` if possible. Returns `-1` and sets an exception on error, otherwise returns the number of copied characters.

*New in version 3.3.*

`Py_ssize_t` PyUnicode\_Fill(`PyObject` \*unicode, `Py_ssize_t` start, `Py_ssize_t` length, `Py_UCS4` fill\_char)

Fill a string with a character: write *fill\_char* into `unicode[start:start+length]`.

Fail if *fill\_char* is bigger than the string maximum character, or if the string has more than 1 reference.

Return the number of written character, or return `-1` and raise an exception on error.

*New in version 3.3.*

`int` PyUnicode\_WriteChar(`PyObject` \*unicode, `Py_ssize_t` index, `Py_UCS4` character)

*Part of the [Stable ABI](#) since version 3.7.*

Write a character to a string. The string must have been created through `PyUnicode_New()`. Since Unicode strings are supposed to be immutable, the string must not be shared, or have been hashed yet.

This function checks that *unicode* is a Unicode object, that the index is not out of bounds, and that the object can be modified safely (i.e. that its reference count is one).

*New in version 3.3.*

`Py_UCS4` PyUnicode\_ReadChar(`PyObject` \*unicode, `Py_ssize_t` index)

*Part of the [Stable ABI](#) since version 3.7.*

Read a character from a string. This function checks that *unicode* is a Unicode object and the index is not out of bounds, in contrast to `PyUnicode_READ_CHAR()`, which performs no error checking.

*New in version 3.3.*

`PyObject *PyUnicode_Substring(PyObject *str, Py_ssize_t start, Py_ssize_t end)`

*Return value:* New reference. Part of the [Stable ABI](#) since version 3.7.

Return a substring of *str*, from character index *start* (included) to character index *end* (excluded). Negative indices are not supported.

*New in version 3.3.*

`Py_UCS4 *PyUnicode_AsUCS4(PyObject *u, Py_UCS4 *buffer, Py_ssize_t buflen, int copy_null)`

*Part of the [Stable ABI](#) since version 3.7.*

Copy the string *u* into a UCS4 buffer, including a null character, if *copy\_null* is set. Returns `NULL` and sets an exception on error (in particular, a [SystemError](#) if *buflen* is smaller than the length of *u*). *buffer* is returned on success.

*New in version 3.3.*

`Py_UCS4 *PyUnicode_AsUCS4Copy(PyObject *u)`

*Part of the [Stable ABI](#) since version 3.7.*

Copy the string *u* into a new UCS4 buffer that is allocated using `PyMem_Malloc()`. If this fails, `NULL` is returned with a [MemoryError](#) set. The returned buffer always has an extra null code point appended.

*New in version 3.3.*

## Deprecated Py\_UNICODE APIs

*Deprecated since version 3.3, will be removed in version 3.12.*

These API functions are deprecated with the implementation of [PEP 393](#) [<https://peps.python.org/pep-0393/>]. Extension modules can continue using them, as they will not be removed in Python 3.x, but need to

be aware that their use can now cause performance and memory hits.

`PyObject *PyUnicode_FromUnicode(const Py_UNICODE *u,  
Py_ssize_t size)`

*Return value:* New reference.

Create a Unicode object from the `Py_UNICODE` buffer `u` of the given size. `u` may be `NULL` which causes the contents to be undefined. It is the user's responsibility to fill in the needed data. The buffer is copied into the new object.

If the buffer is not `NULL`, the return value might be a shared object. Therefore, modification of the resulting Unicode object is only allowed when `u` is `NULL`.

If the buffer is `NULL`, `PyUnicode_READY()` must be called once the string content has been filled before using any of the access macros such as `PyUnicode_KIND()`.

*Deprecated since version 3.3, will be removed in version 3.12:*  
Part of the old-style Unicode API, please migrate to using `PyUnicode_FromKindAndData()`, `PyUnicode_FromWideChar()`, or `PyUnicode_New()`.

`Py_UNICODE *PyUnicode_AsUnicode(PyObject *unicode)`

Return a read-only pointer to the Unicode object's internal `Py_UNICODE` buffer, or `NULL` on error. This will create the `Py_UNICODE*` representation of the object if it is not yet available. The buffer is always terminated with an extra null code point. Note that the resulting `Py_UNICODE` string may also contain embedded null code points, which would cause the string to be truncated when used in most C functions.

*Deprecated since version 3.3, will be removed in version 3.12:*  
Part of the old-style Unicode API, please migrate to using `PyUnicode_AsUCS4()`, `PyUnicode_AsWideChar()`, `PyUnicode_ReadChar()` or similar new APIs.

`Py_UNICODE *PyUnicode_AsUnicodeAndSize(PyObject *unicode,`

`Py_ssize_t *size)`

Like `PyUnicode_AsUnicode()`, but also saves the `Py_UNICODE()` array length (excluding the extra null terminator) in `size`. Note that the resulting `Py_UNICODE*` string may contain embedded null code points, which would cause the string to be truncated when used in most C functions.

*New in version 3.3.*

*Deprecated since version 3.3, will be removed in version 3.12:* Part of the old-style Unicode API, please migrate to using `PyUnicode_AsUCS4()`, `PyUnicode_AsWideChar()`, `PyUnicode_ReadChar()` or similar new APIs.

`Py_ssize_t PyUnicode_GetSize(PyObject *unicode)`

*Part of the [Stable ABI](#).*

Return the size of the deprecated `Py_UNICODE` representation, in code units (this includes surrogate pairs as 2 units).

*Deprecated since version 3.3, will be removed in version 3.12:* Part of the old-style Unicode API, please migrate to using `PyUnicode_GET_LENGTH()`.

## Locale Encoding

The current locale encoding can be used to decode text from the operating system.

`PyObject *PyUnicode_DecodeLocaleAndSize(const char *str,  
Py_ssize_t len, const char *errors)`

*Return value: New reference. Part of the [Stable ABI](#) since version 3.7.*

Decode a string from UTF-8 on Android and VxWorks, or from the current locale encoding on other platforms. The supported error handlers are "strict" and "surrogateescape" ([PEP 383](#) [<https://peps.python.org/pep-0383/>]). The decoder uses "strict" error handler if

`errors` is `NULL`. `str` must end with a null character but cannot contain embedded null characters.

Use `PyUnicode_DecodeFSDefaultAndSize()` to decode a string from `Py_FileSystemDefaultEncoding` (the locale encoding read at Python startup).

This function ignores the [Python UTF-8 Mode](#).

### See also

The `Py_DecodeLocale()` function.

*New in version 3.3.*

*Changed in version 3.7:* The function now also uses the current locale encoding for the `surrogateescape` error handler, except on Android. Previously, `Py_DecodeLocale()` was used for the `surrogateescape`, and the current locale encoding was used for `strict`.

**PyObject\*** `PyUnicode_DecodeLocale(const char *str, const char *errors)`

*Return value:* New reference. Part of the [Stable ABI](#) since version 3.7.

Similar to `PyUnicode_DecodeLocaleAndSize()`, but compute the string length using `strlen()`.

*New in version 3.3.*

**PyObject\*** `PyUnicode_EncodeLocale(PyObject *unicode, const char *errors)`

*Return value:* New reference. Part of the [Stable ABI](#) since version 3.7.

Encode a Unicode object to UTF-8 on Android and VxWorks, or to the current locale encoding on other platforms. The supported error handlers are `"strict"` and `"surrogateescape"` ([PEP 383](#) [<https://peps.python.org/pep-0383/>]). The encoder uses `"strict"` error handler if

`errors` is `NULL`. Return a **bytes** object. `unicode` cannot contain embedded null characters.

Use **`PyUnicode_EncodeFSDefault()`** to encode a string to **`Py_FileSystemDefaultEncoding`** (the locale encoding read at Python startup).

This function ignores the **`Python UTF-8 Mode`**.

### See also

The **`Py_EncodeLocale()`** function.

*New in version 3.3.*

*Changed in version 3.7:* The function now also uses the current locale encoding for the `surrogateescape` error handler, except on Android. Previously, **`Py_EncodeLocale()`** was used for the `surrogateescape`, and the current locale encoding was used for `strict`.

## File System Encoding

To encode and decode file names and other environment strings, **`Py_FileSystemDefaultEncoding`** should be used as the encoding, and **`Py_FileSystemDefaultEncodeErrors`** should be used as the error handler (**`PEP 383`** [<https://peps.python.org/pep-0383/>] and **`PEP 529`** [<https://peps.python.org/pep-0529/>]). To encode file names to **bytes** during argument parsing, the `"O&"` converter should be used, passing **`PyUnicode_FSConverter()`** as the conversion function:

```
int PyUnicode_FSConverter(PyObject *obj, void *result)
```

*Part of the **`Stable ABI`**.*

ParseTuple converter: encode **str** objects – obtained directly or through the **`os.PathLike`** interface – to **bytes** using **`PyUnicode_EncodeFSDefault()`**; **bytes** objects are output as-is. *result* must be a **`PyBytesObject*`** which must be released when it is no longer used.

*New in version 3.1.*

*Changed in version 3.6:* Accepts a [path-like object](#).

To decode file names to [str](#) during argument parsing, the "O&" converter should be used, passing [PyUnicode\\_FSDecoder\(\)](#) as the conversion function:

```
int PyUnicode_FSDecoder(PyObject *obj, void *result)
```

*Part of the [Stable ABI](#).*

ParseTuple converter: decode [bytes](#) objects – obtained either directly or indirectly through the [os.PathLike](#) interface – to [str](#) using [PyUnicode\\_DecodeFSDefaultAndSize\(\)](#); [str](#) objects are output as-is. *result* must be a [PyUnicodeObject](#)\* which must be released when it is no longer used.

*New in version 3.2.*

*Changed in version 3.6:* Accepts a [path-like object](#).

```
PyObject *PyUnicode_DecodeFSDefaultAndSize(const char *s,  
Py\_ssize\_t size)
```

*Return value:* New reference. *Part of the [Stable ABI](#).*

Decode a string from the [filesystem encoding and error handler](#).

If [Py\\_FileSystemDefaultEncoding](#) is not set, fall back to the locale encoding.

[Py\\_FileSystemDefaultEncoding](#) is initialized at startup from the locale encoding and cannot be modified later. If you need to decode a string from the current locale encoding, use [PyUnicode\\_DecodeLocaleAndSize\(\)](#).

**See also**

The [Py\\_DecodeLocale\(\)](#) function.

*Changed in version 3.6:* Use

**Py\_FileSystemDefaultEncodeErrors** error handler.

**PyObject \***PyUnicode\_DecodeFSDefault(const char \*s)

*Return value:* New reference. Part of the [Stable ABI](#).

Decode a null-terminated string from the [filesystem encoding and error handler](#).

If **Py\_FileSystemDefaultEncoding** is not set, fall back to the locale encoding.

Use **PyUnicode\_DecodeFSDefaultAndSize()** if you know the string length.

*Changed in version 3.6:* Use

**Py\_FileSystemDefaultEncodeErrors** error handler.

**PyObject \***PyUnicode\_EncodeFSDefault(PyObject \*unicode)

*Return value:* New reference. Part of the [Stable ABI](#).

Encode a Unicode object to

**Py\_FileSystemDefaultEncoding** with the

**Py\_FileSystemDefaultEncodeErrors** error handler, and return [bytes](#). Note that the resulting [bytes](#) object may contain null bytes.

If **Py\_FileSystemDefaultEncoding** is not set, fall back to the locale encoding.

**Py\_FileSystemDefaultEncoding** is initialized at startup from the locale encoding and cannot be modified later. If you need to encode a string to the current locale encoding, use **PyUnicode\_EncodeLocale()**.

**See also**

The **Py\_EncodeLocale()** function.

*New in version 3.2.*

*Changed in version 3.6:* Use

**Py\_FileSystemDefaultEncodeErrors** error handler.

## wchar\_t Support

wchar\_t support for platforms which support it:

`PyObject *`PyUnicode\_FromWideChar(const wchar\_t \*w, `Py_ssize_t` size)

*Return value: New reference. Part of the [Stable ABI](#).*

Create a Unicode object from the wchar\_t buffer w of the given size. Passing -1 as the size indicates that the function must itself compute the length, using wcslen. Return NULL on failure.

`Py_ssize_t` PyUnicode\_AsWideChar(`PyObject *`unicode, wchar\_t \*w, `Py_ssize_t` size)

*Part of the [Stable ABI](#).*

Copy the Unicode object contents into the wchar\_t buffer w. At most size wchar\_t characters are copied (excluding a possibly trailing null termination character). Return the number of wchar\_t characters copied or -1 in case of an error. Note that the resulting wchar\_t\* string may or may not be null-terminated. It is the responsibility of the caller to make sure that the wchar\_t\* string is null-terminated in case this is required by the application. Also, note that the wchar\_t\* string might contain null characters, which would cause the string to be truncated when used with most C functions.

wchar\_t \*PyUnicode\_AsWideCharString(`PyObject *`unicode, `Py_ssize_t` \*size)

*Part of the [Stable ABI](#) since version 3.7.*

Convert the Unicode object to a wide character string. The output string always ends with a null character. If size is not NULL, write the number of wide characters (excluding the trailing null termination character) into \*size. Note that the resulting wchar\_t string might contain null characters, which would cause the string to be truncated when used with most C functions. If size is NULL and the wchar\_t\* string contains null characters a `ValueError` is raised.

Returns a buffer allocated by `PyMem_Alloc()` (use `PyMem_Free()` to free it) on success. On error, returns `NULL` and `*size` is undefined. Raises a `MemoryError` if memory allocation is failed.

*New in version 3.2.*

*Changed in version 3.7:* Raises a `ValueError` if `size` is `NULL` and the `wchar_t*` string contains null characters.

## Built-in Codecs

Python provides a set of built-in codecs which are written in C for speed. All of these codecs are directly usable via the following functions.

Many of the following APIs take two arguments encoding and errors, and they have the same semantics as the ones of the built-in `str()` string object constructor.

Setting encoding to `NULL` causes the default encoding to be used which is UTF-8. The file system calls should use `PyUnicode_FSConverter()` for encoding file names. This uses the variable `Py_FileSystemDefaultEncoding` internally. This variable should be treated as read-only: on some systems, it will be a pointer to a static string, on others, it will change at run-time (such as when the application invokes `setlocale`).

Error handling is set by errors which may also be set to `NULL` meaning to use the default handling defined for the codec. Default error handling for all built-in codecs is “strict” (`ValueError` is raised).

The codecs all use a similar interface. Only deviations from the following generic ones are documented for simplicity.

## Generic Codecs

These are the generic codec APIs:

**PyObject \***PyUnicode\_Decode(const char \*s, **Py\_ssize\_t** size, const char \*encoding, const char \*errors)

*Return value:* New reference. Part of the [Stable ABI](#).

Create a Unicode object by decoding *size* bytes of the encoded string *s*. *encoding* and *errors* have the same meaning as the parameters of the same name in the [str\(\)](#) built-in function. The codec to be used is looked up using the Python codec registry. Return `NULL` if an exception was raised by the codec.

**PyObject \***PyUnicode\_AsEncodedString(**PyObject \***unicode, const char \*encoding, const char \*errors)

*Return value:* New reference. Part of the [Stable ABI](#).

Encode a Unicode object and return the result as Python bytes object. *encoding* and *errors* have the same meaning as the parameters of the same name in the Unicode [encode\(\)](#) method. The codec to be used is looked up using the Python codec registry. Return `NULL` if an exception was raised by the codec.

## UTF-8 Codecs

These are the UTF-8 codec APIs:

**PyObject \***PyUnicode\_DecodeUTF8(const char \*s, **Py\_ssize\_t** size, const char \*errors)

*Return value:* New reference. Part of the [Stable ABI](#).

Create a Unicode object by decoding *size* bytes of the UTF-8 encoded string *s*. Return `NULL` if an exception was raised by the codec.

**PyObject \***PyUnicode\_DecodeUTF8Stateful(const char \*s, **Py\_ssize\_t** size, const char \*errors, **Py\_ssize\_t** \*consumed)

*Return value:* New reference. Part of the [Stable ABI](#).

If *consumed* is `NULL`, behave like

[PyUnicode\\_DecodeUTF8\(\)](#). If *consumed* is not `NULL`, trailing incomplete UTF-8 byte sequences will not be treated

as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in *consumed*.

`PyObject *PyUnicode_AsUTF8String(PyObject *unicode)`

*Return value:* New reference. Part of the [Stable ABI](#).

Encode a Unicode object using UTF-8 and return the result as Python bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

`const char *PyUnicode_AsUTF8AndSize(PyObject *unicode,  
Py_ssize_t *size)`

*Part of the [Stable ABI](#) since version 3.10.*

Return a pointer to the UTF-8 encoding of the Unicode object, and store the size of the encoded representation (in bytes) in *size*. The *size* argument can be `NULL`; in this case no size will be stored. The returned buffer always has an extra null byte appended (not included in *size*), regardless of whether there are any other null code points.

In the case of an error, `NULL` is returned with an exception set and no *size* is stored.

This caches the UTF-8 representation of the string in the Unicode object, and subsequent calls will return a pointer to the same buffer. The caller is not responsible for deallocating the buffer. The buffer is deallocated and pointers to it become invalid when the Unicode object is garbage collected.

*New in version 3.3.*

*Changed in version 3.7:* The return type is now `const char *` rather of `char *`.

*Changed in version 3.10:* This function is a part of the [limited API](#).

`const char *PyUnicode_AsUTF8(PyObject *unicode)`

As `PyUnicode_AsUTF8AndSize()`, but does not store the size.

*New in version 3.3.*

*Changed in version 3.7:* The return type is now `const char *` rather of `char *`.

## UTF-32 Codecs

These are the UTF-32 codec APIs:

**PyObject** \*PyUnicode\_DecodeUTF32(const char \*s, **Py\_ssize\_t** size, const char \*errors, int \*byteorder)

*Return value:* New reference. Part of the [Stable ABI](#).

Decode *size* bytes from a UTF-32 encoded buffer string and return the corresponding Unicode object. *errors* (if non-NULL) defines the error handling. It defaults to “strict”.

If *byteorder* is non-NULL, the decoder starts decoding using the given byte order:

```
*byteorder == -1: little endian
*byteorder == 0:  native order
*byteorder == 1:  big endian
```

If *\*byteorder* is zero, and the first four bytes of the input data are a byte order mark (BOM), the decoder switches to this byte order and the BOM is not copied into the resulting Unicode string. If *\*byteorder* is `-1` or `1`, any byte order mark is copied to the output.

After completion, *\*byteorder* is set to the current byte order at the end of input data.

If *byteorder* is `NULL`, the codec starts in native order mode.

Return `NULL` if an exception was raised by the codec.

**PyObject** \*PyUnicode\_DecodeUTF32Stateful(const char \*s, **Py\_ssize\_t** size, const char \*errors, int \*byteorder, **Py\_ssize\_t** \*consumed)

*Return value:* New reference. Part of the [Stable ABI](#).

If *consumed* is `NULL`, behave like

`PyUnicode_DecodeUTF32()`. If *consumed* is not `NULL`, `PyUnicode_DecodeUTF32Stateful()` will not treat trailing incomplete UTF-32 byte sequences (such as a number of bytes not divisible by four) as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in *consumed*.

**PyObject \***`PyUnicode_AsUTF32String(PyObject *unicode)`

*Return value:* New reference. Part of the [Stable ABI](#).

Return a Python byte string using the UTF-32 encoding in native byte order. The string always starts with a BOM mark. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

## UTF-16 Codecs

These are the UTF-16 codec APIs:

**PyObject \***`PyUnicode_DecodeUTF16(const char *s, Py_ssize_t size, const char *errors, int *byteorder)`

*Return value:* New reference. Part of the [Stable ABI](#).

Decode *size* bytes from a UTF-16 encoded buffer string and return the corresponding Unicode object. *errors* (if non-`NULL`) defines the error handling. It defaults to “strict”.

If *byteorder* is non-`NULL`, the decoder starts decoding using the given byte order:

```
*byteorder == -1: little endian
*byteorder == 0:  native order
*byteorder == 1:  big endian
```

If *\*byteorder* is zero, and the first two bytes of the input data are a byte order mark (BOM), the decoder switches to this byte order and the BOM is not copied into the resulting Unicode string. If *\*byteorder* is `-1` or `1`, any byte order mark is copied to the output (where it will result in either a

`\ufeff` or a `\ufffe` character).

After completion, `*byteorder` is set to the current byte order at the end of input data.

If `byteorder` is `NULL`, the codec starts in native order mode.

Return `NULL` if an exception was raised by the codec.

**PyObject** \*PyUnicode\_DecodeUTF16Stateful(const char \*s, Py\_ssize\_t size, const char \*errors, int \*byteorder, Py\_ssize\_t \*consumed)

*Return value: New reference. Part of the [Stable ABI](#).*

If `consumed` is `NULL`, behave like

**PyUnicode\_DecodeUTF16()**. If `consumed` is not `NULL`, **PyUnicode\_DecodeUTF16Stateful()** will not treat trailing incomplete UTF-16 byte sequences (such as an odd number of bytes or a split surrogate pair) as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in `consumed`.

**PyObject** \*PyUnicode\_AsUTF16String(PyObject \*unicode)

*Return value: New reference. Part of the [Stable ABI](#).*

Return a Python byte string using the UTF-16 encoding in native byte order. The string always starts with a BOM mark. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

## UTF-7 Codecs

These are the UTF-7 codec APIs:

**PyObject** \*PyUnicode\_DecodeUTF7(const char \*s, Py\_ssize\_t size, const char \*errors)

*Return value: New reference. Part of the [Stable ABI](#).*

Create a Unicode object by decoding `size` bytes of the UTF-7 encoded string `s`. Return `NULL` if an exception was raised by the codec.

`PyObject *`PyUnicode\_DecodeUTF7Stateful(const char \*s, `Py_ssize_t` size, const char \*errors, `Py_ssize_t` \*consumed)

*Return value:* New reference. Part of the [Stable ABI](#).

If *consumed* is `NULL`, behave like

`PyUnicode_DecodeUTF7()`. If *consumed* is not `NULL`, trailing incomplete UTF-7 base-64 sections will not be treated as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in *consumed*.

## Unicode-Escape Codecs

These are the “Unicode Escape” codec APIs:

`PyObject *`PyUnicode\_DecodeUnicodeEscape(const char \*s, `Py_ssize_t` size, const char \*errors)

*Return value:* New reference. Part of the [Stable ABI](#).

Create a Unicode object by decoding *size* bytes of the Unicode-Escape encoded string *s*. Return `NULL` if an exception was raised by the codec.

`PyObject *`PyUnicode\_AsUnicodeEscapeString(`PyObject *`unicode)

*Return value:* New reference. Part of the [Stable ABI](#).

Encode a Unicode object using Unicode-Escape and return the result as a bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

## Raw-Unicode-Escape Codecs

These are the “Raw Unicode Escape” codec APIs:

`PyObject *`PyUnicode\_DecodeRawUnicodeEscape(const char \*s, `Py_ssize_t` size, const char \*errors)

*Return value:* New reference. Part of the [Stable ABI](#).

Create a Unicode object by decoding *size* bytes of the Raw-Unicode-Escape encoded string *s*. Return `NULL` if an exception was raised by the codec.

**PyObject** \*PyUnicode\_AsRawUnicodeEscapeString(**PyObject** \*unicode)

*Return value:* New reference. Part of the [Stable ABI](#).

Encode a Unicode object using Raw-Unicode-Escape and return the result as a bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

## Latin-1 Codecs

These are the Latin-1 codec APIs: Latin-1 corresponds to the first 256 Unicode ordinals and only these are accepted by the codecs during encoding.

**PyObject** \*PyUnicode\_DecodeLatin1(const char \*s, **Py\_ssize\_t** size, const char \*errors)

*Return value:* New reference. Part of the [Stable ABI](#).

Create a Unicode object by decoding *size* bytes of the Latin-1 encoded string *s*. Return `NULL` if an exception was raised by the codec.

**PyObject** \*PyUnicode\_AsLatin1String(**PyObject** \*unicode)

*Return value:* New reference. Part of the [Stable ABI](#).

Encode a Unicode object using Latin-1 and return the result as Python bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

## ASCII Codecs

These are the ASCII codec APIs. Only 7-bit ASCII data is accepted. All other codes generate errors.

**PyObject** \*PyUnicode\_DecodeASCII(const char \*s, **Py\_ssize\_t** size, const char \*errors)

*Return value:* New reference. Part of the [Stable ABI](#).

Create a Unicode object by decoding *size* bytes of the ASCII encoded string *s*. Return `NULL` if an exception was raised by the codec.

`PyObject *PyUnicode_AsASCIIString(PyObject *unicode)`

*Return value:* New reference. Part of the [Stable ABI](#).

Encode a Unicode object using ASCII and return the result as Python bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

## Character Map Codecs

This codec is special in that it can be used to implement many different codecs (and this is in fact what was done to obtain most of the standard codecs included in the **encodings** package). The codec uses mappings to encode and decode characters. The mapping objects provided must support the `__getitem__()` mapping interface; dictionaries and sequences work well.

These are the mapping codec APIs:

`PyObject *PyUnicode_DecodeCharmap(const char *data, Py_ssize_t size, PyObject *mapping, const char *errors)`

*Return value:* New reference. Part of the [Stable ABI](#).

Create a Unicode object by decoding *size* bytes of the encoded string *s* using the given *mapping* object. Return `NULL` if an exception was raised by the codec.

If *mapping* is `NULL`, Latin-1 decoding will be applied. Else *mapping* must map bytes ordinals (integers in the range from 0 to 255) to Unicode strings, integers (which are then interpreted as Unicode ordinals) or `None`. Unmapped data bytes – ones which cause a **LookupError**, as well as ones which get mapped to `None`, `0xFFFE` or `'\ufffe'`, are treated as undefined mappings and cause an error.

`PyObject *PyUnicode_AsCharmapString(PyObject *unicode, PyObject *mapping)`

*Return value:* New reference. Part of the [Stable ABI](#).

Encode a Unicode object using the given *mapping* object and return the result as a bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

The *mapping* object must map Unicode ordinal integers to bytes objects, integers in the range from 0 to 255 or `None`. Unmapped character ordinals (ones which cause a `LookupError`) as well as mapped to `None` are treated as “undefined mapping” and cause an error.

The following codec API is special in that maps Unicode to Unicode.

```
PyObject *PyUnicode_Translate(PyObject *str, PyObject *table,  
const char *errors)
```

*Return value:* New reference. Part of the *Stable ABI*.

Translate a string by applying a character mapping table to it and return the resulting Unicode object. Return `NULL` if an exception was raised by the codec.

The mapping table must map Unicode ordinal integers to Unicode ordinal integers or `None` (causing deletion of the character).

Mapping tables need only provide the `__getitem__()` interface; dictionaries and sequences work well. Unmapped character ordinals (ones which cause a `LookupError`) are left untouched and are copied as-is.

*errors* has the usual meaning for codecs. It may be `NULL` which indicates to use the default error handling.

## MBCS codecs for Windows

These are the MBCS codec APIs. They are currently only available on Windows and use the Win32 MBCS converters to implement the conversions. Note that MBCS (or DBCS) is a class of encodings, not just one. The target encoding is defined by the user settings on the machine running the codec.

```
PyObject *PyUnicode_DecompileMBCS(const char *s, Py_ssize_t size,  
const char *errors)
```

*Return value:* New reference. Part of the *Stable ABI* on Windows since version 3.7.

Create a Unicode object by decoding *size* bytes of the MBCS encoded string *s*. Return `NULL` if an exception was raised by the codec.

**PyObject** \*PyUnicode\_DecodeMBCSStateful(const char \*s, Py\_ssize\_t size, const char \*errors, Py\_ssize\_t \*consumed)

*Return value:* New reference. Part of the [Stable ABI](#) on Windows since version 3.7.

If *consumed* is `NULL`, behave like

**PyUnicode\_DecodeMBCS()**. If *consumed* is not `NULL`, **PyUnicode\_DecodeMBCSStateful()** will not decode trailing lead byte and the number of bytes that have been decoded will be stored in *consumed*.

**PyObject** \*PyUnicode\_AsMBCSString(**PyObject** \*unicode)

*Return value:* New reference. Part of the [Stable ABI](#) on Windows since version 3.7.

Encode a Unicode object using MBCS and return the result as Python bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

**PyObject** \*PyUnicode\_EncodeCodePage(int code\_page, **PyObject** \*unicode, const char \*errors)

*Return value:* New reference. Part of the [Stable ABI](#) on Windows since version 3.7.

Encode the Unicode object using the specified code page and return a Python bytes object. Return `NULL` if an exception was raised by the codec. Use **CP\_ACP** code page to get the MBCS encoder.

*New in version 3.3.*

## Methods & Slots

## Methods and Slot Functions

The following APIs are capable of handling Unicode objects and

strings on input (we refer to them as strings in the descriptions) and return Unicode objects or integers as appropriate.

They all return `NULL` or `-1` if an exception occurs.

`PyObject *PyUnicode_Concat(PyObject *left, PyObject *right)`

*Return value:* New reference. Part of the [Stable ABI](#).

Concat two strings giving a new Unicode string.

`PyObject *PyUnicode_Split(PyObject *s, PyObject *sep, Py_ssize_t maxsplit)`

*Return value:* New reference. Part of the [Stable ABI](#).

Split a string giving a list of Unicode strings. If *sep* is `NULL`, splitting will be done at all whitespace substrings. Otherwise, splits occur at the given separator. At most *maxsplit* splits will be done. If negative, no limit is set. Separators are not included in the resulting list.

`PyObject *PyUnicode_Splitlines(PyObject *s, int keepend)`

*Return value:* New reference. Part of the [Stable ABI](#).

Split a Unicode string at line breaks, returning a list of Unicode strings. CRLF is considered to be one line break. If *keepend* is `0`, the line break characters are not included in the resulting strings.

`PyObject *PyUnicode_Join(PyObject *separator, PyObject *seq)`

*Return value:* New reference. Part of the [Stable ABI](#).

Join a sequence of strings using the given *separator* and return the resulting Unicode string.

`Py_ssize_t PyUnicode_Tailmatch(PyObject *str, PyObject *substr, Py_ssize_t start, Py_ssize_t end, int direction)`

*Part of the [Stable ABI](#).*

Return `1` if *substr* matches `str[start:end]` at the given tail end (*direction* == `-1` means to do a prefix match, *direction* == `1` a suffix match), `0` otherwise. Return `-1` if an error occurred.

`Py_ssize_t PyUnicode_Find(PyObject *str, PyObject *substr,  
Py_ssize_t start, Py_ssize_t end, int direction)`

*Part of the [Stable ABI](#).*

Return the first position of *substr* in `str[start:end]` using the given *direction* (*direction* == 1 means to do a forward search, *direction* == -1 a backward search). The return value is the index of the first match; a value of -1 indicates that no match was found, and -2 indicates that an error occurred and an exception has been set.

`Py_ssize_t PyUnicode_FindChar(PyObject *str, Py_UCS4 ch,  
Py_ssize_t start, Py_ssize_t end, int direction)`

*Part of the [Stable ABI](#) since version 3.7.*

Return the first position of the character *ch* in `str[start:end]` using the given *direction* (*direction* == 1 means to do a forward search, *direction* == -1 a backward search). The return value is the index of the first match; a value of -1 indicates that no match was found, and -2 indicates that an error occurred and an exception has been set.

*New in version 3.3.*

*Changed in version 3.7:* *start* and *end* are now adjusted to behave like `str[start:end]`.

`Py_ssize_t PyUnicode_Count(PyObject *str, PyObject *substr,  
Py_ssize_t start, Py_ssize_t end)`

*Part of the [Stable ABI](#).*

Return the number of non-overlapping occurrences of *substr* in `str[start:end]`. Return -1 if an error occurred.

`PyObject *PyUnicode_Replace(PyObject *str, PyObject *substr,  
PyObject *replstr, Py_ssize_t maxcount)`

*Return value:* *New reference. Part of the [Stable ABI](#).*

Replace at most *maxcount* occurrences of *substr* in *str* with *replstr* and return the resulting Unicode object. *maxcount* ==

-1 means replace all occurrences.

int PyUnicode\_Compare(PyObject \*left, PyObject \*right)

*Part of the [Stable ABI](#).*

Compare two strings and return -1, 0, 1 for less than, equal, and greater than, respectively.

This function returns -1 upon failure, so one should call **PyErr\_Occurred()** to check for errors.

int PyUnicode\_CompareWithASCIIString(PyObject \*uni, const char \*string)

*Part of the [Stable ABI](#).*

Compare a Unicode object, *uni*, with *string* and return -1, 0, 1 for less than, equal, and greater than, respectively. It is best to pass only ASCII-encoded strings, but the function interprets the input string as ISO-8859-1 if it contains non-ASCII characters.

This function does not raise exceptions.

PyObject \*PyUnicode\_RichCompare(PyObject \*left, PyObject \*right, int op)

*Return value: New reference. Part of the [Stable ABI](#).*

Rich compare two Unicode strings and return one of the following:

- NULL in case an exception was raised
- **Py\_True** or **Py\_False** for successful comparisons
- **Py\_NotImplemented** in case the type combination is unknown

Possible values for *op* are **Py\_GT**, **Py\_GE**, **Py\_EQ**, **Py\_NE**, **Py\_LT**, and **Py\_LE**.

PyObject \*PyUnicode\_Format(PyObject \*format, PyObject \*args)

*Return value: New reference. Part of the [Stable ABI](#).*

Return a new string object from *format* and *args*; this is

analogous to `format % args`.

`int PyUnicode_Contains(PyObject *container, PyObject *element)`

*Part of the [Stable ABI](#).*

Check whether *element* is contained in *container* and return true or false accordingly.

*element* has to coerce to a one element Unicode string. `-1` is returned if there was an error.

`void PyUnicode_InternInPlace(PyObject **string)`

*Part of the [Stable ABI](#).*

Intern the argument *\*string* in place. The argument must be the address of a pointer variable pointing to a Python Unicode string object. If there is an existing interned string that is the same as *\*string*, it sets *\*string* to it (decrementing the reference count of the old string object and incrementing the reference count of the interned string object), otherwise it leaves *\*string* alone and interns it (incrementing its reference count). (Clarification: even though there is a lot of talk about reference counts, think of this function as reference-count-neutral; you own the object after the call if and only if you owned it before the call.)

`PyObject *PyUnicode_InternFromString(const char *v)`

*Return value: New reference. Part of the [Stable ABI](#).*

A combination of `PyUnicode_FromString()` and `PyUnicode_InternInPlace()`, returning either a new Unicode string object that has been interned, or a new (“owned”) reference to an earlier interned string object with the same value.

# Tuple Objects

type PyTupleObject

This subtype of `PyObject` represents a Python tuple object.

`PyTypeObject` PyTuple\_Type

*Part of the [Stable ABI](#).*

This instance of `PyTypeObject` represents the Python tuple type; it is the same object as `tuple` in the Python layer.

int PyTuple\_Check(`PyObject` \*p)

Return true if *p* is a tuple object or an instance of a subtype of the tuple type. This function always succeeds.

int PyTuple\_CheckExact(`PyObject` \*p)

Return true if *p* is a tuple object, but not an instance of a subtype of the tuple type. This function always succeeds.

`PyObject` \*PyTuple\_New(`Py_ssize_t` len)

*Return value: New reference. Part of the [Stable ABI](#).*

Return a new tuple object of size *len*, or `NULL` on failure.

`PyObject` \*PyTuple\_Pack(`Py_ssize_t` n, ...)

*Return value: New reference. Part of the [Stable ABI](#).*

Return a new tuple object of size *n*, or `NULL` on failure. The tuple values are initialized to the subsequent *n* C arguments pointing to Python objects. `PyTuple_Pack(2, a, b)` is equivalent to `Py_BuildValue("(OO)", a, b)`.

`Py_ssize_t` PyTuple\_Size(`PyObject` \*p)

*Part of the [Stable ABI](#).*

Take a pointer to a tuple object, and return the size of that

tuple.

`Py_ssize_t PyTuple_GET_SIZE(PyObject *p)`

Return the size of the tuple *p*, which must be non-NULL and point to a tuple; no error checking is performed.

`PyObject *PyTuple_GetItem(PyObject *p, Py_ssize_t pos)`

*Return value:* Borrowed reference. Part of the *Stable ABI*.

Return the object at position *pos* in the tuple pointed to by *p*. If *pos* is negative or out of bounds, return NULL and set an **IndexError** exception.

`PyObject *PyTuple_GET_ITEM(PyObject *p, Py_ssize_t pos)`

*Return value:* Borrowed reference.

Like `PyTuple_GetItem()`, but does no checking of its arguments.

`PyObject *PyTuple_GetSlice(PyObject *p, Py_ssize_t low, Py_ssize_t high)`

*Return value:* New reference. Part of the *Stable ABI*.

Return the slice of the tuple pointed to by *p* between *low* and *high*, or NULL on failure. This is the equivalent of the Python expression `p[low:high]`. Indexing from the end of the list is not supported.

`int PyTuple_SetItem(PyObject *p, Py_ssize_t pos, PyObject *o)`

*Part of the Stable ABI.*

Insert a reference to object *o* at position *pos* of the tuple pointed to by *p*. Return 0 on success. If *pos* is out of bounds, return -1 and set an **IndexError** exception.

## Note

This function “steals” a reference to *o* and discards a reference to an item already in the tuple at the affected position.

`void PyTuple_SET_ITEM(PyObject *p, Py_ssize_t pos, PyObject *o)`

Like `PyTuple_SetItem()`, but does no error checking, and should *only* be used to fill in brand new tuples.

### Note

This function “steals” a reference to *o*, and, unlike `PyTuple_SetItem()`, does *not* discard a reference to any item that is being replaced; any reference in the tuple at position *pos* will be leaked.

`int _PyTuple_Resize(PyObject **p, Py_ssize_t newsize)`

Can be used to resize a tuple. *newsize* will be the new length of the tuple. Because tuples are *supposed* to be immutable, this should only be used if there is only one reference to the object. Do *not* use this if the tuple may already be known to some other part of the code. The tuple will always grow or shrink at the end. Think of this as destroying the old tuple and creating a new one, only more efficiently. Returns 0 on success. Client code should never assume that the resulting value of *\*p* will be the same as before calling this function. If the object referenced by *\*p* is replaced, the original *\*p* is destroyed. On failure, returns -1 and sets *\*p* to NULL, and raises `MemoryError` or `SystemError`.

## Struct Sequence Objects

Struct sequence objects are the C equivalent of `namedtuple()` objects, i.e. a sequence whose items can also be accessed through attributes. To create a struct sequence, you first have to create a specific struct sequence type.

`PyTypeObject *PyStructSequence_NewType(PyStructSequence_Desc *desc)`

*Return value: New reference. Part of the [Stable ABI](#).*

Create a new struct sequence type from the data in *desc*, described below. Instances of the resulting type can be created with [PyStructSequence\\_New\(\)](#).

```
void PyStructSequence_InitType(PyTypeObject *type,  
PyStructSequence\_Desc *desc)
```

Initializes a struct sequence type *type* from *desc* in place.

```
int PyStructSequence_InitType2(PyTypeObject *type,  
PyStructSequence\_Desc *desc)
```

The same as `PyStructSequence_InitType`, but returns 0 on success and -1 on failure.

*New in version 3.4.*

```
type PyStructSequence\_Desc
```

*Part of the [Stable ABI](#) (including all members).*

Contains the meta information of a struct sequence type to create.

#### **Mapping**

---

**name** of the struct sequence type

---

**pointer to docstring** for the type or NULL to omit

---

**pointer to sequence terminated array** with field names of the new type

---

**number of fields** visible to the Python side (if used as tuple)

---

```
type PyStructSequence\_Field
```

*Part of the [Stable ABI](#) (including all members).*

Describes a field of a struct sequence. As a struct sequence is modeled as a tuple, all fields are typed as `PyObject*`. The index in the **fields** array of the [PyStructSequence\\_Desc](#) determines which field of the struct sequence is described.

#### **Mapping**

---

`name` for the field or `NULL` to end the list of named fields,  
set to `PyStructSequence_UnnamedField` to leave  
unnamed  
fields, or `NULL` to omit

---

`const char *const PyStructSequence_UnnamedField`

*Part of the [Stable ABI](#) since version 3.11.*

Special value for a field name to leave it unnamed.

*Changed in version 3.9:* The type was changed from `char *`.

`PyObject *PyStructSequence_New(PyObject *type)`

*Return value:* New reference. *Part of the [Stable ABI](#).*

Creates an instance of `type`, which must have been created  
with `PyStructSequence_NewType()`.

`PyObject *PyStructSequence_GetItem(PyObject *p, Py_ssize_t pos)`

*Return value:* Borrowed reference. *Part of the [Stable ABI](#).*

Return the object at position `pos` in the struct sequence  
pointed to by `p`. No bounds checking is performed.

`PyObject *PyStructSequence_GET_ITEM(PyObject *p, Py_ssize_t pos)`

*Return value:* Borrowed reference.

Macro equivalent of `PyStructSequence_GetItem()`.

`void PyStructSequence_SetItem(PyObject *p, Py_ssize_t pos,  
PyObject *o)`

*Part of the [Stable ABI](#).*

Sets the field at index `pos` of the struct sequence `p` to value `o`.  
Like `PyTuple_SET_ITEM()`, this should only be used to fill  
in brand new instances.

## Note

This function “steals” a reference to `o`.

```
void PyStructSequence_SET_ITEM(PyObject *p, Py_ssize_t *pos,  
PyObject *o)
```

Similar to `PyStructSequence_SetItem()`, but implemented as a static inlined function.

### **Note**

This function “steals” a reference to *o*.

# List Objects

type PyObject

This subtype of `PyObject` represents a Python list object.

`PyTypeObject` `PyList_Type`

*Part of the [Stable ABI](#).*

This instance of `PyTypeObject` represents the Python list type. This is the same object as `list` in the Python layer.

int `PyList_Check(PyObject *p)`

Return true if `p` is a list object or an instance of a subtype of the list type. This function always succeeds.

int `PyList_CheckExact(PyObject *p)`

Return true if `p` is a list object, but not an instance of a subtype of the list type. This function always succeeds.

`PyObject *``PyList_New(Py_ssize_t len)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return a new list of length `len` on success, or `NULL` on failure.

## Note

If `len` is greater than zero, the returned list object's items are set to `NULL`. Thus you cannot use abstract API functions such as `PySequence_SetItem()` or expose the object to Python code before setting all items to a real object with `PyList_SetItem()`.

`Py_ssize_t` `PyList_Size(PyObject *list)`

*Part of the [Stable ABI](#).*

Return the length of the list object in *list*; this is equivalent to `len(list)` on a list object.

`Py_ssize_t PyList_GET_SIZE(PyObject *list)`

Similar to `PyList_Size()`, but without error checking.

`PyObject *PyList_GetItem(PyObject *list, Py_ssize_t index)`

*Return value: Borrowed reference. Part of the [Stable ABI](#).*

Return the object at position *index* in the list pointed to by *list*. The position must be non-negative; indexing from the end of the list is not supported. If *index* is out of bounds ( $< 0$  or  $\geq \text{len}(\text{list})$ ), return `NULL` and set an `IndexError` exception.

`PyObject *PyList_GET_ITEM(PyObject *list, Py_ssize_t i)`

*Return value: Borrowed reference.*

Similar to `PyList_GetItem()`, but without error checking.

`int PyList_SetItem(PyObject *list, Py_ssize_t index, PyObject *item)`

*Part of the [Stable ABI](#).*

Set the item at index *index* in list to *item*. Return `0` on success. If *index* is out of bounds, return `-1` and set an `IndexError` exception.

### Note

This function “steals” a reference to *item* and discards a reference to an item already in the list at the affected position.

`void PyList_SET_ITEM(PyObject *list, Py_ssize_t i, PyObject *o)`

Macro form of `PyList_SetItem()` without error checking. This is normally only used to fill in new lists where there is no previous content.

### Note

This macro “steals” a reference to *item*, and, unlike `PyList_SetItem()`, does *not* discard a reference to any item that is being replaced; any reference in *list* at position *i* will be leaked.

`int PyList_Insert(PyObject *list, Py_ssize_t index, PyObject *item)`

*Part of the [Stable ABI](#).*

Insert the item *item* into list *list* in front of index *index*. Return 0 if successful; return -1 and set an exception if unsuccessful. Analogous to `list.insert(index, item)`.

`int PyList_Append(PyObject *list, PyObject *item)`

*Part of the [Stable ABI](#).*

Append the object *item* at the end of list *list*. Return 0 if successful; return -1 and set an exception if unsuccessful. Analogous to `list.append(item)`.

`PyObject *PyList_GetSlice(PyObject *list, Py_ssize_t low, Py_ssize_t high)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return a list of the objects in *list* containing the objects between *low* and *high*. Return NULL and set an exception if unsuccessful. Analogous to `list[low:high]`. Indexing from the end of the list is not supported.

`int PyList_SetSlice(PyObject *list, Py_ssize_t low, Py_ssize_t high, PyObject *itemlist)`

*Part of the [Stable ABI](#).*

Set the slice of *list* between *low* and *high* to the contents of *itemlist*. Analogous to `list[low:high] = itemlist`. The *itemlist* may be NULL, indicating the assignment of an empty list (slice deletion). Return 0 on success, -1 on failure. Indexing from the end of the list is not supported.

`int PyList_Sort(PyObject *list)`

*Part of the [Stable ABI](#).*

Sort the items of *list* in place. Return 0 on success, -1 on failure. This is equivalent to `list.sort()`.

`int PyList_Reverse(PyObject *list)`

*Part of the [Stable ABI](#).*

Reverse the items of *list* in place. Return 0 on success, -1 on failure. This is the equivalent of `list.reverse()`.

`PyObject *PyList_AsTuple(PyObject *list)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return a new tuple object containing the contents of *list*; equivalent to `tuple(list)`.

# Dictionary Objects

type PyDictObject

This subtype of **PyObject** represents a Python dictionary object.

**PyTypeObject** PyDict\_Type

*Part of the [Stable ABI](#).*

This instance of **PyTypeObject** represents the Python dictionary type. This is the same object as **dict** in the Python layer.

int PyDict\_Check(**PyObject** \*p)

Return true if *p* is a dict object or an instance of a subtype of the dict type. This function always succeeds.

int PyDict\_CheckExact(**PyObject** \*p)

Return true if *p* is a dict object, but not an instance of a subtype of the dict type. This function always succeeds.

**PyObject** \*PyDict\_New()

*Return value: New reference. Part of the [Stable ABI](#).*

Return a new empty dictionary, or `NULL` on failure.

**PyObject** \*PyDictProxy\_New(**PyObject** \*mapping)

*Return value: New reference. Part of the [Stable ABI](#).*

Return a **types.MappingProxyType** object for a mapping which enforces read-only behavior. This is normally used to create a view to prevent modification of the dictionary for non-dynamic class types.

void PyDict\_Clear(**PyObject** \*p)

Part of the *Stable ABI*.

Empty an existing dictionary of all key-value pairs.

`int PyDict_Contains(PyObject *p, PyObject *key)`

Part of the *Stable ABI*.

Determine if dictionary *p* contains *key*. If an item in *p* matches *key*, return 1, otherwise return 0. On error, return -1. This is equivalent to the Python expression `key in p`.

`PyObject *PyDict_Copy(PyObject *p)`

Return value: New reference. Part of the *Stable ABI*.

Return a new dictionary that contains the same key-value pairs as *p*.

`int PyDict_SetItem(PyObject *p, PyObject *key, PyObject *val)`

Part of the *Stable ABI*.

Insert *val* into the dictionary *p* with a key of *key*. *key* must be *hashable*; if it isn't, **TypeError** will be raised. Return 0 on success or -1 on failure. This function *does not* steal a reference to *val*.

`int PyDict_SetItemString(PyObject *p, const char *key, PyObject *val)`

Part of the *Stable ABI*.

Insert *val* into the dictionary *p* using *key* as a key. *key* should be a `const char*`. The key object is created using `PyUnicode_FromString(key)`. Return 0 on success or -1 on failure. This function *does not* steal a reference to *val*.

`int PyDict_DelItem(PyObject *p, PyObject *key)`

Part of the *Stable ABI*.

Remove the entry in dictionary *p* with key *key*. *key* must be *hashable*; if it isn't, **TypeError** is raised. If *key* is not in the dictionary, **KeyError** is raised. Return 0 on success or -1 on failure.

`int PyDict_DelItemString(PyObject *p, const char *key)`

Part of the *Stable ABI*.

Remove the entry in dictionary *p* which has a key specified by the string *key*. If *key* is not in the dictionary, **KeyError** is raised. Return 0 on success or -1 on failure.

**PyObject \***PyDict\_GetItem(**PyObject \***p, **PyObject \***key)

*Return value:* Borrowed reference. Part of the *Stable ABI*.

Return the object from dictionary *p* which has a key *key*.

Return **NULL** if the key *key* is not present, but *without* setting an exception.

### Note

Exceptions that occur while this calls **\_\_hash\_\_()** and **\_\_eq\_\_()** methods are silently ignored. Prefer the **PyDict\_GetItemWithError()** function instead.

*Changed in version 3.10:* Calling this API without **GIL** held had been allowed for historical reason. It is no longer allowed.

**PyObject \***PyDict\_GetItemWithError(**PyObject \***p, **PyObject \***key)

*Return value:* Borrowed reference. Part of the *Stable ABI*.

Variant of **PyDict\_GetItem()** that does not suppress

exceptions. Return **NULL** **with** an exception set if an

exception occurred. Return **NULL** **without** an exception set if the key wasn't present.

**PyObject \***PyDict\_GetItemString(**PyObject \***p, const char \*key)

*Return value:* Borrowed reference. Part of the *Stable ABI*.

This is the same as **PyDict\_GetItem()**, but *key* is specified as a const char\*, rather than a **PyObject\***.

### Note

Exceptions that occur while this calls **\_\_hash\_\_()** and **\_\_eq\_\_()** methods or while creating the temporary **str** object are silently ignored. Prefer using the **PyDict\_GetItemWithError()** function with your own

`PyUnicode_FromString()` key instead.

`PyObject *PyDict_SetDefault(PyObject *p, PyObject *key, PyObject *defaultobj)`

*Return value: Borrowed reference.*

This is the same as the Python-level `dict.setdefault()`. If present, it returns the value corresponding to *key* from the dictionary *p*. If the key is not in the dict, it is inserted with value *defaultobj* and *defaultobj* is returned. This function evaluates the hash function of *key* only once, instead of evaluating it independently for the lookup and the insertion.

*New in version 3.4.*

`PyObject *PyDict_Items(PyObject *p)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return a `PyListObject` containing all the items from the dictionary.

`PyObject *PyDict_Keys(PyObject *p)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return a `PyListObject` containing all the keys from the dictionary.

`PyObject *PyDict_Values(PyObject *p)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return a `PyListObject` containing all the values from the dictionary *p*.

`Py_ssize_t PyDict_Size(PyObject *p)`

*Part of the [Stable ABI](#).*

Return the number of items in the dictionary. This is equivalent to `len(p)` on a dictionary.

`int PyDict_Next(PyObject *p, Py_ssize_t *ppos, PyObject **pkey,`

`PyObject **pvalue)`

*Part of the [Stable ABI](#).*

Iterate over all key-value pairs in the dictionary *p*. The `Py_ssize_t` referred to by *ppos* must be initialized to 0 prior to the first call to this function to start the iteration; the function returns true for each pair in the dictionary, and false once all pairs have been reported. The parameters *pkey* and *pvalue* should either point to `PyObject*` variables that will be filled in with each key and value, respectively, or may be NULL. Any references returned through them are borrowed. *ppos* should not be altered during iteration. Its value represents offsets within the internal dictionary structure, and since the structure is sparse, the offsets are not consecutive.

For example:

```
PyObject *key, *value;
Py_ssize_t pos = 0;

while (PyDict_Next(self->dict, &pos, &key, &value))
    /* do something interesting with the values...
     * ...
    */
}
```

The dictionary *p* should not be mutated during iteration. It is safe to modify the values of the keys as you iterate over the dictionary, but only so long as the set of keys does not change. For example:

```
PyObject *key, *value;
Py_ssize_t pos = 0;

while (PyDict_Next(self->dict, &pos, &key, &value))
    long i = PyLong_AsLong(value);
    if (i == -1 && PyErr_Occurred()) {
        return -1;
    }
    PyObject *o = PyLong_FromLong(i + 1);
    if (o == NULL)
```

```

        return -1;
    if (PyDict_SetItem(self->dict, key, o) < 0) {
        Py_DECREF(o);
        return -1;
    }
    Py_DECREF(o);
}

```

`int PyDict_Merge(PyObject *a, PyObject *b, int override)`

*Part of the [Stable ABI](#).*

Iterate over mapping object *b* adding key-value pairs to dictionary *a*. *b* may be a dictionary, or any object supporting [PyMapping\\_Keys\(\)](#) and [PyObject\\_GetItem\(\)](#). If *override* is true, existing pairs in *a* will be replaced if a matching key is found in *b*, otherwise pairs will only be added if there is not a matching key in *a*. Return 0 on success or -1 if an exception was raised.

`int PyDict_Update(PyObject *a, PyObject *b)`

*Part of the [Stable ABI](#).*

This is the same as `PyDict_Merge(a, b, 1)` in C, and is similar to `a.update(b)` in Python except that [PyDict\\_Update\(\)](#) doesn't fall back to the iterating over a sequence of key value pairs if the second argument has no "keys" attribute. Return 0 on success or -1 if an exception was raised.

`int PyDict_MergeFromSeq2(PyObject *a, PyObject *seq2, int override)`

*Part of the [Stable ABI](#).*

Update or merge into dictionary *a*, from the key-value pairs in *seq2*. *seq2* must be an iterable object producing iterable objects of length 2, viewed as key-value pairs. In case of duplicate keys, the last wins if *override* is true, else the first wins. Return 0 on success or -1 if an exception was raised. Equivalent Python (except for the return value):

```
def PyDict_MergeFromSeq2(a, seq2, override):
```

```
for key, value in seq2:
    if override or key not in a:
        a[key] = value
```

# Set Objects

This section details the public API for `set` and `frozenset` objects. Any functionality not listed below is best accessed using either the abstract object protocol (including `PyObject_CallMethod()`, `PyObject_RichCompareBool()`, `PyObject_Hash()`, `PyObject_Repr()`, `PyObject_IsTrue()`, `PyObject_Print()`, and `PyObject_GetIter()`) or the abstract number protocol (including `PyNumber_And()`, `PyNumber_Subtract()`, `PyNumber_Or()`, `PyNumber_Xor()`, `PyNumber_InPlaceAnd()`, `PyNumber_InPlaceSubtract()`, `PyNumber_InPlaceOr()`, and `PyNumber_InPlaceXor()`).

type `PySetObject`

This subtype of `PyObject` is used to hold the internal data for both `set` and `frozenset` objects. It is like a `PyDictObject` in that it is a fixed size for small sets (much like tuple storage) and will point to a separate, variable sized block of memory for medium and large sized sets (much like list storage). None of the fields of this structure should be considered public and all are subject to change. All access should be done through the documented API rather than by manipulating the values in the structure.

`PyTypeObject` `PySet_Type`

*Part of the [Stable ABI](#).*

This is an instance of `PyTypeObject` representing the Python `set` type.

`PyTypeObject` `PyFrozenSet_Type`

*Part of the [Stable ABI](#).*

This is an instance of `PyTypeObject` representing the Python `frozenset` type.

The following type check macros work on pointers to any Python

object. Likewise, the constructor functions work with any iterable Python object.

`int PySet_Check(PyObject *p)`

Return true if *p* is a **set** object or an instance of a subtype. This function always succeeds.

`int PyFrozenSet_Check(PyObject *p)`

Return true if *p* is a **frozenset** object or an instance of a subtype. This function always succeeds.

`int PyAnySet_Check(PyObject *p)`

Return true if *p* is a **set** object, a **frozenset** object, or an instance of a subtype. This function always succeeds.

`int PySet_CheckExact(PyObject *p)`

Return true if *p* is a **set** object but not an instance of a subtype. This function always succeeds.

*New in version 3.10.*

`int PyAnySet_CheckExact(PyObject *p)`

Return true if *p* is a **set** object or a **frozenset** object but not an instance of a subtype. This function always succeeds.

`int PyFrozenSet_CheckExact(PyObject *p)`

Return true if *p* is a **frozenset** object but not an instance of a subtype. This function always succeeds.

`PyObject *PySet_New(PyObject *iterable)`

*Return value:* New reference. Part of the [Stable ABI](#).

Return a new **set** containing objects returned by the *iterable*. The *iterable* may be `NULL` to create a new empty set. Return the new set on success or `NULL` on failure. Raise **TypeError** if *iterable* is not actually iterable. The constructor is also useful for copying a set (`c=set(s)`).

**PyObject** \*PyFrozenSet\_New(**PyObject** \*iterable)

*Return value: New reference. Part of the [Stable ABI](#).*

Return a new **frozenset** containing objects returned by the *iterable*. The *iterable* may be `NULL` to create a new empty frozenset. Return the new set on success or `NULL` on failure. Raise **TypeError** if *iterable* is not actually iterable.

The following functions and macros are available for instances of **set** or **frozenset** or instances of their subtypes.

**Py\_ssize\_t** PySet\_Size(**PyObject** \*anyset)

*Part of the [Stable ABI](#).*

Return the length of a **set** or **frozenset** object.

Equivalent to `len(anyset)`. Raises a

**PyExc\_SystemError** if *anyset* is not a **set**, **frozenset**, or an instance of a subtype.

**Py\_ssize\_t** PySet\_GET\_SIZE(**PyObject** \*anyset)

Macro form of **PySet\_Size()** without error checking.

**int** PySet\_Contains(**PyObject** \*anyset, **PyObject** \*key)

*Part of the [Stable ABI](#).*

Return `1` if found, `0` if not found, and `-1` if an error is encountered. Unlike the Python `__contains__()` method, this function does not automatically convert unhashable sets into temporary frozensets. Raise a **TypeError** if the *key* is unhashable. Raise **PyExc\_SystemError** if *anyset* is not a **set**, **frozenset**, or an instance of a subtype.

**int** PySet\_Add(**PyObject** \*set, **PyObject** \*key)

*Part of the [Stable ABI](#).*

Add *key* to a **set** instance. Also works with **frozenset** instances (like **PyTuple\_SetItem()** it can be used to fill in the values of brand new frozensets before they are exposed to other code). Return `0` on success or `-1` on failure. Raise a **TypeError** if the *key* is unhashable. Raise a **MemoryError** if there is no room to grow. Raise a **SystemError** if *set* is

not an instance of **set** or its subtype.

The following functions are available for instances of **set** or its subtypes but not for instances of **frozenset** or its subtypes.

`int PySet_Discard(PyObject *set, PyObject *key)`

*Part of the **Stable ABI**.*

Return 1 if found and removed, 0 if not found (no action taken), and -1 if an error is encountered. Does not raise **KeyError** for missing keys. Raise a **TypeError** if the *key* is unhashable. Unlike the Python **discard()** method, this function does not automatically convert unhashable sets into temporary frozensets. Raise **PyExc\_SystemError** if *set* is not an instance of **set** or its subtype.

`PyObject *PySet_Pop(PyObject *set)`

*Return value: New reference. Part of the **Stable ABI**.*

Return a new reference to an arbitrary object in the *set*, and removes the object from the *set*. Return **NULL** on failure.

Raise **KeyError** if the set is empty. Raise a **SystemError** if *set* is not an instance of **set** or its subtype.

`int PySet_Clear(PyObject *set)`

*Part of the **Stable ABI**.*

Empty an existing set of all elements.

# Function Objects

There are a few functions specific to Python functions.

type PyObjectFunctionObject

The C structure used for functions.

PyObject PyFunction\_Type

This is an instance of `PyObject` and represents the Python function type. It is exposed to Python programmers as `types.FunctionType`.

int PyFunction\_Check(PyObject \*o)

Return true if `o` is a function object (has type `PyFunction_Type`). The parameter must not be `NULL`. This function always succeeds.

PyObject \*PyFunction\_New(PyObject \*code, PyObject \*globals)

*Return value:* New reference.

Return a new function object associated with the code object `code`. `globals` must be a dictionary with the global variables accessible to the function.

The function's docstring and name are retrieved from the code object. `__module__` is retrieved from `globals`. The argument defaults, annotations and closure are set to `NULL`. `__qualname__` is set to the same value as the code object's `co_qualname` field.

PyObject \*PyFunction\_NewWithQualName(PyObject \*code,  
PyObject \*globals, PyObject \*qualname)

*Return value:* New reference.

As `PyFunction_New()`, but also allows setting the function object's `__qualname__` attribute. `qualname` should be a

unicode object or `NULL`; if `NULL`, the `__qualname__` attribute is set to the same value as the code object's `co_qualname` field.

*New in version 3.3.*

**PyObject \***`PyFunction_GetCode(PyObject *op)`

*Return value: Borrowed reference.*

Return the code object associated with the function object *op*.

**PyObject \***`PyFunction_GetGlobals(PyObject *op)`

*Return value: Borrowed reference.*

Return the globals dictionary associated with the function object *op*.

**PyObject \***`PyFunction_GetModule(PyObject *op)`

*Return value: Borrowed reference.*

Return a [borrowed reference](#) to the `_module_` attribute of the function object *op*. It can be `NULL`.

This is normally a string containing the module name, but can be set to any other object by Python code.

**PyObject \***`PyFunction_GetDefaults(PyObject *op)`

*Return value: Borrowed reference.*

Return the argument default values of the function object *op*. This can be a tuple of arguments or `NULL`.

**int** `PyFunction_SetDefaults(PyObject *op, PyObject *defaults)`

Set the argument default values for the function object *op*. *defaults* must be `Py_None` or a tuple.

Raises [SystemError](#) and returns `-1` on failure.

**PyObject \***`PyFunction_GetClosure(PyObject *op)`

*Return value: Borrowed reference.*

Return the closure associated with the function object *op*.

This can be `NULL` or a tuple of cell objects.

`int PyFunction_SetClosure(PyObject *op, PyObject *closure)`

Set the closure associated with the function object *op*. *closure* must be `Py_None` or a tuple of cell objects.

Raises **SystemError** and returns `-1` on failure.

`PyObject *PyFunction_GetAnnotations(PyObject *op)`

*Return value: Borrowed reference.*

Return the annotations of the function object *op*. This can be a mutable dictionary or `NULL`.

`int PyFunction_SetAnnotations(PyObject *op, PyObject *annotations)`

Set the annotations for the function object *op*. *annotations* must be a dictionary or `Py_None`.

Raises **SystemError** and returns `-1` on failure.

# Instance Method Objects

An instance method is a wrapper for a `PyCFunction` and the new way to bind a `PyCFunction` to a class object. It replaces the former call `PyMethod_New(func, NULL, class)`.

`PyTypeObject` `PyInstanceMethod_Type`

This instance of `PyTypeObject` represents the Python instance method type. It is not exposed to Python programs.

`int` `PyInstanceMethod_Check(PyObject *o)`

Return true if `o` is an instance method object (has type `PyInstanceMethod_Type`). The parameter must not be `NULL`. This function always succeeds.

`PyObject *``PyInstanceMethod_New(PyObject *func)`

*Return value:* New reference.

Return a new instance method object, with `func` being any callable object. `func` is the function that will be called when the instance method is called.

`PyObject *``PyInstanceMethod_Function(PyObject *im)`

*Return value:* Borrowed reference.

Return the function object associated with the instance method `im`.

`PyObject *``PyInstanceMethod_GET_FUNCTION(PyObject *im)`

*Return value:* Borrowed reference.

Macro version of `PyInstanceMethod_Function()` which avoids error checking.

# Method Objects

Methods are bound function objects. Methods are always bound to an instance of a user-defined class. Unbound methods (methods bound to a class object) are no longer available.

**PyObject** PyMethod\_Type

This instance of **PyObject** represents the Python method type. This is exposed to Python programs as `types.MethodType`.

`int PyMethod_Check(PyObject *o)`

Return true if `o` is a method object (has type **PyMethod\_Type**). The parameter must not be `NULL`. This function always succeeds.

**PyObject** \*PyMethod\_New(PyObject \*func, PyObject \*self)

*Return value: New reference.*

Return a new method object, with `func` being any callable object and `self` the instance the method should be bound. `func` is the function that will be called when the method is called. `self` must not be `NULL`.

**PyObject** \*PyMethod\_Function(PyObject \*meth)

*Return value: Borrowed reference.*

Return the function object associated with the method `meth`.

**PyObject** \*PyMethod\_GET\_FUNCTION(PyObject \*meth)

*Return value: Borrowed reference.*

Macro version of **PyMethod\_Function()** which avoids error checking.

**PyObject** \*PyMethod\_Self(PyObject \*meth)

*Return value: Borrowed reference.*

Return the instance associated with the method `meth`.

`PyObject *PyMethod_GET_SELF(PyObject *meth)`

*Return value: Borrowed reference.*

Macro version of `PyMethod_Self()` which avoids error checking.

# Cell Objects

“Cell” objects are used to implement variables referenced by multiple scopes. For each such variable, a cell object is created to store the value; the local variables of each stack frame that references the value contains a reference to the cells from outer scopes which also use that variable. When the value is accessed, the value contained in the cell is used instead of the cell object itself. This de-referencing of the cell object requires support from the generated byte-code; these are not automatically de-referenced when accessed. Cell objects are not likely to be useful elsewhere.

type PyCellObject

The C structure used for cell objects.

PyTypeObject PyCell\_Type

The type object corresponding to cell objects.

int PyCell\_Check(ob)

Return true if *ob* is a cell object; *ob* must not be `NULL`. This function always succeeds.

PyObject \*PyCell\_New(PyObject \*ob)

*Return value:* New reference.

Create and return a new cell object containing the value *ob*. The parameter may be `NULL`.

PyObject \*PyCell\_Get(PyObject \*cell)

*Return value:* New reference.

Return the contents of the cell *cell*.

PyObject \*PyCell\_GET(PyObject \*cell)

*Return value:* Borrowed reference.

Return the contents of the cell *cell*, but without checking that *cell* is non-NULL and a cell object.

int PyCell\_Set(PyObject \*cell, PyObject \*value)

Set the contents of the cell object *cell* to *value*. This releases the reference to any current content of the cell. *value* may be NULL. *cell* must be non-NULL; if it is not a cell object, -1 will be returned. On success, 0 will be returned.

void PyCell\_SET(PyObject \*cell, PyObject \*value)

Sets the value of the cell object *cell* to *value*. No reference counts are adjusted, and no checks are made for safety; *cell* must be non-NULL and must be a cell object.

# Code Objects

Code objects are a low-level detail of the CPython implementation. Each one represents a chunk of executable code that hasn't yet been bound into a function.

type PyCodeObject

The C structure of the objects used to describe code objects. The fields of this type are subject to change at any time.

PyTypeObject PyCode\_Type

This is an instance of `PyTypeObject` representing the Python `code` type.

int PyCode\_Check(PyObject \*co)

Return true if `co` is a `code` object. This function always succeeds.

int PyCode\_GetNumFree(PyCodeObject \*co)

Return the number of free variables in `co`.

`PyCodeObject` \*PyCode\_New(int argcount, int kwnonlyargcount, int nlocals, int stacksize, int flags, `PyObject` \*code, `PyObject` \*consts, `PyObject` \*names, `PyObject` \*varnames, `PyObject` \*freevars, `PyObject` \*cellvars, `PyObject` \*filename, `PyObject` \*name, int firstlineno, `PyObject` \*linetable, `PyObject` \*exceptiontable)

*Return value: New reference.*

Return a new code object. If you need a dummy code object to create a frame, use `PyCode_NewEmpty()` instead. Calling `PyCode_New()` directly will bind you to a precise Python version since the definition of the bytecode changes often. The many arguments of this function are inter-dependent in complex ways, meaning that subtle changes to values are likely to result in incorrect execution or VM crashes. Use this

function only with extreme care.

*Changed in version 3.11:* Added `exceptiontable` parameter.

`PyCodeObject` \*PyCode\_NewWithPosOnlyArgs(int argcount, int posonlyargcount, int kwnonlyargcount, int nlocals, int stacksize, int flags, `PyObject` \*code, `PyObject` \*consts, `PyObject` \*names, `PyObject` \*varnames, `PyObject` \*freevars, `PyObject` \*cellvars, `PyObject` \*filename, `PyObject` \*name, int firstlineno, `PyObject` \*linetable, `PyObject` \*exceptiontable)

*Return value:* New reference.

Similar to `PyCode_New()`, but with an extra “posonlyargcount” for positional-only arguments. The same caveats that apply to `PyCode_New` also apply to this function.

*New in version 3.8.*

*Changed in version 3.11:* Added `exceptiontable` parameter.

`PyCodeObject` \*PyCode\_NewEmpty(const char \*filename, const char \*funcname, int firstlineno)

*Return value:* New reference.

Return a new empty code object with the specified filename, function name, and first line number. The resulting code object will raise an `Exception` if executed.

int PyCode\_Addr2Line(`PyCodeObject` \*co, int byte\_offset)

Return the line number of the instruction that occurs on or before `byte_offset` and ends after it. If you just need the line number of a frame, use `PyFrame_GetLineNumber()` instead.

For efficiently iterating over the line numbers in a code object, use [the API described in PEP 626](https://peps.python.org/pep-0626/#out-of-process-debuggers-and-profilers) [https://peps.python.org/pep-0626/#out-of-process-debuggers-and-profilers].

`int PyCode_Addr2Location(PyObject *co, int byte_offset, int *start_line, int *start_column, int *end_line, int *end_column)`

Sets the passed `int` pointers to the source code line and column numbers for the instruction at `byte_offset`. Sets the value to 0 when information is not available for any particular element.

Returns 1 if the function succeeds and 0 otherwise.

*New in version 3.11.*

`PyObject *PyCode_GetCode(PyCodeObject *co)`

Equivalent to the Python code `getattr(co, 'co_code')`. Returns a strong reference to a **PyBytesObject** representing the bytecode in a code object. On error, `NULL` is returned and an exception is raised.

This **PyBytesObject** may be created on-demand by the interpreter and does not necessarily represent the bytecode actually executed by CPython. The primary use case for this function is debuggers and profilers.

*New in version 3.11.*

`PyObject *PyCode_GetVarnames(PyCodeObject *co)`

Equivalent to the Python code `getattr(co, 'co_varnames')`. Returns a new reference to a **PyTupleObject** containing the names of the local variables. On error, `NULL` is returned and an exception is raised.

*New in version 3.11.*

`PyObject *PyCode_GetCellvars(PyCodeObject *co)`

Equivalent to the Python code `getattr(co, 'co_cellvars')`. Returns a new reference to a **PyTupleObject** containing the names of the local variables that are referenced by nested functions. On error, `NULL` is returned and an exception is raised.

*New in version 3.11.*

**PyObject \***PyCode\_GetFreevars(**PyCodeObject \***co)

Equivalent to the Python code `getattr(co, 'co_freevars')`. Returns a new reference to a **PyTupleObject** containing the names of the free variables. On error, `NULL` is returned and an exception is raised.

*New in version 3.11.*

# File Objects

These APIs are a minimal emulation of the Python 2 C API for built-in file objects, which used to rely on the buffered I/O (FILE\*) support from the C standard library. In Python 3, files and streams use the new `io` module, which defines several layers over the low-level unbuffered I/O of the operating system. The functions described below are convenience C wrappers over these new APIs, and meant mostly for internal error reporting in the interpreter; third-party code is advised to access the `io` APIs instead.

**PyObject** \*PyFile\_FromFd(int fd, const char \*name, const char \*mode, int buffering, const char \*encoding, const char \*errors, const char \*newline, int closefd)

*Return value:* New reference. Part of the [Stable ABI](#).

Create a Python file object from the file descriptor of an already opened file *fd*. The arguments *name*, *encoding*, *errors* and *newline* can be `NULL` to use the defaults; *buffering* can be `-1` to use the default. *name* is ignored and kept for backward compatibility. Return `NULL` on failure. For a more comprehensive description of the arguments, please refer to the [io.open\(\)](#) function documentation.

## Warning

Since Python streams have their own buffering layer, mixing them with OS-level file descriptors can produce various issues (such as unexpected ordering of data).

*Changed in version 3.2:* Ignore *name* attribute.

int PyObject\_AsFileDescriptor(PyObject \*p)

*Part of the [Stable ABI](#).*

Return the file descriptor associated with *p* as an int. If the object is an integer, its value is returned. If not, the object's

`fileno()` method is called if it exists; the method must return an integer, which is returned as the file descriptor value. Sets an exception and returns `-1` on failure.

`PyObject *PyFile_GetLine(PyObject *p, int n)`

*Return value:* New reference. Part of the [Stable ABI](#).

Equivalent to `p.readline([n])`, this function reads one line from the object `p`. `p` may be a file object or any object with a `readline()` method. If `n` is `0`, exactly one line is read, regardless of the length of the line. If `n` is greater than `0`, no more than `n` bytes will be read from the file; a partial line can be returned. In both cases, an empty string is returned if the end of the file is reached immediately. If `n` is less than `0`, however, one line is read regardless of length, but `EOFError` is raised if the end of the file is reached immediately.

`int PyFile_SetOpenCodeHook(Py_OpenCodeHookFunction handler)`

Overrides the normal behavior of `io.open_code()` to pass its parameter through the provided handler.

The handler is a function of type `PyObject (*)(PyObject *path, void *userData)`, where `path` is guaranteed to be `PyUnicodeObject`.

The `userData` pointer is passed into the hook function. Since hook functions may be called from different runtimes, this pointer should not refer directly to Python state.

As this hook is intentionally used during import, avoid importing new modules during its execution unless they are known to be frozen or available in `sys.modules`.

Once a hook has been set, it cannot be removed or replaced, and later calls to `PyFile_SetOpenCodeHook()` will fail. On failure, the function returns `-1` and sets an exception if the interpreter has been initialized.

This function is safe to call before `Py_Initialize()`.

Raises an [auditing event](#) `setopencodehook` with no arguments.

*New in version 3.8.*

`int PyFile_WriteObject(PyObject *obj, PyObject *p, int flags)`

*Part of the [Stable ABI](#).*

Write object *obj* to file object *p*. The only supported flag for *flags* is `Py_PRINT_RAW`; if given, the `str()` of the object is written instead of the `repr()`. Return 0 on success or -1 on failure; the appropriate exception will be set.

`int PyFile_WriteString(const char *s, PyObject *p)`

*Part of the [Stable ABI](#).*

Write string *s* to file object *p*. Return 0 on success or -1 on failure; the appropriate exception will be set.

# Module Objects

**PyTypeObject** PyModule\_Type

*Part of the [Stable ABI](#).*

This instance of **PyTypeObject** represents the Python module type. This is exposed to Python programs as `types.ModuleType`.

`int PyModule_Check(PyObject *p)`

Return true if *p* is a module object, or a subtype of a module object. This function always succeeds.

`int PyModule_CheckExact(PyObject *p)`

Return true if *p* is a module object, but not a subtype of **PyModule\_Type**. This function always succeeds.

**PyObject** \*PyModule\_NewObject(PyObject \*name)

*Return value: New reference. Part of the [Stable ABI](#) since version 3.7.*

Return a new module object with the `__name__` attribute set to *name*. The module's `__name__`, `__doc__`, `__package__`, and `__loader__` attributes are filled in (all but `__name__` are set to `None`); the caller is responsible for providing a `__file__` attribute.

*New in version 3.3.*

*Changed in version 3.4:* `__package__` and `__loader__` are set to `None`.

**PyObject** \*PyModule\_New(const char \*name)

*Return value: New reference. Part of the [Stable ABI](#).*

Similar to **PyModule\_NewObject()**, but the name is a UTF-8 encoded string instead of a Unicode object.

**PyObject \***PyModule\_GetDict(**PyObject \***module)

*Return value: Borrowed reference. Part of the [Stable ABI](#).*

Return the dictionary object that implements *module*'s namespace; this object is the same as the `__dict__` attribute of the module object. If *module* is not a module object (or a subtype of a module object), **SystemError** is raised and `NULL` is returned.

It is recommended extensions use other `PyModule_*` and `PyObject_*` functions rather than directly manipulate a module's `__dict__`.

**PyObject \***PyModule\_GetNameObject(**PyObject \***module)

*Return value: New reference. Part of the [Stable ABI](#) since version 3.7.*

Return *module*'s `__name__` value. If the module does not provide one, or if it is not a string, **SystemError** is raised and `NULL` is returned.

*New in version 3.3.*

**const char \***PyModule\_GetName(**PyObject \***module)

*Part of the [Stable ABI](#).*

Similar to `PyModule_GetNameObject()` but return the name encoded to `'utf-8'`.

**void \***PyModule\_GetState(**PyObject \***module)

*Part of the [Stable ABI](#).*

Return the “state” of the module, that is, a pointer to the block of memory allocated at module creation time, or `NULL`. See `PyModuleDef.m_size`.

**PyModuleDef \***PyModule\_GetDef(**PyObject \***module)

*Part of the [Stable ABI](#).*

Return a pointer to the `PyModuleDef` struct from which the module was created, or `NULL` if the module wasn't created from a definition.

`PyObject *PyModule_GetFilenameObject(PyObject *module)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return the name of the file from which *module* was loaded using *module*'s `__file__` attribute. If this is not defined, or if it is not a unicode string, raise `SystemError` and return `NULL`; otherwise return a reference to a Unicode object.

*New in version 3.2.*

`const char *PyModule_GetFilename(PyObject *module)`

*Part of the [Stable ABI](#).*

Similar to `PyModule_GetFilenameObject()` but return the filename encoded to 'utf-8'.

*Deprecated since version 3.2: `PyModule_GetFilename()` raises `UnicodeEncodeError` on unencodable filenames, use `PyModule_GetFilenameObject()` instead.*

## Initializing C modules

Modules objects are usually created from extension modules (shared libraries which export an initialization function), or compiled-in modules (where the initialization function is added using `PyImport_AppendInittab()`). See [Building C and C++ Extensions](#) or [Extending Embedded Python](#) for details.

The initialization function can either pass a module definition instance to `PyModule_Create()`, and return the resulting module object, or request “multi-phase initialization” by returning the definition struct itself.

`type PyModuleDef`

*Part of the [Stable ABI](#) (including all members).*

The module definition struct, which holds all information needed to create a module object. There is usually only one statically initialized variable of this type for each module.

`PyModuleDef_Base m_base`

Always initialize this member to

**PyModuleDef\_HEAD\_INIT.**

const char \*m\_name

Name for the new module.

const char \*m\_doc

Docstring for the module; usually a docstring variable created with **PyDoc\_STRVAR** is used.

**Py\_ssize\_t** m\_size

Module state may be kept in a per-module memory area that can be retrieved with **PyModule\_GetState()**, rather than in static globals. This makes modules safe for use in multiple sub-interpreters.

This memory area is allocated based on *m\_size* on module creation, and freed when the module object is deallocated, after the **m\_free** function has been called, if present.

Setting *m\_size* to -1 means that the module does not support sub-interpreters, because it has global state.

Setting it to a non-negative value means that the module can be re-initialized and specifies the additional amount of memory it requires for its state. Non-negative *m\_size* is required for multi-phase initialization.

See **PEP 3121** [<https://peps.python.org/pep-3121/>] for more details.

**PyMethodDef** \*m\_methods

A pointer to a table of module-level functions, described by **PyMethodDef** values. Can be **NULL** if no functions are present.

**PyModuleDef\_Slot** \*m\_slots

An array of slot definitions for multi-phase initialization, terminated by a `{0, NULL}` entry. When using single-phase initialization, `m_slots` must be `NULL`.

*Changed in version 3.5:* Prior to version 3.5, this member was always set to `NULL`, and was defined as:

`inquiry m_reload`

`traverseproc m_traverse`

A traversal function to call during GC traversal of the module object, or `NULL` if not needed.

This function is not called if the module state was requested but is not allocated yet. This is the case immediately after the module is created and before the module is executed (`Py_mod_exec` function). More precisely, this function is not called if `m_size` is greater than 0 and the module state (as returned by `PyModule_GetState()`) is `NULL`.

*Changed in version 3.9:* No longer called before the module state is allocated.

`inquiry m_clear`

A clear function to call during GC clearing of the module object, or `NULL` if not needed.

This function is not called if the module state was requested but is not allocated yet. This is the case immediately after the module is created and before the module is executed (`Py_mod_exec` function). More precisely, this function is not called if `m_size` is greater than 0 and the module state (as returned by `PyModule_GetState()`) is `NULL`.

Like `PyTypeObject.tp_clear`, this function is not *always* called before a module is deallocated. For example, when reference counting is enough to

determine that an object is no longer used, the cyclic garbage collector is not involved and `m_free` is called directly.

*Changed in version 3.9:* No longer called before the module state is allocated.

`freefunc m_free`

A function to call during deallocation of the module object, or `NULL` if not needed.

This function is not called if the module state was requested but is not allocated yet. This is the case immediately after the module is created and before the module is executed (`Py_mod_exec` function). More precisely, this function is not called if `m_size` is greater than 0 and the module state (as returned by `PyModule_GetState()`) is `NULL`.

*Changed in version 3.9:* No longer called before the module state is allocated.

## Single-phase initialization

The module initialization function may create and return the module object directly. This is referred to as “single-phase initialization”, and uses one of the following two module creation functions:

`PyObject *PyModule_Create(PyModuleDef *def)`

*Return value:* New reference.

Create a new module object, given the definition in *def*. This behaves like `PyModule_Create2()` with *module\_api\_version* set to `PYTHON_API_VERSION`.

`PyObject *PyModule_Create2(PyModuleDef *def, int module_api_version)`

*Return value:* New reference. Part of the [Stable ABI](#).

Create a new module object, given the definition in *def*,

assuming the API version *module\_api\_version*. If that version does not match the version of the running interpreter, a **RuntimeWarning** is emitted.

### Note

Most uses of this function should be using **PyModule\_Create()** instead; only use this if you are sure you need it.

Before it is returned from in the initialization function, the resulting module object is typically populated using functions like **PyModule\_AddObjectRef()**.

## Multi-phase initialization

An alternate way to specify extensions is to request “multi-phase initialization”. Extension modules created this way behave more like Python modules: the initialization is split between the *creation phase*, when the module object is created, and the *execution phase*, when it is populated. The distinction is similar to the **\_\_new\_\_()** and **\_\_init\_\_()** methods of classes.

Unlike modules created using single-phase initialization, these modules are not singletons: if the *sys.modules* entry is removed and the module is re-imported, a new module object is created, and the old module is subject to normal garbage collection – as with Python modules. By default, multiple modules created from the same definition should be independent: changes to one should not affect the others. This means that all state should be specific to the module object (using e.g. using **PyModule\_GetState()**), or its contents (such as the module’s **\_\_dict\_\_** or individual classes created with **PyType\_FromSpec()**).

All modules created using multi-phase initialization are expected to support **sub-interpreters**. Making sure multiple modules are independent is typically enough to achieve this.

To request multi-phase initialization, the initialization function

(PyInit\_modulename) returns a `PyModuleDef` instance with non-empty `m_slots`. Before it is returned, the `PyModuleDef` instance must be initialized with the following function:

`PyObject *PyModuleDef_Init(PyModuleDef *def)`

*Return value: Borrowed reference. Part of the [Stable ABI](#) since version 3.5.*

Ensures a module definition is a properly initialized Python object that correctly reports its type and reference count.

Returns `def` cast to `PyObject*`, or `NULL` if an error occurred.

*New in version 3.5.*

The `m_slots` member of the module definition must point to an array of `PyModuleDef_Slot` structures:

`type PyModuleDef_Slot`

`int slot`

A slot ID, chosen from the available values explained below.

`void *value`

Value of the slot, whose meaning depends on the slot ID.

*New in version 3.5.*

The `m_slots` array must be terminated by a slot with id 0.

The available slot types are:

`Py_mod_create`

Specifies a function that is called to create the module object itself. The *value* pointer of this slot must point to a function of the signature:

`PyObject *create_module(PyObject *spec, PyModuleDef *def)`

The function receives a `ModuleSpec` instance, as defined in [PEP 451](https://peps.python.org/pep-0451/) [https://peps.python.org/pep-0451/], and the module definition. It should return a new module object, or set an error and return `NULL`.

This function should be kept minimal. In particular, it should not call arbitrary Python code, as trying to import the same module again may result in an infinite loop.

Multiple `Py_mod_create` slots may not be specified in one module definition.

If `Py_mod_create` is not specified, the import machinery will create a normal module object using `PyModule_New()`. The name is taken from `spec`, not the definition, to allow extension modules to dynamically adjust to their place in the module hierarchy and be imported under different names through symlinks, all while sharing a single module definition.

There is no requirement for the returned object to be an instance of `PyModule_Type`. Any type can be used, as long as it supports setting and getting import-related attributes. However, only `PyModule_Type` instances may be returned if the `PyModuleDef` has non-NULL `m_traverse`, `m_clear`, `m_free`; non-zero `m_size`; or slots other than `Py_mod_create`.

## `Py_mod_exec`

Specifies a function that is called to *execute* the module. This is equivalent to executing the code of a Python module: typically, this function adds classes and constants to the module. The signature of the function is:

`int exec_module(PyObject *module)`

If multiple `Py_mod_exec` slots are specified, they are processed in the order they appear in the `m_slots` array.

See [PEP 489](https://peps.python.org/pep-0489/) [https://peps.python.org/pep-0489/] for more details on multi-phase initialization.

## Low-level module creation functions

The following functions are called under the hood when using multi-phase initialization. They can be used directly, for example when creating module objects dynamically. Note that both `PyModule_FromDefAndSpec` and `PyModule_ExecDef` must be called to fully initialize a module.

`PyObject *``PyModule_FromDefAndSpec(PyModuleDef *def,`  
`PyObject *spec)`

*Return value:* New reference.

Create a new module object, given the definition in `def` and the `ModuleSpec spec`. This behaves like

`PyModule_FromDefAndSpec2()` with `module_api_version` set to `PYTHON_API_VERSION`.

*New in version 3.5.*

`PyObject *``PyModule_FromDefAndSpec2(PyModuleDef *def,`  
`PyObject *spec, int module_api_version)`

*Return value:* New reference. Part of the [Stable ABI](#) since version 3.7.

Create a new module object, given the definition in `def` and the `ModuleSpec spec`, assuming the API version `module_api_version`. If that version does not match the version of the running interpreter, a [RuntimeWarning](#) is emitted.

### Note

Most uses of this function should be using `PyModule_FromDefAndSpec()` instead; only use this if you are sure you need it.

*New in version 3.5.*

int PyModule\_ExecDef(PyObject \*module, PyModuleDef \*def)

*Part of the [Stable ABI](#) since version 3.7.*

Process any execution slots ([Py\\_mod\\_exec](#)) given in *def*.

*New in version 3.5.*

int PyModule\_SetDocString(PyObject \*module, const char  
\*docstring)

*Part of the [Stable ABI](#) since version 3.7.*

Set the docstring for *module* to *docstring*. This function is called automatically when creating a module from PyModuleDef, using either PyModule\_Create or PyModule\_FromDefAndSpec.

*New in version 3.5.*

int PyModule\_AddFunctions(PyObject \*module, PyMethodDef  
\*functions)

*Part of the [Stable ABI](#) since version 3.7.*

Add the functions from the NULL terminated *functions* array to *module*. Refer to the [PyMethodDef](#) documentation for details on individual entries (due to the lack of a shared module namespace, module level “functions” implemented in C typically receive the module as their first parameter, making them similar to instance methods on Python classes). This function is called automatically when creating a module from PyModuleDef, using either PyModule\_Create or PyModule\_FromDefAndSpec.

*New in version 3.5.*

## Support functions

The module initialization function (if using single phase initialization) or a function called from a module execution slot (if using multi-phase initialization), can use the following functions to help initialize the module state:

`int PyModule_AddObjectRef(PyObject *module, const char *name, PyObject *value)`

Part of the *Stable ABI* since version 3.10.

Add an object to *module* as *name*. This is a convenience function which can be used from the module's initialization function.

On success, return 0. On error, raise an exception and return -1.

Return NULL if *value* is NULL. It must be called with an exception raised in this case.

Example usage:

```
static int
add_spam(PyObject *module, int value)
{
    PyObject *obj = PyLong_FromLong(value);
    if (obj == NULL) {
        return -1;
    }
    int res = PyModule_AddObjectRef(module, "spam",
    Py_DECREF(obj);
    return res;
}
```

The example can also be written without checking explicitly if *obj* is NULL:

```
static int
add_spam(PyObject *module, int value)
{
    PyObject *obj = PyLong_FromLong(value);
    int res = PyModule_AddObjectRef(module, "spam",
    Py_XDECREF(obj);
    return res;
}
```

Note that `Py_XDECREF()` should be used instead of

`Py_DECREF()` in this case, since *obj* can be `NULL`.

*New in version 3.10.*

```
int PyModule_AddObject(PyObject *module, const char *name,  
PyObject *value)
```

Part of the *Stable ABI*.

Similar to `PyModule_AddObjectRef()`, but steals a reference to *value* on success (if it returns `0`).

The new `PyModule_AddObjectRef()` function is recommended, since it is easy to introduce reference leaks by misusing the `PyModule_AddObject()` function.

### Note

Unlike other functions that steal references, `PyModule_AddObject()` only decrements the reference count of *value* **on success**.

This means that its return value must be checked, and calling code must `Py_DECREF()` *value* manually on error.

Example usage:

```
static int  
add_spam(PyObject *module, int value)  
{  
    PyObject *obj = PyLong_FromLong(value);  
    if (obj == NULL) {  
        return -1;  
    }  
    if (PyModule_AddObject(module, "spam", obj) < 0)  
        Py_DECREF(obj);  
    return -1;  
}  
// PyModule_AddObject() stole a reference to ob  
// Py_DECREF(obj) is not needed here  
return 0;
```

```
}
```

The example can also be written without checking explicitly if *obj* is `NULL`:

```
static int
add_spam(PyObject *module, int value)
{
    PyObject *obj = PyLong_FromLong(value);
    if (PyModule_AddObject(module, "spam", obj) < 0)
        Py_XDECREF(obj);
    return -1;
}
// PyModule_AddObject() stole a reference to obj
// Py_DECREF(obj) is not needed here
return 0;
}
```

Note that `Py_XDECREF()` should be used instead of `Py_DECREF()` in this case, since *obj* can be `NULL`.

`int PyModule_AddIntConstant(PyObject *module, const char *name, long value)`

*Part of the [Stable ABI](#).*

Add an integer constant to *module* as *name*. This convenience function can be used from the module's initialization function. Return `-1` on error, `0` on success.

`int PyModule_AddStringConstant(PyObject *module, const char *name, const char *value)`

*Part of the [Stable ABI](#).*

Add a string constant to *module* as *name*. This convenience function can be used from the module's initialization function. The string *value* must be `NULL`-terminated. Return `-1` on error, `0` on success.

`int PyModule_AddIntMacro(PyObject *module, macro)`

Add an int constant to *module*. The name and the value are

taken from *macro*. For example

`PyModule_AddIntMacro(module, AF_INET)` adds the int constant `AF_INET` with the value of `AF_INET` to *module*.

Return `-1` on error, `0` on success.

`int PyModule_AddStringMacro(PyObject *module, macro)`

Add a string constant to *module*.

`int PyModule_AddType(PyObject *module, PyTypeObject *type)`

Part of the *Stable ABI* since version 3.10.

Add a type object to *module*. The type object is finalized by calling internally `PyType_Ready()`. The name of the type object is taken from the last component of `tp_name` after dot. Return `-1` on error, `0` on success.

*New in version 3.9.*

## Module lookup

Single-phase initialization creates singleton modules that can be looked up in the context of the current interpreter. This allows the module object to be retrieved later with only a reference to the module definition.

These functions will not work on modules created using multi-phase initialization, since multiple such modules can be created from a single definition.

`PyObject *PyState_FindModule(PyModuleDef *def)`

*Return value:* Borrowed reference. Part of the *Stable ABI*.

Returns the module object that was created from *def* for the current interpreter. This method requires that the module object has been attached to the interpreter state with `PyState_AddModule()` beforehand. In case the corresponding module object is not found or has not been attached to the interpreter state yet, it returns `NULL`.

`int PyState_AddModule(PyObject *module, PyModuleDef *def)`

*Part of the [Stable ABI](#) since version 3.3.*

Attaches the module object passed to the function to the interpreter state. This allows the module object to be accessible via `PyState_FindModule()`.

Only effective on modules created using single-phase initialization.

Python calls `PyState_AddModule` automatically after importing a module, so it is unnecessary (but harmless) to call it from module initialization code. An explicit call is needed only if the module's own init code subsequently calls `PyState_FindModule`. The function is mainly intended for implementing alternative import mechanisms (either by calling it directly, or by referring to its implementation for details of the required state updates).

The caller must hold the GIL.

Return 0 on success or -1 on failure.

*New in version 3.3.*

`int PyState_RemoveModule(PyModuleDef *def)`

*Part of the [Stable ABI](#) since version 3.3.*

Removes the module object created from *def* from the interpreter state. Return 0 on success or -1 on failure.

The caller must hold the GIL.

*New in version 3.3.*

# Iterator Objects

Python provides two general-purpose iterator objects. The first, a sequence iterator, works with an arbitrary sequence supporting the `__getitem__()` method. The second works with a callable object and a sentinel value, calling the callable for each item in the sequence, and ending the iteration when the sentinel value is returned.

**PyObject** PySeqIter\_Type

*Part of the [Stable ABI](#).*

Type object for iterator objects returned by [PySeqIter\\_New\(\)](#) and the one-argument form of the [iter\(\)](#) built-in function for built-in sequence types.

int PySeqIter\_Check(op)

Return true if the type of *op* is [PySeqIter\\_Type](#). This function always succeeds.

**PyObject** \*PySeqIter\_New(**PyObject** \*seq)

*Return value: New reference. Part of the [Stable ABI](#).*

Return an iterator that works with a general sequence object, *seq*. The iteration ends when the sequence raises [IndexError](#) for the subscripting operation.

**PyObject** PyCallIter\_Type

*Part of the [Stable ABI](#).*

Type object for iterator objects returned by [PyCallIter\\_New\(\)](#) and the two-argument form of the [iter\(\)](#) built-in function.

int PyCallIter\_Check(op)

Return true if the type of *op* is [PyCallIter\\_Type](#). This function always succeeds.

`PyObject *PyCallIter_New(PyObject *callable, PyObject *sentinel)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return a new iterator. The first parameter, *callable*, can be any Python callable object that can be called with no parameters; each call to it should return the next item in the iteration. When *callable* returns a value equal to *sentinel*, the iteration will be terminated.

# Descriptor Objects

“Descriptors” are objects that describe some attribute of an object. They are found in the dictionary of type objects.

`PyTypeObject` `PyProperty_Type`

*Part of the [Stable ABI](#).*

The type object for the built-in descriptor types.

`PyObject` \*`PyDescr_NewGetSet(PyTypeObject` \*type, struct `PyGetSetDef` \*getset)

*Return value: New reference. Part of the [Stable ABI](#).*

`PyObject` \*`PyDescr_NewMember(PyTypeObject` \*type, struct `PyMemberDef` \*meth)

*Return value: New reference. Part of the [Stable ABI](#).*

`PyObject` \*`PyDescr_NewMethod(PyTypeObject` \*type, struct `PyMethodDef` \*meth)

*Return value: New reference. Part of the [Stable ABI](#).*

`PyObject` \*`PyDescr_NewWrapper(PyTypeObject` \*type, struct `wrapperbase` \*wrapper, void \*wrapped)

*Return value: New reference.*

`PyObject` \*`PyDescr_NewClassMethod(PyTypeObject` \*type, `PyMethodDef` \*method)

*Return value: New reference. Part of the [Stable ABI](#).*

`int` `PyDescr_IsData(PyObject` \*descr)

Return non-zero if the descriptor objects *descr* describes a

data attribute, or 0 if it describes a method. *descr* must be a descriptor object; there is no error checking.

`PyObject*` `PyWrapper_New(PyObject*, PyObject*)`

*Return value:* New reference. Part of the [Stable ABI](#).

# Slice Objects

`PyTypeObject` `PySlice_Type`

*Part of the [Stable ABI](#).*

The type object for slice objects. This is the same as `slice` in the Python layer.

`int` `PySlice_Check(PyObject *ob)`

Return true if `ob` is a slice object; `ob` must not be `NULL`. This function always succeeds.

`PyObject *``PySlice_New(PyObject *start, PyObject *stop, PyObject *step)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return a new slice object with the given values. The `start`, `stop`, and `step` parameters are used as the values of the slice object attributes of the same names. Any of the values may be `NULL`, in which case the `None` will be used for the corresponding attribute. Return `NULL` if the new object could not be allocated.

`int` `PySlice_GetIndices(PyObject *slice, Py_ssize_t length, Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t *step)`

*Part of the [Stable ABI](#).*

Retrieve the start, stop and step indices from the slice object `slice`, assuming a sequence of length `length`. Treats indices greater than `length` as errors.

Returns `0` on success and `-1` on error with no exception set (unless one of the indices was not `None` and failed to be converted to an integer, in which case `-1` is returned with an exception set).

You probably do not want to use this function.

*Changed in version 3.2:* The parameter type for the *slice* parameter was `PySliceObject*` before.

```
int PySlice_GetIndicesEx(PyObject *slice, Py_ssize_t length,  
Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t *step, Py_ssize_t  
*slicelength)
```

Part of the *Stable ABI*.

Usable replacement for `PySlice_GetIndices()`. Retrieve the start, stop, and step indices from the slice object *slice* assuming a sequence of length *length*, and store the length of the slice in *slicelength*. Out of bounds indices are clipped in a manner consistent with the handling of normal slices.

Returns 0 on success and -1 on error with exception set.

### Note

This function is considered not safe for resizable sequences. Its invocation should be replaced by a combination of `PySlice_Unpack()` and `PySlice_AdjustIndices()` where

```
if (PySlice_GetIndicesEx(slice, length, &start, &stop, &step, &slicelength) != 0)  
    // return error  
}
```

is replaced by

```
if (PySlice_Unpack(slice, &start, &stop, &step) < 0)  
    // return error  
}  
slicelength = PySlice_AdjustIndices(length, &start, &stop, &step);
```

*Changed in version 3.2:* The parameter type for the *slice* parameter was `PySliceObject*` before.

*Changed in version 3.6.1:* If `Py_LIMITED_API` is not set or set to the value between `0x03050400` and `0x03060000` (not including) or `0x03060100` or higher `PySlice_GetIndicesEx()` is implemented as a macro

using **PySlice\_Unpack()** and **PySlice\_AdjustIndices()**. Arguments *start*, *stop* and *step* are evaluated more than once.

*Deprecated since version 3.6.1:* If `Py_LIMITED_API` is set to the value less than `0x03050400` or between `0x03060000` and `0x03060100` (not including)

**PySlice\_GetIndicesEx()** is a deprecated function.

```
int PySlice_Unpack(PyObject *slice, Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t *step)
```

*Part of the [Stable ABI](#) since version 3.7.*

Extract the start, stop and step data members from a slice object as C integers. Silently reduce values larger than `PY_SSIZE_T_MAX` to `PY_SSIZE_T_MAX`, silently boost the start and stop values less than `PY_SSIZE_T_MIN` to `PY_SSIZE_T_MIN`, and silently boost the step values less than `-PY_SSIZE_T_MAX` to `-PY_SSIZE_T_MAX`.

Return `-1` on error, `0` on success.

*New in version 3.6.1.*

```
Py_ssize_t PySlice_AdjustIndices(Py_ssize_t length, Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t step)
```

*Part of the [Stable ABI](#) since version 3.7.*

Adjust start/end slice indices assuming a sequence of the specified length. Out of bounds indices are clipped in a manner consistent with the handling of normal slices.

Return the length of the slice. Always successful. Doesn't call Python code.

*New in version 3.6.1.*

## Ellipsis Object

```
PyObject *Py_Ellipsis
```

The Python `Ellipsis` object. This object has no methods. It needs to be treated just like any other object with respect to reference counts. Like `Py_None` it is a singleton object.

# MemoryView objects

A **memoryview** object exposes the C level **buffer interface** as a Python object which can then be passed around like any other object.

**PyObject** \*PyMemoryView\_FromObject(PyObject \*obj)

*Return value:* New reference. Part of the **Stable ABI**.

Create a memoryview object from an object that provides the buffer interface. If *obj* supports writable buffer exports, the memoryview object will be read/write, otherwise it may be either read-only or read/write at the discretion of the exporter.

**PyObject** \*PyMemoryView\_FromMemory(char \*mem, Py\_ssize\_t size, int flags)

*Return value:* New reference. Part of the **Stable ABI** since version 3.7.

Create a memoryview object using *mem* as the underlying buffer. *flags* can be one of **PyBUF\_READ** or **PyBUF\_WRITE**.

*New in version 3.3.*

**PyObject** \*PyMemoryView\_FromBuffer(const **Py\_buffer** \*view)

*Return value:* New reference. Part of the **Stable ABI** since version 3.11.

Create a memoryview object wrapping the given buffer structure *view*. For simple byte buffers,

**PyMemoryView\_FromMemory()** is the preferred function.

**PyObject** \*PyMemoryView\_GetContiguous(PyObject \*obj, int buffertype, char order)

*Return value:* New reference. Part of the **Stable ABI**.

Create a memoryview object to a **contiguous** chunk of

memory (in either 'C' or 'F' or *tran order*) from an object that defines the buffer interface. If memory is contiguous, the `memoryview` object points to the original memory. Otherwise, a copy is made and the `memoryview` points to a new bytes object.

`int PyMemoryView_Check(PyObject *obj)`

Return true if the object *obj* is a `memoryview` object. It is not currently allowed to create subclasses of `memoryview`. This function always succeeds.

`Py_buffer *PyMemoryView_GET_BUFFER(PyObject *mview)`

Return a pointer to the `memoryview`'s private copy of the exporter's buffer. *mview* **must** be a `memoryview` instance; this macro doesn't check its type, you must do it yourself or you will risk crashes.

`PyObject *PyMemoryView_GET_BASE(PyObject *mview)`

Return either a pointer to the exporting object that the `memoryview` is based on or `NULL` if the `memoryview` has been created by one of the functions

`PyMemoryView_FromMemory()` or

`PyMemoryView_FromBuffer()`. *mview* **must** be a `memoryview` instance.

# Weak Reference Objects

Python supports *weak references* as first-class objects. There are two specific object types which directly implement weak references. The first is a simple reference object, and the second acts as a proxy for the original object as much as it can.

`int PyWeakref_Check(ob)`

Return true if *ob* is either a reference or proxy object. This function always succeeds.

`int PyWeakref_CheckRef(ob)`

Return true if *ob* is a reference object. This function always succeeds.

`int PyWeakref_CheckProxy(ob)`

Return true if *ob* is a proxy object. This function always succeeds.

`PyObject *PyWeakref_NewRef(PyObject *ob, PyObject *callback)`

*Return value:* New reference. Part of the [Stable ABI](#).

Return a weak reference object for the object *ob*. This will always return a new reference, but is not guaranteed to create a new object; an existing reference object may be returned. The second parameter, *callback*, can be a callable object that receives notification when *ob* is garbage collected; it should accept a single parameter, which will be the weak reference object itself. *callback* may also be `None` or `NULL`. If *ob* is not a weakly referencable object, or if *callback* is not callable, `None`, or `NULL`, this will return `NULL` and raise [TypeError](#).

`PyObject *PyWeakref_NewProxy(PyObject *ob, PyObject *callback)`

*Return value: New reference. Part of the [Stable ABI](#).*

Return a weak reference proxy object for the object *ob*. This will always return a new reference, but is not guaranteed to create a new object; an existing proxy object may be returned. The second parameter, *callback*, can be a callable object that receives notification when *ob* is garbage collected; it should accept a single parameter, which will be the weak reference object itself. *callback* may also be `None` or `NULL`. If *ob* is not a weakly referencable object, or if *callback* is not callable, `None`, or `NULL`, this will return `NULL` and raise **`TypeError`**.

**`PyObject *`**`PyWeakref_GetObject(PyObject *ref)`

*Return value: Borrowed reference. Part of the [Stable ABI](#).*

Return the referenced object from a weak reference, *ref*. If the referent is no longer live, returns **`Py_None`**.

### Note

This function returns a [borrowed reference](#) to the referenced object. This means that you should always call **`Py_INCREF()`** on the object except when it cannot be destroyed before the last usage of the borrowed reference.

**`PyObject *`**`PyWeakref_GET_OBJECT(PyObject *ref)`

*Return value: Borrowed reference.*

Similar to **`PyWeakref_GetObject()`**, but does no error checking.

**`void`** `PyObject_ClearWeakRefs(PyObject *object)`

*Part of the [Stable ABI](#).*

This function is called by the **`tp_dealloc`** handler to clear weak references.

This iterates through the weak references for *object* and calls callbacks for those references which have one. It returns when all callbacks have been attempted.

# Capsules

Refer to [Providing a C API for an Extension Module](#) for more information on using these objects.

*New in version 3.1.*

type `PyCapsule`

This subtype of `PyObject` represents an opaque value, useful for C extension modules who need to pass an opaque value (as a `void*` pointer) through Python code to other C code. It is often used to make a C function pointer defined in one module available to other modules, so the regular import mechanism can be used to access C APIs defined in dynamically loaded modules.

type `PyCapsule_Destructor`

*Part of the [Stable ABI](#).*

The type of a destructor callback for a capsule. Defined as:

```
typedef void (*PyCapsule_Destructor) (PyObject *);
```

See `PyCapsule_New()` for the semantics of `PyCapsule_Destructor` callbacks.

int `PyCapsule_CheckExact(PyObject *p)`

Return true if its argument is a `PyCapsule`. This function always succeeds.

`PyObject *``PyCapsule_New(void *pointer, const char *name, PyCapsule_Destructor destructor)`

*Return value:* New reference. *Part of the [Stable ABI](#).*

Create a `PyCapsule` encapsulating the *pointer*. The *pointer* argument may not be `NULL`.

On failure, set an exception and return `NULL`.

The *name* string may either be `NULL` or a pointer to a valid C string. If non-`NULL`, this string must outlive the capsule. (Though it is permitted to free it inside the *destructor*.)

If the *destructor* argument is not `NULL`, it will be called with the capsule as its argument when it is destroyed.

If this capsule will be stored as an attribute of a module, the *name* should be specified as `modulename.attributename`. This will enable other modules to import the capsule using `PyCapsule_Import()`.

`void *PyCapsule_GetPointer(PyObject *capsule, const char *name)`

*Part of the [Stable ABI](#).*

Retrieve the *pointer* stored in the capsule. On failure, set an exception and return `NULL`.

The *name* parameter must compare exactly to the name stored in the capsule. If the name stored in the capsule is `NULL`, the *name* passed in must also be `NULL`. Python uses the C function `strcmp()` to compare capsule names.

`PyCapsule_Destructor PyCapsule_GetDestructor(PyObject *capsule)`

*Part of the [Stable ABI](#).*

Return the current destructor stored in the capsule. On failure, set an exception and return `NULL`.

It is legal for a capsule to have a `NULL` destructor. This makes a `NULL` return code somewhat ambiguous; use `PyCapsule_IsValid()` or `PyErr_Occurred()` to disambiguate.

`void *PyCapsule_GetContext(PyObject *capsule)`

*Part of the [Stable ABI](#).*

Return the current context stored in the capsule. On failure, set an exception and return `NULL`.

It is legal for a capsule to have a `NULL` context. This makes a `NULL` return code somewhat ambiguous; use `PyCapsule_IsValid()` or `PyErr_Occurred()` to disambiguate.

```
const char *PyCapsule_GetName(PyObject *capsule)
```

*Part of the [Stable ABI](#).*

Return the current name stored in the capsule. On failure, set an exception and return `NULL`.

It is legal for a capsule to have a `NULL` name. This makes a `NULL` return code somewhat ambiguous; use `PyCapsule_IsValid()` or `PyErr_Occurred()` to disambiguate.

```
void *PyCapsule_Import(const char *name, int no_block)
```

*Part of the [Stable ABI](#).*

Import a pointer to a C object from a capsule attribute in a module. The *name* parameter should specify the full name to the attribute, as in `module.attribute`. The *name* stored in the capsule must match this string exactly.

Return the capsule's internal *pointer* on success. On failure, set an exception and return `NULL`.

*Changed in version 3.3: `no_block` has no effect anymore.*

```
int PyCapsule_IsValid(PyObject *capsule, const char *name)
```

*Part of the [Stable ABI](#).*

Determines whether or not *capsule* is a valid capsule. A valid capsule is non-`NULL`, passes `PyCapsule_CheckExact()`, has a non-`NULL` pointer stored in it, and its internal name matches the *name* parameter. (See `PyCapsule_GetPointer()` for information on how capsule names are compared.)

In other words, if `PyCapsule_IsValid()` returns a true value, calls to any of the accessors (any function starting with `PyCapsule_Get()`) are guaranteed to succeed.

Return a nonzero value if the object is valid and matches the name passed in. Return 0 otherwise. This function will not fail.

int PyCapsule\_SetContext(PyObject \*capsule, void \*context)

*Part of the [Stable ABI](#).*

Set the context pointer inside *capsule* to *context*.

Return 0 on success. Return nonzero and set an exception on failure.

int PyCapsule\_SetDestructor(PyObject \*capsule,  
[PyCapsule\\_Destructor](#) destructor)

*Part of the [Stable ABI](#).*

Set the destructor inside *capsule* to *destructor*.

Return 0 on success. Return nonzero and set an exception on failure.

int PyCapsule\_SetName(PyObject \*capsule, const char \*name)

*Part of the [Stable ABI](#).*

Set the name inside *capsule* to *name*. If non-NULL, the name must outlive the capsule. If the previous *name* stored in the capsule was not NULL, no attempt is made to free it.

Return 0 on success. Return nonzero and set an exception on failure.

int PyCapsule\_SetPointer(PyObject \*capsule, void \*pointer)

*Part of the [Stable ABI](#).*

Set the void pointer inside *capsule* to *pointer*. The pointer may not be NULL.

Return 0 on success. Return nonzero and set an exception on failure.

# Frame Objects

type PyFrameObject

*Part of the [Limited API](#) (as an opaque struct).*

The C structure of the objects used to describe frame objects.

There are no public members in this structure.

*Changed in version 3.11:* The members of this structure were removed from the public C API. Refer to the [What's New entry](#) for details.

The [PyEval\\_GetFrame\(\)](#) and [PyThreadState\\_GetFrame\(\)](#) functions can be used to get a frame object.

See also [Reflection](#).

[PyTypeObject](#) PyFrame\_Type

The type of frame objects. It is the same object as [types.FrameType](#) in the Python layer.

*Changed in version 3.11:* Previously, this type was only available after including `<frameobject.h>`.

int PyFrame\_Check([PyObject](#) \*obj)

Return non-zero if *obj* is a frame object.

*Changed in version 3.11:* Previously, this function was only available after including `<frameobject.h>`.

[PyFrameObject](#) \*PyFrame\_GetBack([PyFrameObject](#) \*frame)

Get the *frame* next outer frame.

Return a [strong reference](#), or NULL if *frame* has no outer frame.

*New in version 3.9.*

**PyObject \***PyFrame\_GetBuiltins(**PyFrameObject \***frame)

Get the *frame*'s `f_builtins` attribute.

Return a [strong reference](#). The result cannot be `NULL`.

*New in version 3.11.*

**PyCodeObject \***PyFrame\_GetCode(**PyFrameObject \***frame)

Part of the [Stable ABI](#) since version 3.10.

Get the *frame* code.

Return a [strong reference](#).

The result (frame code) cannot be `NULL`.

*New in version 3.9.*

**PyObject \***PyFrame\_GetGenerator(**PyFrameObject \***frame)

Get the generator, coroutine, or async generator that owns this frame, or `NULL` if this frame is not owned by a generator. Does not raise an exception, even if the return value is `NULL`.

Return a [strong reference](#), or `NULL`.

*New in version 3.11.*

**PyObject \***PyFrame\_GetGlobals(**PyFrameObject \***frame)

Get the *frame*'s `f_globals` attribute.

Return a [strong reference](#). The result cannot be `NULL`.

*New in version 3.11.*

**int** PyFrame\_GetLasti(**PyFrameObject \***frame)

Get the *frame*'s `f_lasti` attribute.

Returns -1 if `frame.f_lasti` is `None`.

*New in version 3.11.*

`PyObject *``PyFrame_GetLocals(PyFrameObject *frame)`

Get the *frame*'s `f_locals` attribute (`dict`).

Return a [strong reference](#).

*New in version 3.11.*

`int` `PyFrame_GetLineNumber(PyFrameObject *frame)`

*Part of the [Stable ABI](#) since version 3.10.*

Return the line number that *frame* is currently executing.

# Generator Objects

Generator objects are what Python uses to implement generator iterators. They are normally created by iterating over a function that yields values, rather than explicitly calling `PyGen_New()` or `PyGen_NewWithQualName()`.

type PyGenObject

The C structure used for generator objects.

PyTypeObject PyGen\_Type

The type object corresponding to generator objects.

int PyGen\_Check(PyObject \*ob)

Return true if *ob* is a generator object; *ob* must not be NULL. This function always succeeds.

int PyGen\_CheckExact(PyObject \*ob)

Return true if *ob*'s type is `PyGen_Type`; *ob* must not be NULL. This function always succeeds.

PyObject \*PyGen\_New(PyFrameObject \*frame)

*Return value:* New reference.

Create and return a new generator object based on the *frame* object. A reference to *frame* is stolen by this function. The argument must not be NULL.

PyObject \*PyGen\_NewWithQualName(PyFrameObject \*frame,  
PyObject \*name, PyObject \*qualname)

*Return value:* New reference.

Create and return a new generator object based on the *frame* object, with `__name__` and `__qualname__` set to *name* and *qualname*. A reference to *frame* is stolen by this function. The

*frame* argument must not be NULL.

# Coroutine Objects

*New in version 3.5.*

Coroutine objects are what functions declared with an `async` keyword return.

`type PyCoroObject`

The C structure used for coroutine objects.

`PyTypeObject PyCoro_Type`

The type object corresponding to coroutine objects.

`int PyCoro_CheckExact(PyObject *ob)`

Return true if *ob*'s type is `PyCoro_Type`; *ob* must not be NULL. This function always succeeds.

`PyObject *PyCoro_New(PyFrameObject *frame, PyObject *name, PyObject *qualname)`

*Return value:* New reference.

Create and return a new coroutine object based on the *frame* object, with `__name__` and `__qualname__` set to *name* and *qualname*. A reference to *frame* is stolen by this function. The *frame* argument must not be NULL.

# Context Variables Objects

*Changed in version 3.7.1:*

## Note

In Python 3.7.1 the signatures of all context variables C APIs were **changed** to use `PyObject` pointers instead of `PyContext`, `PyContextVar`, and `PyContextToken`, e.g.:

```
// in 3.7.0:  
PyContext *PyContext_New(void);
```

```
// in 3.7.1+:  
PyObject *PyContext_New(void);
```

See [bpo-34762](https://bugs.python.org/issue?@action=redirect&bpo=34762) [<https://bugs.python.org/issue?@action=redirect&bpo=34762>] for more details.

*New in version 3.7.*

This section details the public C API for the `contextvars` module.

type `PyContext`

The C structure used to represent a `contextvars.Context` object.

type `PyContextVar`

The C structure used to represent a `contextvars.ContextVar` object.

type `PyContextToken`

The C structure used to represent a `contextvars.Token` object.

**PyObject** PyContext\_Type

The type object representing the *context* type.

**PyObject** PyContextVar\_Type

The type object representing the *context variable* type.

**PyObject** PyContextToken\_Type

The type object representing the *context variable token* type.

Type-check macros:

int PyContext\_CheckExact(**PyObject** \*o)

Return true if *o* is of type **PyContext\_Type**. *o* must not be NULL. This function always succeeds.

int PyContextVar\_CheckExact(**PyObject** \*o)

Return true if *o* is of type **PyContextVar\_Type**. *o* must not be NULL. This function always succeeds.

int PyContextToken\_CheckExact(**PyObject** \*o)

Return true if *o* is of type **PyContextToken\_Type**. *o* must not be NULL. This function always succeeds.

Context object management functions:

**PyObject** \*PyContext\_New(void)

*Return value:* New reference.

Create a new empty context object. Returns NULL if an error has occurred.

**PyObject** \*PyContext\_Copy(**PyObject** \*ctx)

*Return value:* New reference.

Create a shallow copy of the passed *ctx* context object. Returns NULL if an error has occurred.

**PyObject** \*PyContext\_CopyCurrent(void)

*Return value: New reference.*

Create a shallow copy of the current thread context. Returns `NULL` if an error has occurred.

`int PyContext_Enter(PyObject *ctx)`

Set `ctx` as the current context for the current thread. Returns `0` on success, and `-1` on error.

`int PyContext_Exit(PyObject *ctx)`

Deactivate the `ctx` context and restore the previous context as the current context for the current thread. Returns `0` on success, and `-1` on error.

Context variable functions:

`PyObject *PyContextVar_New(const char *name, PyObject *def)`

*Return value: New reference.*

Create a new `ContextVar` object. The *name* parameter is used for introspection and debug purposes. The *def* parameter specifies a default value for the context variable, or `NULL` for no default. If an error has occurred, this function returns `NULL`.

`int PyContextVar_Get(PyObject *var, PyObject *default_value, PyObject **value)`

Get the value of a context variable. Returns `-1` if an error has occurred during lookup, and `0` if no error occurred, whether or not a value was found.

If the context variable was found, *value* will be a pointer to it. If the context variable was *not* found, *value* will point to:

- *default value*, if not `NULL`;
- the default value of *var*, if not `NULL`;
- `NULL`

Except for `NULL`, the function returns a new reference.

`PyObject *PyContextVar_Set(PyObject *var, PyObject *value)`

*Return value: New reference.*

Set the value of *var* to *value* in the current context. Returns a new token object for this change, or `NULL` if an error has occurred.

`int PyContextVar_Reset(PyObject *var, PyObject *token)`

Reset the state of the *var* context variable to that it was in before `PyContextVar_Set ()` that returned the *token* was called. This function returns `0` on success and `-1` on error.

# DateTime Objects

Various date and time objects are supplied by the `datetime` module. Before using any of these functions, the header file `datetime.h` must be included in your source (note that this is not included by `Python.h`), and the macro `PyDateTime_IMPORT` must be invoked, usually as part of the module initialisation function. The macro puts a pointer to a C structure into a static variable, `PyDateTimeAPI`, that is used by the following macros.

Macro for access to the UTC singleton:

`PyObject *PyDateTime_TimeZone_UTC`

Returns the time zone singleton representing UTC, the same object as `datetime.timezone.utc`.

*New in version 3.7.*

Type-check macros:

`int PyDate_Check(PyObject *ob)`

Return true if `ob` is of type `PyDateTime_DateType` or a subtype of `PyDateTime_DateType`. `ob` must not be `NULL`. This function always succeeds.

`int PyDate_CheckExact(PyObject *ob)`

Return true if `ob` is of type `PyDateTime_DateType`. `ob` must not be `NULL`. This function always succeeds.

`int PyDateTime_Check(PyObject *ob)`

Return true if `ob` is of type `PyDateTime_DateTimeType` or a subtype of `PyDateTime_DateTimeType`. `ob` must not be `NULL`. This function always succeeds.

`int PyDateTime_CheckExact(PyObject *ob)`

Return true if *ob* is of type **PyDateTime\_DateTimeType**.  
*ob* must not be `NULL`. This function always succeeds.

`int PyTime_Check(PyObject *ob)`

Return true if *ob* is of type **PyDateTime\_TimeType** or a  
subtype of **PyDateTime\_TimeType**. *ob* must not be `NULL`.  
This function always succeeds.

`int PyTime_CheckExact(PyObject *ob)`

Return true if *ob* is of type **PyDateTime\_TimeType**. *ob*  
must not be `NULL`. This function always succeeds.

`int PyDelta_Check(PyObject *ob)`

Return true if *ob* is of type **PyDateTime\_DeltaType** or a  
subtype of **PyDateTime\_DeltaType**. *ob* must not be `NULL`.  
This function always succeeds.

`int PyDelta_CheckExact(PyObject *ob)`

Return true if *ob* is of type **PyDateTime\_DeltaType**. *ob*  
must not be `NULL`. This function always succeeds.

`int PyTZInfo_Check(PyObject *ob)`

Return true if *ob* is of type **PyDateTime\_TZInfoType** or a  
subtype of **PyDateTime\_TZInfoType**. *ob* must not be  
`NULL`. This function always succeeds.

`int PyTZInfo_CheckExact(PyObject *ob)`

Return true if *ob* is of type **PyDateTime\_TZInfoType**. *ob*  
must not be `NULL`. This function always succeeds.

Macros to create objects:

`PyObject *PyDate_FromDate(int year, int month, int day)`

*Return value:* New reference.

Return a `datetime.date` object with the specified year,

month and day.

**PyObject \***PyDateTime\_FromDateAndTime(int year, int month, int day, int hour, int minute, int second, int usecond)

*Return value: New reference.*

Return a **datetime.datetime** object with the specified year, month, day, hour, minute, second and microsecond.

**PyObject \***PyDateTime\_FromDateAndTimeAndFold(int year, int month, int day, int hour, int minute, int second, int usecond, int fold)

*Return value: New reference.*

Return a **datetime.datetime** object with the specified year, month, day, hour, minute, second, microsecond and fold.

*New in version 3.6.*

**PyObject \***PyTime\_FromTime(int hour, int minute, int second, int usecond)

*Return value: New reference.*

Return a **datetime.time** object with the specified hour, minute, second and microsecond.

**PyObject \***PyTime\_FromTimeAndFold(int hour, int minute, int second, int usecond, int fold)

*Return value: New reference.*

Return a **datetime.time** object with the specified hour, minute, second, microsecond and fold.

*New in version 3.6.*

**PyObject \***PyDelta\_FromDSU(int days, int seconds, int useconds)

*Return value: New reference.*

Return a **datetime.timedelta** object representing the given number of days, seconds and microseconds.

Normalization is performed so that the resulting number of

microseconds and seconds lie in the ranges documented for `datetime.timedelta` objects.

**PyObject** \*PyTimeZone\_FromOffset(PyDateTime\_DeltaType \*offset)

*Return value:* New reference.

Return a `datetime.timezone` object with an unnamed fixed offset represented by the *offset* argument.

*New in version 3.7.*

**PyObject**

\*PyTimeZone\_FromOffsetAndName(PyDateTime\_DeltaType \*offset,  
PyUnicode \*name)

*Return value:* New reference.

Return a `datetime.timezone` object with a fixed offset represented by the *offset* argument and with tzname *name*.

*New in version 3.7.*

Macros to extract fields from date objects. The argument must be an instance of **PyDateTime\_Date**, including subclasses (such as **PyDateTime\_DateTime**). The argument must not be `NULL`, and the type is not checked:

int PyDateTime\_GET\_YEAR(PyDateTime\_Date \*o)

Return the year, as a positive int.

int PyDateTime\_GET\_MONTH(PyDateTime\_Date \*o)

Return the month, as an int from 1 through 12.

int PyDateTime\_GET\_DAY(PyDateTime\_Date \*o)

Return the day, as an int from 1 through 31.

Macros to extract fields from datetime objects. The argument must be an instance of **PyDateTime\_DateTime**, including subclasses. The argument must not be `NULL`, and the type is not checked:

`int PyDateTime_DATE_GET_HOUR(PyDateTime_DateTime *o)`

Return the hour, as an int from 0 through 23.

`int PyDateTime_DATE_GET_MINUTE(PyDateTime_DateTime *o)`

Return the minute, as an int from 0 through 59.

`int PyDateTime_DATE_GET_SECOND(PyDateTime_DateTime *o)`

Return the second, as an int from 0 through 59.

`int PyDateTime_DATE_GET_MICROSECOND(PyDateTime_DateTime *o)`

Return the microsecond, as an int from 0 through 999999.

`int PyDateTime_DATE_GET_FOLD(PyDateTime_DateTime *o)`

Return the fold, as an int from 0 through 1.

*New in version 3.6.*

`PyObject *PyDateTime_DATE_GET_TZINFO(PyDateTime_DateTime *o)`

Return the tzinfo (which may be `None`).

*New in version 3.10.*

Macros to extract fields from time objects. The argument must be an instance of **PyDateTime\_Time**, including subclasses. The argument must not be `NULL`, and the type is not checked:

`int PyDateTime_TIME_GET_HOUR(PyDateTime_Time *o)`

Return the hour, as an int from 0 through 23.

`int PyDateTime_TIME_GET_MINUTE(PyDateTime_Time *o)`

Return the minute, as an int from 0 through 59.

`int PyDateTime_TIME_GET_SECOND(PyDateTime_Time *o)`

Return the second, as an int from 0 through 59.

`int PyDateTime_TIME_GET_MICROSECOND(PyDateTime_Time *o)`

Return the microsecond, as an int from 0 through 999999.

`int PyDateTime_TIME_GET_FOLD(PyDateTime_Time *o)`

Return the fold, as an int from 0 through 1.

*New in version 3.6.*

`PyObject *PyDateTime_TIME_GET_TZINFO(PyDateTime_Time *o)`

Return the tzinfo (which may be `None`).

*New in version 3.10.*

Macros to extract fields from time delta objects. The argument must be an instance of **`PyDateTime_Delta`**, including subclasses. The argument must not be `NULL`, and the type is not checked:

`int PyDateTime_DELTA_GET_DAYS(PyDateTime_Delta *o)`

Return the number of days, as an int from -999999999 to 999999999.

*New in version 3.3.*

`int PyDateTime_DELTA_GET_SECONDS(PyDateTime_Delta *o)`

Return the number of seconds, as an int from 0 through 86399.

*New in version 3.3.*

`int PyDateTime_DELTA_GET_MICROSECONDS(PyDateTime_Delta *o)`

Return the number of microseconds, as an int from 0 through 999999.

*New in version 3.3.*

Macros for the convenience of modules implementing the DB API:

`PyObject *PyDateTime_FromTimestamp(PyObject *args)`

*Return value: New reference.*

Create and return a new `datetime.datetime` object given an argument tuple suitable for passing to `datetime.datetime.fromtimestamp()`.

`PyObject *PyDate_FromTimestamp(PyObject *args)`

*Return value: New reference.*

Create and return a new `datetime.date` object given an argument tuple suitable for passing to `datetime.date.fromtimestamp()`.

# Objects for Type Hinting

Various built-in types for type hinting are provided. Currently, two types exist – [GenericAlias](#) and [Union](#). Only `GenericAlias` is exposed to C.

`PyObject *Py_GenericAlias(PyObject *origin, PyObject *args)`

*Part of the [Stable ABI](#) since version 3.9.*

Create a [GenericAlias](#) object. Equivalent to calling the Python class `types.GenericAlias`. The *origin* and *args* arguments set the `GenericAlias`'s `__origin__` and `__args__` attributes respectively. *origin* should be a [PyTypeObject\\*](#), and *args* can be a [PyTupleObject\\*](#) or any `PyObject*`. If *args* passed is not a tuple, a 1-tuple is automatically constructed and `__args__` is set to `(args,)`. Minimal checking is done for the arguments, so the function will succeed even if *origin* is not a type. The `GenericAlias`'s `__parameters__` attribute is constructed lazily from `__args__`. On failure, an exception is raised and `NULL` is returned.

Here's an example of how to make an extension type generic:

```
...
static PyMethodDef my_obj_methods[] = {
    // Other methods.
    ...
    {"__class_getitem__", Py_GenericAlias, METH_O|METH_NOARGS},
    ...
}
```

## See also

The data model method `__class_getitem__()`.

*New in version 3.9.*

**PyTypeObject** `Py_GenericAliasType`

*Part of the [Stable ABI](#) since version 3.9.*

The C type of the object returned by `Py_GenericAlias()`.  
Equivalent to `types.GenericAlias` in Python.

*New in version 3.9.*

# Initialization, Finalization, and Threads

See also [Python Initialization Configuration](#).

## Before Python Initialization

In an application embedding Python, the `Py_Initialize()` function must be called before using any other Python/C API functions; with the exception of a few functions and the [global configuration variables](#).

The following functions can be safely called before Python is initialized:

- Configuration functions:
  - `PyImport_AppendInittab()`
  - `PyImport_ExtendInittab()`
  - `PyInitFrozenExtensions()`
  - `PyMem_SetAllocator()`
  - `PyMem_SetupDebugHooks()`
  - `PyObject_SetArenaAllocator()`
  - `Py_SetPath()`
  - `Py_SetProgramName()`
  - `Py_SetPythonHome()`
  - `Py_SetStandardStreamEncoding()`
  - `PySys_AddWarnOption()`
  - `PySys_AddXOption()`
  - `PySys_ResetWarnOptions()`
- Informative functions:
  - `Py_IsInitialized()`
  - `PyMem_GetAllocator()`
  - `PyObject_GetArenaAllocator()`
  - `Py_GetBuildInfo()`
  - `Py_GetCompiler()`

- `Py_GetCopyright()`
- `Py_GetPlatform()`
- `Py_GetVersion()`
- Utilities:
  - `Py_DecodeLocale()`
- Memory allocators:
  - `PyMem_RawMalloc()`
  - `PyMem_RawRealloc()`
  - `PyMem_RawCalloc()`
  - `PyMem_RawFree()`

## Note

The following functions **should not be called** before

`Py_Initialize()`: `Py_EncodeLocale()`, `Py_GetPath()`,  
`Py_GetPrefix()`, `Py_GetExecPrefix()`,  
`Py_GetProgramFullPath()`, `Py_GetPythonHome()`,  
`Py_GetProgramName()` and `PyEval_InitThreads()`.

## Global configuration variables

Python has variables for the global configuration to control different features and options. By default, these flags are controlled by [command line options](#).

When a flag is set by an option, the value of the flag is the number of times that the option was set. For example, `-b` sets

`Py_BytesWarningFlag` to 1 and `-bb` sets  
`Py_BytesWarningFlag` to 2.

`int Py_BytesWarningFlag`

Issue a warning when comparing `bytes` or `bytearray` with `str` or `bytes` with `int`. Issue an error if greater or equal to 2.

Set by the `-b` option.

`int Py_DebugFlag`

Turn on parser debugging output (for expert only, depending

on compilation options).

Set by the **-d** option and the **PYTHONDEBUG** environment variable.

int Py\_DontWriteBytecodeFlag

If set to non-zero, Python won't try to write `.pyc` files on the import of source modules.

Set by the **-B** option and the **PYTHONDONTWRITEBYTECODE** environment variable.

int Py\_FrozenFlag

Suppress error messages when calculating the module search path in **Py\_GetPath()**.

Private flag used by `_freeze_module` and `frozenmain` programs.

int Py\_HashRandomizationFlag

Set to 1 if the **PYTHONHASHSEED** environment variable is set to a non-empty string.

If the flag is non-zero, read the **PYTHONHASHSEED** environment variable to initialize the secret hash seed.

int Py\_IgnoreEnvironmentFlag

Ignore all **PYTHON\*** environment variables, e.g. **PYTHONPATH** and **PYTHONHOME**, that might be set.

Set by the **-E** and **-I** options.

int Py\_InspectFlag

When a script is passed as first argument or the **-c** option is used, enter interactive mode after executing the script or the command, even when **sys.stdin** does not appear to be a terminal.

Set by the **-i** option and the **PYTHONINSPECT** environment

variable.

int Py\_InteractiveFlag

Set by the `-i` option.

int Py\_IsolatedFlag

Run Python in isolated mode. In isolated mode `sys.path` contains neither the script's directory nor the user's site-packages directory.

Set by the `-I` option.

*New in version 3.4.*

int Py\_LegacyWindowsFSEncodingFlag

If the flag is non-zero, use the `mbcs` encoding with `replace` error handler, instead of the UTF-8 encoding with `surrogatepass` error handler, for the [filesystem encoding and error handler](#).

Set to `1` if the `PYTHONLEGACYWINDOWSFSENCODING` environment variable is set to a non-empty string.

See [PEP 529](#) [<https://peps.python.org/pep-0529/>] for more details.

[Availability](#): Windows.

int Py\_LegacyWindowsStdioFlag

If the flag is non-zero, use `io.FileIO` instead of `WindowsConsoleIO` for `sys` standard streams.

Set to `1` if the `PYTHONLEGACYWINDOWSSTDIO` environment variable is set to a non-empty string.

See [PEP 528](#) [<https://peps.python.org/pep-0528/>] for more details.

[Availability](#): Windows.

int Py\_NoSiteFlag

Disable the import of the module `site` and the site-dependent manipulations of `sys.path` that it entails. Also disable these manipulations if `site` is explicitly imported later (call `site.main()` if you want them to be triggered).

Set by the `-S` option.

`int Py_NoUserSiteDirectory`

Don't add the `user site-packages directory` to `sys.path`.

Set by the `-s` and `-I` options, and the `PYTHONNOUSERSITE` environment variable.

`int Py_OptimizeFlag`

Set by the `-O` option and the `PYTHONOPTIMIZE` environment variable.

`int Py_QuietFlag`

Don't display the copyright and version messages even in interactive mode.

Set by the `-q` option.

*New in version 3.2.*

`int Py_UnbufferedStdioFlag`

Force the stdout and stderr streams to be unbuffered.

Set by the `-u` option and the `PYTHONUNBUFFERED` environment variable.

`int Py_VerboseFlag`

Print a message each time a module is initialized, showing the place (filename or built-in module) from which it is loaded. If greater or equal to 2, print a message for each file that is checked for when searching for a module. Also provides information on module cleanup at exit.

Set by the `-v` option and the `PYTHONVERBOSE` environment variable.

## Initializing and finalizing the interpreter

`void Py_Initialize()`

*Part of the [Stable ABI](#).*

Initialize the Python interpreter. In an application embedding Python, this should be called before using any other Python/C API functions; see [Before Python Initialization](#) for the few exceptions.

This initializes the table of loaded modules (`sys.modules`), and creates the fundamental modules `builtins`, `__main__` and `sys`. It also initializes the module search path (`sys.path`). It does not set `sys.argv`; use `PySys_SetArgvEx()` for that. This is a no-op when called for a second time (without calling `Py_FinalizeEx()` first). There is no return value; it is a fatal error if the initialization fails.

### Note

On Windows, changes the console mode from `O_TEXT` to `O_BINARY`, which will also affect non-Python uses of the console using the C Runtime.

`void Py_InitializeEx(int initsigs)`

*Part of the [Stable ABI](#).*

This function works like `Py_Initialize()` if `initsigs` is 1. If `initsigs` is 0, it skips initialization registration of signal handlers, which might be useful when Python is embedded.

`int Py_IsInitialized()`

*Part of the [Stable ABI](#).*

Return true (nonzero) when the Python interpreter has been initialized, false (zero) if not. After `Py_FinalizeEx()` is

called, this returns false until `Py_Initialize()` is called again.

`int Py_FinalizeEx()`

*Part of the [Stable ABI](#) since version 3.6.*

Undo all initializations made by `Py_Initialize()` and subsequent use of Python/C API functions, and destroy all sub-interpreters (see `Py_NewInterpreter()` below) that were created and not yet destroyed since the last call to `Py_Initialize()`. Ideally, this frees all memory allocated by the Python interpreter. This is a no-op when called for a second time (without calling `Py_Initialize()` again first). Normally the return value is 0. If there were errors during finalization (flushing buffered data), -1 is returned.

This function is provided for a number of reasons. An embedding application might want to restart Python without having to restart the application itself. An application that has loaded the Python interpreter from a dynamically loadable library (or DLL) might want to free all memory allocated by Python before unloading the DLL. During a hunt for memory leaks in an application a developer might want to free all memory allocated by Python before exiting from the application.

**Bugs and caveats:** The destruction of modules and objects in modules is done in random order; this may cause destructors (`__del__()` methods) to fail when they depend on other objects (even functions) or modules. Dynamically loaded extension modules loaded by Python are not unloaded. Small amounts of memory allocated by the Python interpreter may not be freed (if you find a leak, please report it). Memory tied up in circular references between objects is not freed. Some memory allocated by extension modules may not be freed. Some extensions may not work properly if their initialization routine is called more than once; this can happen if an application calls `Py_Initialize()` and `Py_FinalizeEx()` more than once.

Raises an [auditing event](#)

`cpython._PySys_ClearAuditHooks` with no arguments.

*New in version 3.6.*

`void Py_Finalize()`

Part of the [Stable ABI](#).

This is a backwards-compatible version of [Py\\_FinalizeEx\(\)](#) that disregards the return value.

## Process-wide parameters

`int Py_SetStandardStreamEncoding(const char *encoding, const char *errors)`

This API is kept for backward compatibility: setting [PyConfig.stdio\\_encoding](#) and [PyConfig.stdio\\_errors](#) should be used instead, see [Python Initialization Configuration](#).

This function should be called before [Py\\_Initialize\(\)](#), if it is called at all. It specifies which encoding and error handling to use with standard IO, with the same meanings as in [str.encode\(\)](#).

It overrides [PYTHONIOENCODING](#) values, and allows embedding code to control IO encoding when the environment variable does not work.

*encoding* and/or *errors* may be `NULL` to use [PYTHONIOENCODING](#) and/or default values (depending on other settings).

Note that [sys.stderr](#) always uses the “backslashreplace” error handler, regardless of this (or any other) setting.

If [Py\\_FinalizeEx\(\)](#) is called, this function will need to be called again in order to affect subsequent calls to [Py\\_Initialize\(\)](#).

Returns `0` if successful, a nonzero value on error (e.g. calling

after the interpreter has already been initialized).

*New in version 3.4.*

*Deprecated since version 3.11.*

`void Py_SetProgramName(const wchar_t *name)`

*Part of the [Stable ABI](#).*

This API is kept for backward compatibility: setting [PyConfig.program\\_name](#) should be used instead, see [Python Initialization Configuration](#).

This function should be called before [Py\\_Initialize\(\)](#) is called for the first time, if it is called at all. It tells the interpreter the value of the `argv[0]` argument to the `main()` function of the program (converted to wide characters). This is used by [Py\\_GetPath\(\)](#) and some other functions below to find the Python run-time libraries relative to the interpreter executable. The default value is `'python'`. The argument should point to a zero-terminated wide character string in static storage whose contents will not change for the duration of the program's execution. No code in the Python interpreter will change the contents of this storage.

Use [Py\\_DecodeLocale\(\)](#) to decode a bytes string to get a `wchar_t*` string.

*Deprecated since version 3.11.*

`wchar_t* Py_GetProgramName()`

*Part of the [Stable ABI](#).*

Return the program name set with [Py\\_SetProgramName\(\)](#), or the default. The returned string points into static storage; the caller should not modify its value.

This function should not be called before [Py\\_Initialize\(\)](#), otherwise it returns `NULL`.

*Changed in version 3.10:* It now returns `NULL` if called before

`Py_Initialize()`.

`wchar_t *Py_GetPrefix()`

*Part of the [Stable ABI](#).*

Return the *prefix* for installed platform-independent files. This is derived through a number of complicated rules from the program name set with `Py_SetProgramName()` and some environment variables; for example, if the program name is `'/usr/local/bin/python'`, the prefix is `'/usr/local'`. The returned string points into static storage; the caller should not modify its value. This corresponds to the **prefix** variable in the top-level `Makefile` and the `--prefix` argument to the **configure** script at build time. The value is available to Python code as `sys.prefix`. It is only useful on Unix. See also the next function.

This function should not be called before `Py_Initialize()`, otherwise it returns `NULL`.

*Changed in version 3.10:* It now returns `NULL` if called before `Py_Initialize()`.

`wchar_t *Py_GetExecPrefix()`

*Part of the [Stable ABI](#).*

Return the *exec-prefix* for installed platform-dependent files. This is derived through a number of complicated rules from the program name set with `Py_SetProgramName()` and some environment variables; for example, if the program name is `'/usr/local/bin/python'`, the exec-prefix is `'/usr/local'`. The returned string points into static storage; the caller should not modify its value. This corresponds to the **exec\_prefix** variable in the top-level `Makefile` and the `--exec-prefix` argument to the **configure** script at build time. The value is available to Python code as `sys.exec_prefix`. It is only useful on Unix.

Background: The exec-prefix differs from the prefix when platform dependent files (such as executables and shared

libraries) are installed in a different directory tree. In a typical installation, platform dependent files may be installed in the `/usr/local/plat` subtree while platform independent may be installed in `/usr/local`.

Generally speaking, a platform is a combination of hardware and software families, e.g. Sparc machines running the Solaris 2.x operating system are considered the same platform, but Intel machines running Solaris 2.x are another platform, and Intel machines running Linux are yet another platform. Different major revisions of the same operating system generally also form different platforms. Non-Unix operating systems are a different story; the installation strategies on those systems are so different that the prefix and exec-prefix are meaningless, and set to the empty string. Note that compiled Python bytecode files are platform independent (but not independent from the Python version by which they were compiled!).

System administrators will know how to configure the **mount** or **automount** programs to share `/usr/local` between platforms while having `/usr/local/plat` be a different filesystem for each platform.

This function should not be called before `Py_Initialize()`, otherwise it returns `NULL`.

*Changed in version 3.10:* It now returns `NULL` if called before `Py_Initialize()`.

`wchar_t *Py_GetProgramFullPath()`

*Part of the [Stable ABI](#).*

Return the full program name of the Python executable; this is computed as a side-effect of deriving the default module search path from the program name (set by `Py_SetProgramName()` above). The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.executable`.

This function should not be called before

`Py_Initialize()`, otherwise it returns `NULL`.

*Changed in version 3.10:* It now returns `NULL` if called before `Py_Initialize()`.

`wchar_t *Py_GetPath()`

*Part of the [Stable ABI](#).*

Return the default module search path; this is computed from the program name (set by `Py_SetProgramName()` above) and some environment variables. The returned string consists of a series of directory names separated by a platform dependent delimiter character. The delimiter character is `' : '` on Unix and macOS, `' ; '` on Windows. The returned string points into static storage; the caller should not modify its value. The list `sys.path` is initialized with this value on interpreter startup; it can be (and usually is) modified later to change the search path for loading modules.

This function should not be called before `Py_Initialize()`, otherwise it returns `NULL`.

*Changed in version 3.10:* It now returns `NULL` if called before `Py_Initialize()`.

`void Py_SetPath(const wchar_t*)`

*Part of the [Stable ABI](#) since version 3.7.*

This API is kept for backward compatibility: setting `PyConfig.module_search_paths` and `PyConfig.module_search_paths_set` should be used instead, see [Python Initialization Configuration](#).

Set the default module search path. If this function is called before `Py_Initialize()`, then `Py_GetPath()` won't attempt to compute a default search path but uses the one provided instead. This is useful if Python is embedded by an application that has full knowledge of the location of all modules. The path components should be separated by the platform dependent delimiter character, which is `' : '` on Unix and macOS, `' ; '` on Windows.

This also causes `sys.executable` to be set to the program full path (see `Py_GetProgramFullPath()`) and for `sys.prefix` and `sys.exec_prefix` to be empty. It is up to the caller to modify these if required after calling `Py_Initialize()`.

Use `Py_DecodeLocale()` to decode a bytes string to get a `wchar_*` string.

The path argument is copied internally, so the caller may free it after the call completes.

*Changed in version 3.8:* The program full path is now used for `sys.executable`, instead of the program name.

*Deprecated since version 3.11.*

`const char *Py_GetVersion()`

*Part of the [Stable ABI](#).*

Return the version of this Python interpreter. This is a string that looks something like

```
"3.0a5+ (py3k:63103M, May 12 2008, 00:53:55) \n[GCC
```

The first word (up to the first space character) is the current Python version; the first characters are the major and minor version separated by a period. The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.version`.

See also the `Py_Version` constant.

`const char *Py_GetPlatform()`

*Part of the [Stable ABI](#).*

Return the platform identifier for the current platform. On Unix, this is formed from the “official” name of the operating system, converted to lower case, followed by the major revision number; e.g., for Solaris 2.x, which is also known as SunOS 5.x, the value is `'sunos5'`. On macOS, it is `'darwin'`. On Windows, it is `'win'`. The returned string

points into static storage; the caller should not modify its value. The value is available to Python code as `sys.platform`.

`const char *Py_GetCopyright()`

*Part of the [Stable ABI](#).*

Return the official copyright string for the current Python version, for example

```
'Copyright 1991-1995 Stichting Mathematisch  
Centrum, Amsterdam'
```

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.copyright`.

`const char *Py_GetCompiler()`

*Part of the [Stable ABI](#).*

Return an indication of the compiler used to build the current Python version, in square brackets, for example:

```
"[GCC 2.7.2.2]"
```

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as part of the variable `sys.version`.

`const char *Py_GetBuildInfo()`

*Part of the [Stable ABI](#).*

Return information about the sequence number and build date and time of the current Python interpreter instance, for example

```
"#67, Aug 1 1997, 22:34:28"
```

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as part of the variable `sys.version`.

`void PySys_SetArgvEx(int argc, wchar_t **argv, int updatepath)`

Part of the [Stable ABI](#).

This API is kept for backward compatibility: setting `PyConfig.argv`, `PyConfig.parse_argv` and `PyConfig.safe_path` should be used instead, see [Python Initialization Configuration](#).

Set `sys.argv` based on `argc` and `argv`. These parameters are similar to those passed to the program's `main()` function with the difference that the first entry should refer to the script file to be executed rather than the executable hosting the Python interpreter. If there isn't a script that will be run, the first entry in `argv` can be an empty string. If this function fails to initialize `sys.argv`, a fatal condition is signalled using `Py_FatalError()`.

If `updatepath` is zero, this is all the function does. If `updatepath` is non-zero, the function also modifies `sys.path` according to the following algorithm:

- If the name of an existing script is passed in `argv[0]`, the absolute path of the directory where the script is located is prepended to `sys.path`.
- Otherwise (that is, if `argc` is 0 or `argv[0]` doesn't point to an existing file name), an empty string is prepended to `sys.path`, which is the same as prepending the current working directory (`"."`).

Use `Py_DecodeLocale()` to decode a bytes string to get a `wchar_t*` string.

See also `PyConfig.orig_argv` and `PyConfig.argv` members of the [Python Initialization Configuration](#).

## Note

It is recommended that applications embedding the Python interpreter for purposes other than executing a single script pass 0 as `updatepath`, and update `sys.path` themselves if desired. See [CVE-2008-5983](https://cve.mitre.org/cgi-bin/cvename.cgi?name=CVE-2008-5983) [https://cve.mitre.org/cgi-bin/cvename.cgi?name=CVE-2008-5983].

On versions before 3.1.3, you can achieve the same effect by manually popping the first `sys.path` element after having called `PySys_SetArgv()`, for example using:

```
PyRun_SimpleString("import sys; sys.path.pop(0)\n"
```

*New in version 3.1.3.*

*Deprecated since version 3.11.*

`void PySys_SetArgv(int argc, wchar_t **argv)`

*Part of the [Stable ABI](#).*

This API is kept for backward compatibility: setting `PyConfig.argv` and `PyConfig.parse_argv` should be used instead, see [Python Initialization Configuration](#).

This function works like `PySys_SetArgvEx()` with `updatepath` set to 1 unless the `python` interpreter was started with the `-I`.

Use `Py_DecodeLocale()` to decode a bytes string to get a `wchar_t*` string.

See also `PyConfig.orig_argv` and `PyConfig.argv` members of the [Python Initialization Configuration](#).

*Changed in version 3.4:* The `updatepath` value depends on `-I`.

*Deprecated since version 3.11.*

`void Py_SetPythonHome(const wchar_t *home)`

*Part of the [Stable ABI](#).*

This API is kept for backward compatibility: setting `PyConfig.home` should be used instead, see [Python Initialization Configuration](#).

Set the default “home” directory, that is, the location of the standard Python libraries. See `PYTHONHOME` for the meaning of the argument string.

The argument should point to a zero-terminated character string in static storage whose contents will not change for the duration of the program's execution. No code in the Python interpreter will change the contents of this storage.

Use `Py_DecodeLocale()` to decode a bytes string to get a `wchar_t*` string.

*Deprecated since version 3.11.*

`wchar_t *Py_GetPythonHome()`

Part of the *Stable ABI*.

Return the default “home”, that is, the value set by a previous call to `Py_SetPythonHome()`, or the value of the `PYTHONHOME` environment variable if it is set.

This function should not be called before `Py_Initialize()`, otherwise it returns `NULL`.

*Changed in version 3.10:* It now returns `NULL` if called before `Py_Initialize()`.

## Thread State and the Global Interpreter Lock

The Python interpreter is not fully thread-safe. In order to support multi-threaded Python programs, there's a global lock, called the [global interpreter lock](#) or [GIL](#), that must be held by the current thread before it can safely access Python objects. Without the lock, even the simplest operations could cause problems in a multi-threaded program: for example, when two threads simultaneously increment the reference count of the same object, the reference count could end up being incremented only once instead of twice.

Therefore, the rule exists that only the thread that has acquired the [GIL](#) may operate on Python objects or call Python/C API functions. In order to emulate concurrency of execution, the interpreter regularly tries to switch threads (see `sys.setswitchinterval()`). The lock is also released around

potentially blocking I/O operations like reading or writing a file, so that other Python threads can run in the meantime.

The Python interpreter keeps some thread-specific bookkeeping information inside a data structure called `PyThreadState`. There's also one global variable pointing to the current `PyThreadState`: it can be retrieved using `PyThreadState_Get()`.

## Releasing the GIL from extension code

Most extension code manipulating the GIL has the following simple structure:

```
Save the thread state in a local variable.  
Release the global interpreter lock.  
... Do some blocking I/O operation ...  
Reacquire the global interpreter lock.  
Restore the thread state from the local variable.
```

This is so common that a pair of macros exists to simplify it:

```
Py_BEGIN_ALLOW_THREADS  
... Do some blocking I/O operation ...  
Py_END_ALLOW_THREADS
```

The `Py_BEGIN_ALLOW_THREADS` macro opens a new block and declares a hidden local variable; the `Py_END_ALLOW_THREADS` macro closes the block.

The block above expands to the following code:

```
PyThreadState *_save;  
  
_save = PyEval_SaveThread();  
... Do some blocking I/O operation ...  
PyEval_RestoreThread(_save);
```

Here is how these functions work: the global interpreter lock is used to protect the pointer to the current thread state. When releasing the lock and saving the thread state, the current thread state pointer

must be retrieved before the lock is released (since another thread could immediately acquire the lock and store its own thread state in the global variable). Conversely, when acquiring the lock and restoring the thread state, the lock must be acquired before storing the thread state pointer.

## Note

Calling system I/O functions is the most common use case for releasing the GIL, but it can also be useful before calling long-running computations which don't need access to Python objects, such as compression or cryptographic functions operating over memory buffers. For example, the standard `zlib` and `hashlib` modules release the GIL when compressing or hashing data.

## Non-Python created threads

When threads are created using the dedicated Python APIs (such as the `threading` module), a thread state is automatically associated to them and the code showed above is therefore correct. However, when threads are created from C (for example by a third-party library with its own thread management), they don't hold the GIL, nor is there a thread state structure for them.

If you need to call Python code from these threads (often this will be part of a callback API provided by the aforementioned third-party library), you must first register these threads with the interpreter by creating a thread state data structure, then acquiring the GIL, and finally storing their thread state pointer, before you can start using the Python/C API. When you are done, you should reset the thread state pointer, release the GIL, and finally free the thread state data structure.

The `PyGILState_Ensure()` and `PyGILState_Release()` functions do all of the above automatically. The typical idiom for calling into Python from a C thread is:

```
PyGILState_STATE gstate;  
gstate = PyGILState_Ensure();
```

```
/* Perform Python actions here. */  
result = CallSomeFunction();  
/* evaluate result or handle exception */  
  
/* Release the thread. No Python API allowed beyond this  
PyGILState_Release(gstate);
```

Note that the `PyGILState_*` functions assume there is only one global interpreter (created automatically by `Py_Initialize()`). Python supports the creation of additional interpreters (using `Py_NewInterpreter()`), but mixing multiple interpreters and the `PyGILState_*` API is unsupported.

## Cautions about `fork()`

Another important thing to note about threads is their behaviour in the face of the C `fork()` call. On most systems with `fork()`, after a process forks only the thread that issued the fork will exist. This has a concrete impact both on how locks must be handled and on all stored state in CPython's runtime.

The fact that only the “current” thread remains means any locks held by other threads will never be released. Python solves this for `os.fork()` by acquiring the locks it uses internally before the fork, and releasing them afterwards. In addition, it resets any `Lock Objects` in the child. When extending or embedding Python, there is no way to inform Python of additional (non-Python) locks that need to be acquired before or reset after a fork. OS facilities such as `pthread_atfork()` would need to be used to accomplish the same thing. Additionally, when extending or embedding Python, calling `fork()` directly rather than through `os.fork()` (and returning to or calling into Python) may result in a deadlock by one of Python's internal locks being held by a thread that is defunct after the fork. `PyOS_AfterFork_Child()` tries to reset the necessary locks, but is not always able to.

The fact that all other threads go away also means that CPython's runtime state there must be cleaned up properly, which `os.fork()` does. This means finalizing all other `PyThreadState`

objects belonging to the current interpreter and all other **PyInterpreterState** objects. Due to this and the special nature of the “main” interpreter, **fork()** should only be called in that interpreter’s “main” thread, where the CPython global runtime was originally initialized. The only exception is if **exec()** will be called immediately after.

## High-level API

These are the most commonly used types and functions when writing C extension code, or when embedding the Python interpreter:

type **PyInterpreterState**

*Part of the **Limited API** (as an opaque struct).*

This data structure represents the state shared by a number of cooperating threads. Threads belonging to the same interpreter share their module administration and a few other internal items. There are no public members in this structure.

Threads belonging to different interpreters initially share nothing, except process state like available memory, open file descriptors and such. The global interpreter lock is also shared by all threads, regardless of to which interpreter they belong.

type **PyThreadState**

*Part of the **Limited API** (as an opaque struct).*

This data structure represents the state of a single thread. The only public data member is **interp** (**PyInterpreterState\***), which points to this thread’s interpreter state.

void **PyEval\_InitThreads()**

*Part of the **Stable ABI**.*

Deprecated function which does nothing.

In Python 3.6 and older, this function created the GIL if it didn’t exist.

*Changed in version 3.9:* The function now does nothing.

*Changed in version 3.7:* This function is now called by `Py_Initialize()`, so you don't have to call it yourself anymore.

*Changed in version 3.2:* This function cannot be called before `Py_Initialize()` anymore.

*Deprecated since version 3.9.*

`int PyEval_ThreadsInitialized()`

*Part of the [Stable ABI](#).*

Returns a non-zero value if `PyEval_InitThreads()` has been called. This function can be called without holding the GIL, and therefore can be used to avoid calls to the locking API when running single-threaded.

*Changed in version 3.7:* The [GIL](#) is now initialized by `Py_Initialize()`.

*Deprecated since version 3.9.*

`PyThreadState *PyEval_SaveThread()`

*Part of the [Stable ABI](#).*

Release the global interpreter lock (if it has been created) and reset the thread state to `NULL`, returning the previous thread state (which is not `NULL`). If the lock has been created, the current thread must have acquired it.

`void PyEval_RestoreThread(PyThreadState *tstate)`

*Part of the [Stable ABI](#).*

Acquire the global interpreter lock (if it has been created) and set the thread state to `tstate`, which must not be `NULL`. If the lock has been created, the current thread must not have acquired it, otherwise deadlock ensues.

## Note

Calling this function from a thread when the runtime is finalizing will terminate the thread, even if the thread was not created by Python. You can use

`_Py_IsFinalizing()` or `sys.is_finalizing()` to check if the interpreter is in process of being finalized before calling this function to avoid unwanted termination.

`PyThreadState *PyThreadState_Get()`

*Part of the [Stable ABI](#).*

Return the current thread state. The global interpreter lock must be held. When the current thread state is `NULL`, this issues a fatal error (so that the caller needn't check for `NULL`).

`PyThreadState *PyThreadState_Swap(PyThreadState *tstate)`

*Part of the [Stable ABI](#).*

Swap the current thread state with the thread state given by the argument *tstate*, which may be `NULL`. The global interpreter lock must be held and is not released.

The following functions use thread-local storage, and are not compatible with sub-interpreters:

`PyGILState_STATE PyGILState_Ensure()`

*Part of the [Stable ABI](#).*

Ensure that the current thread is ready to call the Python C API regardless of the current state of Python, or of the global interpreter lock. This may be called as many times as desired by a thread as long as each call is matched with a call to `PyGILState_Release()`. In general, other thread-related APIs may be used between `PyGILState_Ensure()` and `PyGILState_Release()` calls as long as the thread state is restored to its previous state before the `Release()`. For example, normal usage of the `Py_BEGIN_ALLOW_THREADS` and `Py_END_ALLOW_THREADS` macros is acceptable.

The return value is an opaque “handle” to the thread state when `PyGILState_Ensure()` was called, and must be passed to `PyGILState_Release()` to ensure Python is left in the same state. Even though recursive calls are allowed, these handles *cannot* be shared - each unique call to `PyGILState_Ensure()` must save the handle for its call to `PyGILState_Release()`.

When the function returns, the current thread will hold the GIL and be able to call arbitrary Python code. Failure is a fatal error.

### Note

Calling this function from a thread when the runtime is finalizing will terminate the thread, even if the thread was not created by Python. You can use `_Py_IsFinalizing()` or `sys.is_finalizing()` to check if the interpreter is in process of being finalized before calling this function to avoid unwanted termination.

`void PyGILState_Release(PyGILState_STATE)`

*Part of the [Stable ABI](#).*

Release any resources previously acquired. After this call, Python’s state will be the same as it was prior to the corresponding `PyGILState_Ensure()` call (but generally this state will be unknown to the caller, hence the use of the GILState API).

Every call to `PyGILState_Ensure()` must be matched by a call to `PyGILState_Release()` on the same thread.

`PyThreadState *PyGILState_GetThisThreadState()`

*Part of the [Stable ABI](#).*

Get the current thread state for this thread. May return `NULL` if no GILState API has been used on the current thread. Note that the main thread always has such a thread-state, even if no auto-thread-state call has been made on the main thread.

This is mainly a helper/diagnostic function.

`int PyGILState_Check()`

Return 1 if the current thread is holding the GIL and 0 otherwise. This function can be called from any thread at any time. Only if it has had its Python thread state initialized and currently is holding the GIL will it return 1. This is mainly a helper/diagnostic function. It can be useful for example in callback contexts or memory allocation functions when knowing that the GIL is locked can allow the caller to perform sensitive actions or otherwise behave differently.

*New in version 3.4.*

The following macros are normally used without a trailing semicolon; look for example usage in the Python source distribution.

`Py_BEGIN_ALLOW_THREADS`

*Part of the [Stable ABI](#).*

This macro expands to `{ PyThreadState *_save; _save = PyEval_SaveThread();`. Note that it contains an opening brace; it must be matched with a following [Py\\_END\\_ALLOW\\_THREADS](#) macro. See above for further discussion of this macro.

`Py_END_ALLOW_THREADS`

*Part of the [Stable ABI](#).*

This macro expands to `PyEval_RestoreThread(_save);`. Note that it contains a closing brace; it must be matched with an earlier [Py\\_BEGIN\\_ALLOW\\_THREADS](#) macro. See above for further discussion of this macro.

`Py_BLOCK_THREADS`

*Part of the [Stable ABI](#).*

This macro expands to

`PyEval_RestoreThread(_save);`; it is equivalent to [Py\\_END\\_ALLOW\\_THREADS](#) without the closing brace.

## Py\_UNBLOCK\_THREADS

*Part of the [Stable ABI](#).*

This macro expands to `_save =`

`PyEval_SaveThread()`; it is equivalent to

[Py\\_BEGIN\\_ALLOW\\_THREADS](#) without the opening brace and variable declaration.

## Low-level API

All of the following functions must be called after

[Py\\_Initialize\(\)](#).

*Changed in version 3.7:* [Py\\_Initialize\(\)](#) now initializes the [GIL](#).

[PyInterpreterState](#) \*PyInterpreterState\_New()

*Part of the [Stable ABI](#).*

Create a new interpreter state object. The global interpreter lock need not be held, but may be held if it is necessary to serialize calls to this function.

Raises an [auditing event](#)

`cpython.PyInterpreterState_New` with no arguments.

void PyInterpreterState\_Clear([PyInterpreterState](#) \*interp)

*Part of the [Stable ABI](#).*

Reset all information in an interpreter state object. The global interpreter lock must be held.

Raises an [auditing event](#)

`cpython.PyInterpreterState_Clear` with no arguments.

void PyInterpreterState\_Delete([PyInterpreterState](#) \*interp)

*Part of the [Stable ABI](#).*

Destroy an interpreter state object. The global interpreter lock need not be held. The interpreter state must have been reset with a previous call to [PyInterpreterState\\_Clear\(\)](#).

`PyThreadState *PyThreadState_New(PyInterpreterState *interp)`

*Part of the [Stable ABI](#).*

Create a new thread state object belonging to the given interpreter object. The global interpreter lock need not be held, but may be held if it is necessary to serialize calls to this function.

`void PyThreadState_Clear(PyThreadState *tstate)`

*Part of the [Stable ABI](#).*

Reset all information in a thread state object. The global interpreter lock must be held.

*Changed in version 3.9:* This function now calls the **`PyThreadState.on_delete`** callback. Previously, that happened in `PyThreadState_Delete()`.

`void PyThreadState_Delete(PyThreadState *tstate)`

*Part of the [Stable ABI](#).*

Destroy a thread state object. The global interpreter lock need not be held. The thread state must have been reset with a previous call to `PyThreadState_Clear()`.

`void PyThreadState_DeleteCurrent(void)`

Destroy the current thread state and release the global interpreter lock. Like `PyThreadState_Delete()`, the global interpreter lock need not be held. The thread state must have been reset with a previous call to `PyThreadState_Clear()`.

`PyFrameObject *PyThreadState_GetFrame(PyThreadState *tstate)`

*Part of the [Stable ABI](#) since version 3.10.*

Get the current frame of the Python thread state *tstate*.

Return a [strong reference](#). Return `NULL` if no frame is currently executing.

See also `PyEval_GetFrame()`.

*tstate* must not be `NULL`.

*New in version 3.9.*

`uint64_t PyThreadState_GetID(PyThreadState *tstate)`

Part of the *Stable ABI* since version 3.10.

Get the unique thread state identifier of the Python thread state *tstate*.

*tstate* must not be `NULL`.

*New in version 3.9.*

`PyInterpreterState *PyThreadState_GetInterpreter(PyThreadState *tstate)`

Part of the *Stable ABI* since version 3.10.

Get the interpreter of the Python thread state *tstate*.

*tstate* must not be `NULL`.

*New in version 3.9.*

`void PyThreadState_EnterTracing(PyThreadState *tstate)`

Suspend tracing and profiling in the Python thread state *tstate*.

Resume them using the

`PyThreadState_LeaveTracing()` function.

*New in version 3.11.*

`void PyThreadState_LeaveTracing(PyThreadState *tstate)`

Resume tracing and profiling in the Python thread state *tstate* suspended by the `PyThreadState_EnterTracing()` function.

See also `PyEval_SetTrace()` and `PyEval_SetProfile()` functions.

*New in version 3.11.*

**PyInterpreterState** \*PyInterpreterState\_Get(void)

Part of the *Stable ABI* since version 3.9.

Get the current interpreter.

Issue a fatal error if there no current Python thread state or no current interpreter. It cannot return NULL.

The caller must hold the GIL.

*New in version 3.9.*

int64\_t PyInterpreterState\_GetID(**PyInterpreterState** \*interp)

Part of the *Stable ABI* since version 3.7.

Return the interpreter's unique ID. If there was any error in doing so then `-1` is returned and an error is set.

The caller must hold the GIL.

*New in version 3.7.*

**PyObject** \*PyInterpreterState\_GetDict(**PyInterpreterState** \*interp)

Part of the *Stable ABI* since version 3.8.

Return a dictionary in which interpreter-specific data may be stored. If this function returns `NULL` then no exception has been raised and the caller should assume no interpreter-specific dict is available.

This is not a replacement for **PyModule\_GetState()**, which extensions should use to store interpreter-specific state information.

*New in version 3.8.*

typedef **PyObject** \*(\*\_PyFrameEvalFunction)(**PyThreadState** \*tstate, **PyInterpreterFrame** \*frame, int throwflag)

Type of a frame evaluation function.

The *throwflag* parameter is used by the `throw()` method of generators: if non-zero, handle the current exception.

*Changed in version 3.9:* The function now takes a *tstate* parameter.

*Changed in version 3.11:* The *frame* parameter changed from `PyFrameObject*` to `_PyInterpreterFrame*`.

### `_PyFrameEvalFunction`

`_PyInterpreterState_GetEvalFrameFunc(PyInterpreterState *interp)`

Get the frame evaluation function.

See the [PEP 523](https://peps.python.org/pep-0523/) [https://peps.python.org/pep-0523/] “Adding a frame evaluation API to CPython”.

*New in version 3.9.*

`void _PyInterpreterState_SetEvalFrameFunc(PyInterpreterState *interp, _PyFrameEvalFunction eval_frame)`

Set the frame evaluation function.

See the [PEP 523](https://peps.python.org/pep-0523/) [https://peps.python.org/pep-0523/] “Adding a frame evaluation API to CPython”.

*New in version 3.9.*

### `PyObject *PyThreadState_GetDict()`

*Return value: Borrowed reference. Part of the [Stable ABI](#).*

Return a dictionary in which extensions can store thread-specific state information. Each extension should use a unique key to use to store state in the dictionary. It is okay to call this function when no current thread state is available. If this function returns `NULL`, no exception has been raised and the caller should assume no current thread state is available.

`int PyThreadState_SetAsyncExc(unsigned long id, PyObject *exc)`

*Part of the [Stable ABI](#).*

Asynchronously raise an exception in a thread. The *id* argument is the thread id of the target thread; *exc* is the exception object to be raised. This function does not steal any references to *exc*. To prevent naive misuse, you must write your own C extension to call this. Must be called with the GIL held. Returns the number of thread states modified; this is normally one, but will be zero if the thread id isn't found. If *exc* is **NULL**, the pending exception (if any) for the thread is cleared. This raises no exceptions.

*Changed in version 3.7:* The type of the *id* parameter changed from long to unsigned long.

void PyEval\_AcquireThread(PyThreadState \*tstate)

Part of the *Stable ABI*.

Acquire the global interpreter lock and set the current thread state to *tstate*, which must not be **NULL**. The lock must have been created earlier. If this thread already has the lock, deadlock ensues.

### Note

Calling this function from a thread when the runtime is finalizing will terminate the thread, even if the thread was not created by Python. You can use `_Py_IsFinalizing()` or `sys.is_finalizing()` to check if the interpreter is in process of being finalized before calling this function to avoid unwanted termination.

*Changed in version 3.8:* Updated to be consistent with `PyEval_RestoreThread()`, `Py_END_ALLOW_THREADS()`, and `PyGILState_Ensure()`, and terminate the current thread if called while the interpreter is finalizing.

`PyEval_RestoreThread()` is a higher-level function which is always available (even when threads have not been initialized).

void PyEval\_ReleaseThread(PyThreadState \*tstate)

Part of the *Stable ABI*.

Reset the current thread state to `NULL` and release the global interpreter lock. The lock must have been created earlier and must be held by the current thread. The *tstate* argument, which must not be `NULL`, is only used to check that it represents the current thread state — if it isn't, a fatal error is reported.

**`PyEval_SaveThread()`** is a higher-level function which is always available (even when threads have not been initialized).

`void PyEval_AcquireLock()`

Part of the *Stable ABI*.

Acquire the global interpreter lock. The lock must have been created earlier. If this thread already has the lock, a deadlock ensues.

*Deprecated since version 3.2:* This function does not update the current thread state. Please use **`PyEval_RestoreThread()`** or **`PyEval_AcquireThread()`** instead.

### Note

Calling this function from a thread when the runtime is finalizing will terminate the thread, even if the thread was not created by Python. You can use **`_Py_IsFinalizing()`** or **`sys.is_finalizing()`** to check if the interpreter is in process of being finalized before calling this function to avoid unwanted termination.

*Changed in version 3.8:* Updated to be consistent with **`PyEval_RestoreThread()`**, **`Py_END_ALLOW_THREADS()`**, and **`PyGILState_Ensure()`**, and terminate the current thread if called while the interpreter is finalizing.

`void PyEval_ReleaseLock()`

Part of the *Stable ABI*.

Release the global interpreter lock. The lock must have been

created earlier.

*Deprecated since version 3.2:* This function does not update the current thread state. Please use `PyEval_SaveThread()` or `PyEval_ReleaseThread()` instead.

## Sub-interpreter support

While in most uses, you will only embed a single Python interpreter, there are cases where you need to create several independent interpreters in the same process and perhaps even in the same thread. Sub-interpreters allow you to do that.

The “main” interpreter is the first one created when the runtime initializes. It is usually the only Python interpreter in a process. Unlike sub-interpreters, the main interpreter has unique process-global responsibilities like signal handling. It is also responsible for execution during runtime initialization and is usually the active interpreter during runtime finalization. The `PyInterpreterState_Main()` function returns a pointer to its state.

You can switch between sub-interpreters using the `PyThreadState_Swap()` function. You can create and destroy them using the following functions:

`PyThreadState *Py_NewInterpreter()`

*Part of the [Stable ABI](#).*

Create a new sub-interpreter. This is an (almost) totally separate environment for the execution of Python code. In particular, the new interpreter has separate, independent versions of all imported modules, including the fundamental modules `builtins`, `__main__` and `sys`. The table of loaded modules (`sys.modules`) and the module search path (`sys.path`) are also separate. The new environment has no `sys.argv` variable. It has new standard I/O stream file objects `sys.stdin`, `sys.stdout` and `sys.stderr` (however these refer to the same underlying file descriptors).

The return value points to the first thread state created in the

new sub-interpreter. This thread state is made in the current thread state. Note that no actual thread is created; see the discussion of thread states below. If creation of the new interpreter is unsuccessful, `NULL` is returned; no exception is set since the exception state is stored in the current thread state and there may not be a current thread state. (Like all other Python/C API functions, the global interpreter lock must be held before calling this function and is still held when it returns; however, unlike most other Python/C API functions, there needn't be a current thread state on entry.)

Extension modules are shared between (sub-)interpreters as follows:

- For modules using multi-phase initialization, e.g. `PyModule_FromDefAndSpec()`, a separate module object is created and initialized for each interpreter. Only C-level static and global variables are shared between these module objects.
- For modules using single-phase initialization, e.g. `PyModule_Create()`, the first time a particular extension is imported, it is initialized normally, and a (shallow) copy of its module's dictionary is squirreled away. When the same extension is imported by another (sub-)interpreter, a new module is initialized and filled with the contents of this copy; the extension's `init` function is not called. Objects in the module's dictionary thus end up shared across (sub-)interpreters, which might cause unwanted behavior (see [Bugs and caveats](#) below).

Note that this is different from what happens when an extension is imported after the interpreter has been completely re-initialized by calling `Py_FinalizeEx()` and `Py_Initialize()`; in that case, the extension's `inittestmodule` function is called again. As with multi-phase initialization, this means that only C-level static and global variables are shared between these modules.

`void Py_EndInterpreter(PyThreadState *tstate)`

*Part of the [Stable ABI](#).*

Destroy the (sub-)interpreter represented by the given thread state. The given thread state must be the current thread state. See the discussion of thread states below. When the call returns, the current thread state is `NULL`. All thread states associated with this interpreter are destroyed. (The global interpreter lock must be held before calling this function and is still held when it returns.) `Py_FinalizeEx()` will destroy all sub-interpreters that haven't been explicitly destroyed at that point.

## Bugs and caveats

Because sub-interpreters (and the main interpreter) are part of the same process, the insulation between them isn't perfect — for example, using low-level file operations like `os.close()` they can (accidentally or maliciously) affect each other's open files. Because of the way extensions are shared between (sub-)interpreters, some extensions may not work properly; this is especially likely when using single-phase initialization or (static) global variables. It is possible to insert objects created in one sub-interpreter into a namespace of another (sub-)interpreter; this should be avoided if possible.

Special care should be taken to avoid sharing user-defined functions, methods, instances or classes between sub-interpreters, since import operations executed by such objects may affect the wrong (sub-)interpreter's dictionary of loaded modules. It is equally important to avoid sharing objects from which the above are reachable.

Also note that combining this functionality with `PyGILState_*` APIs is delicate, because these APIs assume a bijection between Python thread states and OS-level threads, an assumption broken by the presence of sub-interpreters. It is highly recommended that you don't switch sub-interpreters between a pair of matching

`PyGILState_Ensure()` and `PyGILState_Release()` calls. Furthermore, extensions (such as `ctypes`) using these APIs to allow calling of Python code from non-Python created threads will probably be broken when using sub-interpreters.

## Asynchronous Notifications

A mechanism is provided to make asynchronous notifications to the main interpreter thread. These notifications take the form of a function pointer and a void pointer argument.

```
int Py_AddPendingCall(int (*func)(void*), void *arg)
```

*Part of the [Stable ABI](#).*

Schedule a function to be called from the main interpreter thread. On success, `0` is returned and *func* is queued for being called in the main thread. On failure, `-1` is returned without setting any exception.

When successfully queued, *func* will be *eventually* called from the main interpreter thread with the argument *arg*. It will be called asynchronously with respect to normally running Python code, but with both these conditions met:

- on a [bytecode](#) boundary;
- with the main thread holding the [global interpreter lock](#) (*func* can therefore use the full C API).

*func* must return `0` on success, or `-1` on failure with an exception set. *func* won't be interrupted to perform another asynchronous notification recursively, but it can still be interrupted to switch threads if the global interpreter lock is released.

This function doesn't need a current thread state to run, and it doesn't need the global interpreter lock.

To call this function in a subinterpreter, the caller must hold the GIL. Otherwise, the function *func* can be scheduled to be called from the wrong interpreter.

## Warning

This is a low-level function, only useful for very special cases. There is no guarantee that *func* will be called as quick as possible. If the main thread is busy executing a system call, *func* won't be called before the system call returns. This function is generally **not** suitable for calling Python code from arbitrary C threads. Instead, use the [PyGILState API](#).

*Changed in version 3.9:* If this function is called in a subinterpreter, the function *func* is now scheduled to be called from the subinterpreter, rather than being called from the main interpreter. Each subinterpreter now has its own list of scheduled calls.

*New in version 3.1.*

## Profiling and Tracing

The Python interpreter provides some low-level support for attaching profiling and execution tracing facilities. These are used for profiling, debugging, and coverage analysis tools.

This C interface allows the profiling or tracing code to avoid the overhead of calling through Python-level callable objects, making a direct C function call instead. The essential attributes of the facility have not changed; the interface allows trace functions to be installed per-thread, and the basic events reported to the trace function are the same as had been reported to the Python-level trace functions in previous versions.

```
typedef int (*Py_tracefunc)(PyObject *obj, PyFrameObject *frame,  
int what, PyObject *arg)
```

The type of the trace function registered using [PyEval\\_SetProfile\(\)](#) and [PyEval\\_SetTrace\(\)](#). The first parameter is the object passed to the registration function as *obj*, *frame* is the frame object to which the event pertains, *what* is one of the constants **PyTrace\_CALL**, **PyTrace\_EXCEPTION**, **PyTrace\_LINE**,

`PyTrace_RETURN`, `PyTrace_C_CALL`,  
`PyTrace_C_EXCEPTION`, `PyTrace_C_RETURN`, or  
`PyTrace_OPCODE`, and *arg* depends on the value of *what*:

### Meaning of *what*

---

`PyTrace_CALL`.

---

`PyTrace_EXCEPTION` is returned by `sys.exc_info()`.

---

`PyTrace_LINE`.

---

`PyTrace_RETURN` is returned to the caller, or `NULL` if caused by an exception.

---

`PyTrace_C_CALL` is called.

---

`PyTrace_C_EXCEPTION` is called.

---

`PyTrace_C_RETURN` is called.

---

`PyTrace_OPCODE`.

---

`int PyTrace_CALL`

The value of the *what* parameter to a `Py_tracefunc` function when a new call to a function or method is being reported, or a new entry into a generator. Note that the creation of the iterator for a generator function is not reported as there is no control transfer to the Python bytecode in the corresponding frame.

`int PyTrace_EXCEPTION`

The value of the *what* parameter to a `Py_tracefunc` function when an exception has been raised. The callback function is called with this value for *what* when after any bytecode is processed after which the exception becomes set within the frame being executed. The effect of this is that as exception propagation causes the Python stack to unwind, the callback is called upon return to each frame as the exception propagates. Only trace functions receives these events; they are not needed by the profiler.

`int PyTrace_LINE`

The value passed as the *what* parameter to a `Py_tracefunc` function (but not a profiling function) when a line-number event is being reported. It may be disabled for a frame by setting `f_trace_lines` to 0 on that frame.

int PyTrace\_RETURN

The value for the *what* parameter to `Py_tracefunc` functions when a call is about to return.

int PyTrace\_C\_CALL

The value for the *what* parameter to `Py_tracefunc` functions when a C function is about to be called.

int PyTrace\_C\_EXCEPTION

The value for the *what* parameter to `Py_tracefunc` functions when a C function has raised an exception.

int PyTrace\_C\_RETURN

The value for the *what* parameter to `Py_tracefunc` functions when a C function has returned.

int PyTrace\_OPCODE

The value for the *what* parameter to `Py_tracefunc` functions (but not profiling functions) when a new opcode is about to be executed. This event is not emitted by default: it must be explicitly requested by setting `f_trace_opcodes` to 1 on the frame.

void PyEval\_SetProfile(`Py_tracefunc` func, `PyObject` \*obj)

Set the profiler function to *func*. The *obj* parameter is passed to the function as its first parameter, and may be any Python object, or `NULL`. If the profile function needs to maintain state, using a different value for *obj* for each thread provides a convenient and thread-safe place to store it. The profile function is called for all monitored events except `PyTrace_LINE` `PyTrace_OPCODE` and `PyTrace_EXCEPTION`.

See also the `sys.setprofile()` function.

The caller must hold the `GIL`.

void PyEval\_SetTrace(`Py_tracefunc` func, `PyObject` \*obj)

Set the tracing function to *func*. This is similar to `PyEval_SetProfile()`, except the tracing function does receive line-number events and per-opcode events, but does not receive any event related to C function objects being called. Any trace function registered using `PyEval_SetTrace()` will not receive `PyTrace_C_CALL`, `PyTrace_C_EXCEPTION` or `PyTrace_C_RETURN` as a value for the *what* parameter.

See also the `sys.settrace()` function.

The caller must hold the GIL.

## Advanced Debugger Support

These functions are only intended to be used by advanced debugging tools.

`PyInterpreterState *PyInterpreterState_Head()`

Return the interpreter state object at the head of the list of all such objects.

`PyInterpreterState *PyInterpreterState_Main()`

Return the main interpreter state object.

`PyInterpreterState *PyInterpreterState_Next(PyInterpreterState *interp)`

Return the next interpreter state object after *interp* from the list of all such objects.

`PyThreadState *PyInterpreterState_ThreadHead(PyInterpreterState *interp)`

Return the pointer to the first `PyThreadState` object in the list of threads associated with the interpreter *interp*.

`PyThreadState *PyThreadState_Next(PyThreadState *tstate)`

Return the next thread state object after *tstate* from the list of

all such objects belonging to the same `PyInterpreterState` object.

## Thread Local Storage Support

The Python interpreter provides low-level support for thread-local storage (TLS) which wraps the underlying native TLS implementation to support the Python-level thread local storage API (`threading.local`). The CPython C level APIs are similar to those offered by pthreads and Windows: use a thread key and functions to associate a `void*` value per thread.

The GIL does *not* need to be held when calling these functions; they supply their own locking.

Note that `Python.h` does not include the declaration of the TLS APIs, you need to include `pythread.h` to use thread-local storage.

### Note

None of these API functions handle memory management on behalf of the `void*` values. You need to allocate and deallocate them yourself. If the `void*` values happen to be `PyObject*`, these functions don't do refcount operations on them either.

## Thread Specific Storage (TSS) API

TSS API is introduced to supersede the use of the existing TLS API within the CPython interpreter. This API uses a new type `Py_tss_t` instead of `int` to represent thread keys.

*New in version 3.7.*

### See also

“A New C-API for Thread-Local Storage in CPython” ([PEP 539](https://peps.python.org/pep-0539/))  
[<https://peps.python.org/pep-0539/>]

type `Py_tss_t`

This data structure represents the state of a thread key, the definition of which may depend on the underlying TLS implementation, and it has an internal field representing the key's initialization state. There are no public members in this structure.

When `Py_LIMITED_API` is not defined, static allocation of this type by `Py_tss_NEEDS_INIT` is allowed.

`Py_tss_NEEDS_INIT`

This macro expands to the initializer for `Py_tss_t` variables. Note that this macro won't be defined with `Py_LIMITED_API`.

## Dynamic Allocation

Dynamic allocation of the `Py_tss_t`, required in extension modules built with `Py_LIMITED_API`, where static allocation of this type is not possible due to its implementation being opaque at build time.

`Py_tss_t *PyThread_tss_alloc()`

*Part of the [Stable ABI](#) since version 3.7.*

Return a value which is the same state as a value initialized with `Py_tss_NEEDS_INIT`, or `NULL` in the case of dynamic allocation failure.

`void PyThread_tss_free(Py_tss_t *key)`

*Part of the [Stable ABI](#) since version 3.7.*

Free the given `key` allocated by `PyThread_tss_alloc()`, after first calling `PyThread_tss_delete()` to ensure any associated thread locals have been unassigned. This is a no-op if the `key` argument is `NULL`.

### Note

A freed key becomes a dangling pointer. You should reset the key to `NULL`.

## Methods

The parameter *key* of these functions must not be `NULL`. Moreover, the behaviors of `PyThread_tss_set()` and `PyThread_tss_get()` are undefined if the given `Py_tss_t` has not been initialized by `PyThread_tss_create()`.

`int PyThread_tss_is_created(Py_tss_t *key)`

*Part of the [Stable ABI](#) since version 3.7.*

Return a non-zero value if the given `Py_tss_t` has been initialized by `PyThread_tss_create()`.

`int PyThread_tss_create(Py_tss_t *key)`

*Part of the [Stable ABI](#) since version 3.7.*

Return a zero value on successful initialization of a TSS key. The behavior is undefined if the value pointed to by the *key* argument is not initialized by `Py_tss_NEEDS_INIT`. This function can be called repeatedly on the same key – calling it on an already initialized key is a no-op and immediately returns success.

`void PyThread_tss_delete(Py_tss_t *key)`

*Part of the [Stable ABI](#) since version 3.7.*

Destroy a TSS key to forget the values associated with the key across all threads, and change the key's initialization state to uninitialized. A destroyed key is able to be initialized again by `PyThread_tss_create()`. This function can be called repeatedly on the same key – calling it on an already destroyed key is a no-op.

`int PyThread_tss_set(Py_tss_t *key, void *value)`

*Part of the [Stable ABI](#) since version 3.7.*

Return a zero value to indicate successfully associating a `void*` value with a TSS key in the current thread. Each thread has a distinct mapping of the key to a `void*` value.

`void *PyThread_tss_get(Py_tss_t *key)`

*Part of the [Stable ABI](#) since version 3.7.*

Return the `void*` value associated with a TSS key in the current thread. This returns `NULL` if no value is associated with the key in the current thread.

## Thread Local Storage (TLS) API

*Deprecated since version 3.7:* This API is superseded by [Thread Specific Storage \(TSS\) API](#).

### Note

This version of the API does not support platforms where the native TLS key is defined in a way that cannot be safely cast to `int`. On such platforms, `PyThread_create_key()` will return immediately with a failure status, and the other TLS functions will all be no-ops on such platforms.

Due to the compatibility problem noted above, this version of the API should not be used in new code.

`int PyThread_create_key()`

*Part of the [Stable ABI](#).*

`void PyThread_delete_key(int key)`

*Part of the [Stable ABI](#).*

`int PyThread_set_key_value(int key, void *value)`

*Part of the [Stable ABI](#).*

`void *PyThread_get_key_value(int key)`

*Part of the [Stable ABI](#).*

`void PyThread_delete_key_value(int key)`

*Part of the [Stable ABI](#).*

`void PyThread_ReInitTLS()`

*Part of the [Stable ABI](#).*

# Python Initialization Configuration

*New in version 3.8.*

Python can be initialized with `Py_InitializeFromConfig()` and the `PyConfig` structure. It can be preinitialized with `Py_PreInitialize()` and the `PyPreConfig` structure.

There are two kinds of configuration:

- The [Python Configuration](#) can be used to build a customized Python which behaves as the regular Python. For example, environment variables and command line arguments are used to configure Python.
- The [Isolated Configuration](#) can be used to embed Python into an application. It isolates Python from the system. For example, environment variables are ignored, the LC\_CTYPE locale is left unchanged and no signal handler is registered.

The `Py_RunMain()` function can be used to write a customized Python program.

See also [Initialization](#), [Finalization](#), and [Threads](#).

**See also**

**PEP 587** [<https://peps.python.org/pep-0587/>] “Python Initialization Configuration”.

## Example

Example of customized Python always running in isolated mode:

```
int main(int argc, char **argv)
```

```

{
    PyStatus status;

    PyConfig config;
    PyConfig_InitPythonConfig(&config);
    config.isolated = 1;

    /* Decode command line arguments.
       Implicitly preinitialize Python (in isolated mode)
    status = PyConfig_SetBytesArgv(&config, argc, argv);
    if (PyStatus_Exception(status)) {
        goto exception;
    }

    status = Py_InitializeFromConfig(&config);
    if (PyStatus_Exception(status)) {
        goto exception;
    }
    PyConfig_Clear(&config);

    return Py_RunMain();

exception:
    PyConfig_Clear(&config);
    if (PyStatus_IsExit(status)) {
        return status.exitcode;
    }
    /* Display the error message and exit the process with
       non-zero exit code */
    Py_ExitStatusException(status);
}

```

## PyWideStringList

type PyWideStringList

List of `wchar_t*` strings.

If *length* is non-zero, *items* must be non-NULL and all strings

must be non-NULL.

Methods:

**PyStatus** PyWideStringList\_Append(**PyWideStringList** \*list,  
const wchar\_t \*item)

Append *item* to *list*.

Python must be preinitialized to call this function.

**PyStatus** PyWideStringList\_Insert(**PyWideStringList** \*list,  
**Py\_ssize\_t** index, const wchar\_t \*item)

Insert *item* into *list* at *index*.

If *index* is greater than or equal to *list* length, append *item* to *list*.

*index* must be greater than or equal to 0.

Python must be preinitialized to call this function.

Structure fields:

**Py\_ssize\_t** length  
List length.

wchar\_t \*\*items  
List items.

## PyStatus

type PyStatus

Structure to store an initialization function status: success, error or exit.

For an error, it can store the C function name which created the error.

Structure fields:

`int exitcode`

Exit code. Argument passed to `exit()`.

`const char *err_msg`

Error message.

`const char *func`

Name of the function which created an error, can be `NULL`.

Functions to create a status:

`PyStatus` `PyStatus_Ok(void)`

Success.

`PyStatus` `PyStatus_Error(const char *err_msg)`

Initialization error with a message.

*err\_msg* must not be `NULL`.

`PyStatus` `PyStatus_NoMemory(void)`

Memory allocation failure (out of memory).

`PyStatus` `PyStatus_Exit(int exitcode)`

Exit Python with the specified exit code.

Functions to handle a status:

`int` `PyStatus_Exception(PyStatus status)`

Is the status an error or an exit? If true, the exception must be handled; by calling

`Py_ExitStatusException()` for example.

`int` `PyStatus_IsError(PyStatus status)`

Is the result an error?

`int PyStatus_IsExit(PyStatus status)`

Is the result an exit?

`void Py_ExitStatusException(PyStatus status)`

Call `exit(exitcode)` if *status* is an exit. Print the error message and exit with a non-zero exit code if *status* is an error. Must only be called if `PyStatus_Exception(status)` is non-zero.

## Note

Internally, Python uses macros which set `PyStatus.func`, whereas functions to create a status set `func` to `NULL`.

## Example:

```
PyStatus alloc(void **ptr, size_t size)
{
    *ptr = PyMem_RawMalloc(size);
    if (*ptr == NULL) {
        return PyStatus_NoMemory();
    }
    return PyStatus_Ok();
}

int main(int argc, char **argv)
{
    void *ptr;
    PyStatus status = alloc(&ptr, 16);
    if (PyStatus_Exception(status)) {
        Py_ExitStatusException(status);
    }
    PyMem_Free(ptr);
    return 0;
}
```

# PyPreConfig

type PyPreConfig

Structure used to preinitialize Python.

Function to initialize a preconfiguration:

void PyPreConfig\_InitPythonConfig(PyPreConfig \*preconfig)

Initialize the preconfiguration with [Python Configuration](#).

void PyPreConfig\_InitIsolatedConfig(PyPreConfig \*preconfig)

Initialize the preconfiguration with [Isolated Configuration](#).

Structure fields:

int allocator

Name of the Python memory allocators:

- PYMEM\_ALLOCATOR\_NOT\_SET (0): don't change memory allocators (use defaults).
- PYMEM\_ALLOCATOR\_DEFAULT (1): [default memory allocators](#).
- PYMEM\_ALLOCATOR\_DEBUG (2): [default memory allocators with debug hooks](#).
- PYMEM\_ALLOCATOR\_MALLOC (3): use `malloc()` of the C library.
- PYMEM\_ALLOCATOR\_MALLOC\_DEBUG (4): force usage of `malloc()` with [debug hooks](#).
- PYMEM\_ALLOCATOR\_PYMALLOC (5): [Python pymalloc memory allocator](#).
- PYMEM\_ALLOCATOR\_PYMALLOC\_DEBUG (6): [Python pymalloc memory allocator with debug hooks](#).

PYMEM\_ALLOCATOR\_PYMALLOC and PYMEM\_ALLOCATOR\_PYMALLOC\_DEBUG are not supported if Python is [configured using --](#)

`without-pymalloc`.

See [Memory Management](#).

Default: `PYMEM_ALLOCATOR_NOT_SET`.

`int configure_locale`

Set the `LC_CTYPE` locale to the user preferred locale.

If equals to `0`, set `coerce_c_locale` and `coerce_c_locale_warn` members to `0`.

See the [locale encoding](#).

Default: `1` in Python config, `0` in isolated config.

`int coerce_c_locale`

If equals to `2`, coerce the C locale.

If equals to `1`, read the `LC_CTYPE` locale to decide if it should be coerced.

See the [locale encoding](#).

Default: `-1` in Python config, `0` in isolated config.

`int coerce_c_locale_warn`

If non-zero, emit a warning if the C locale is coerced.

Default: `-1` in Python config, `0` in isolated config.

`int dev_mode`

[Python Development Mode](#): see `PyConfig.dev_mode`.

Default: `-1` in Python mode, `0` in isolated mode.

`int isolated`

Isolated mode: see `PyConfig.isolated`.

Default: 0 in Python mode, 1 in isolated mode.

int legacy\_windows\_fs\_encoding

If non-zero:

- Set `PyPreConfig.utf8_mode` to 0,
- Set `PyConfig.filesystem_encoding` to "mbcs",
- Set `PyConfig.filesystem_errors` to "replace".

Initialized the from

`PYTHONLEGACYWINDOWSFSENCODING` environment variable value.

Only available on Windows. `#ifdef MS_WINDOWS` macro can be used for Windows specific code.

Default: 0.

int parse\_argv

If non-zero, `Py_PreInitializeFromArgs()` and `Py_PreInitializeFromBytesArgs()` parse their argv argument the same way the regular Python parses command line arguments: see [Command Line Arguments](#).

Default: 1 in Python config, 0 in isolated config.

int use\_environment

Use [environment variables](#)? See `PyConfig.use_environment`.

Default: 1 in Python config and 0 in isolated config.

int utf8\_mode

If non-zero, enable the [Python UTF-8 Mode](#).

Set to 0 or 1 by the `-X utf8` command line option and the `PYTHONUTF8` environment variable.

Also set to 1 if the LC\_CTYPE locale is C or POSIX.

Default: -1 in Python config and 0 in isolated config.

## Preinitialize Python with PyPreConfig

The preinitialization of Python:

- Set the Python memory allocators (`PyPreConfig.allocators`)
- Configure the LC\_CTYPE locale (`locale encoding`)
- Set the `Python UTF-8 Mode` (`PyPreConfig.utf8_mode`)

The current preconfiguration (PyPreConfig type) is stored in `_PyRuntime.preconfig`.

Functions to preinitialize Python:

`PyStatus` `Py_PreInitialize(const PyPreConfig *preconfig)`

Preinitialize Python from *preconfig* preconfiguration.

*preconfig* must not be `NULL`.

`PyStatus` `Py_PreInitializeFromBytesArgs(const PyPreConfig *preconfig, int argc, char *const *argv)`

Preinitialize Python from *preconfig* preconfiguration.

Parse *argv* command line arguments (bytes strings) if `parse_argv` of *preconfig* is non-zero.

*preconfig* must not be `NULL`.

`PyStatus` `Py_PreInitializeFromArgs(const PyPreConfig *preconfig, int argc, wchar_t *const *argv)`

Preinitialize Python from *preconfig* preconfiguration.

Parse *argv* command line arguments (wide strings) if `parse_argv` of *preconfig* is non-zero.

*preconfig* must not be `NULL`.

The caller is responsible to handle exceptions (error or exit) using `PyStatus_Exception()` and `Py_ExitStatusException()`.

For [Python Configuration](#)

(`PyPreConfig_InitPythonConfig()`), if Python is initialized with command line arguments, the command line arguments must also be passed to preinitialize Python, since they have an effect on the pre-configuration like encodings. For example, the `-X utf8` command line option enables the [Python UTF-8 Mode](#).

`PyMem_SetAllocator()` can be called after `Py_PreInitialize()` and before `Py_InitializeFromConfig()` to install a custom memory allocator. It can be called before `Py_PreInitialize()` if `PyPreConfig.allocator` is set to `PYMEM_ALLOCATOR_NOT_SET`.

Python memory allocation functions like `PyMem_RawMalloc()` must not be used before the Python preinitialization, whereas calling directly `malloc()` and `free()` is always safe. `Py_DecodeLocale()` must not be called before the Python preinitialization.

Example using the preinitialization to enable the [Python UTF-8 Mode](#):

```
PyStatus status;
PyPreConfig preconfig;
PyPreConfig_InitPythonConfig(&preconfig);

preconfig.utf8_mode = 1;

status = Py_PreInitialize(&preconfig);
if (PyStatus_Exception(status)) {
    Py_ExitStatusException(status);
}

/* at this point, Python speaks UTF-8 */
```

```
Py_Initialize();  
/* ... use Python API here ... */  
Py_Finalize();
```

## PyConfig

type PyConfig

Structure containing most parameters to configure Python.

When done, the [PyConfig\\_Clear\(\)](#) function must be used to release the configuration memory.

Structure methods:

`void PyConfig_InitPythonConfig(PyConfig *config)`

Initialize configuration with the [Python Configuration](#).

`void PyConfig_InitIsolatedConfig(PyConfig *config)`

Initialize configuration with the [Isolated Configuration](#).

[PyStatus](#) `PyConfig_SetString(PyConfig *config, wchar_t *const *config_str, const wchar_t *str)`

Copy the wide character string *str* into *\*config\_str*.

[Preinitialize Python](#) if needed.

[PyStatus](#) `PyConfig_SetBytesString(PyConfig *config, wchar_t *const *config_str, const char *str)`

Decode *str* using [Py\\_DecodeLocale\(\)](#) and set the result into *\*config\_str*.

[Preinitialize Python](#) if needed.

[PyStatus](#) `PyConfig_SetArgv(PyConfig *config, int argc, wchar_t *const *argv)`

Set command line arguments ([argv](#) member of *config*)

from the *argv* list of wide character strings.

Preinitialize Python if needed.

**PyStatus** PyConfig\_SetBytesArgv(**PyConfig** \*config, int argc, char \*const \*argv)

Set command line arguments (**argv** member of *config*) from the *argv* list of bytes strings. Decode bytes using **Py\_DecodeLocale()**.

Preinitialize Python if needed.

**PyStatus** PyConfig\_SetWideStringList(**PyConfig** \*config, PyWideStringList \*list, **Py\_ssize\_t** length, wchar\_t \*\*items)

Set the list of wide strings *list* to *length* and *items*.

Preinitialize Python if needed.

**PyStatus** PyConfig\_Read(**PyConfig** \*config)

Read all Python configuration.

Fields which are already initialized are left unchanged.

Fields for **path configuration** are no longer calculated or modified when calling this function, as of Python 3.11.

The **PyConfig\_Read()** function only parses **PyConfig.argv** arguments once: **PyConfig.parse\_argv** is set to 2 after arguments are parsed. Since Python arguments are stripped from **PyConfig.argv**, parsing arguments twice would parse the application options as Python options.

Preinitialize Python if needed.

*Changed in version 3.10:* The **PyConfig.argv** arguments are now only parsed once, **PyConfig.parse\_argv** is set to 2 after arguments are parsed, and arguments are only parsed if

`PyConfig.parse_argv` equals 1.

*Changed in version 3.11:* `PyConfig_Read()` no longer calculates all paths, and so fields listed under [Python Path Configuration](#) may no longer be updated until `Py_InitializeFromConfig()` is called.

`void PyConfig_Clear(PyConfig *config)`

Release configuration memory.

Most `PyConfig` methods [preinitialize Python](#) if needed. In that case, the Python preinitialization configuration (`PyPreConfig`) is based on the `PyConfig`. If configuration fields which are in common with `PyPreConfig` are tuned, they must be set before calling a `PyConfig` method:

- `PyConfig.dev_mode`
- `PyConfig.isolated`
- `PyConfig.parse_argv`
- `PyConfig.use_environment`

Moreover, if `PyConfig_SetArgv()` or `PyConfig_SetBytesArgv()` is used, this method must be called before other methods, since the preinitialization configuration depends on command line arguments (if `parse_argv` is non-zero).

The caller of these methods is responsible to handle exceptions (error or exit) using `PyStatus_Exception()` and `Py_ExitStatusException()`.

Structure fields:

`PyWideStringList argv`

Command line arguments: `sys.argv`.

Set `parse_argv` to 1 to parse `argv` the same way the regular Python parses Python command line arguments and then to strip Python arguments from `argv`.

If `argv` is empty, an empty string is added to ensure that `sys.argv` always exists and is never empty.

Default: `NULL`.

See also the `orig_argv` member.

`int safe_path`

If equals to zero, `Py_RunMain()` prepends a potentially unsafe path to `sys.path` at startup:

- If `argv[0]` is equal to `L"-m"` (`python -m module`), prepend the current working directory.
- If running a script (`python script.py`), prepend the script's directory. If it's a symbolic link, resolve symbolic links.
- Otherwise (`python -c code` and `python`), prepend an empty string, which means the current working directory.

Set to `1` by the `-P` command line option and the `PYTHONSAFEPATH` environment variable.

Default: `0` in Python config, `1` in isolated config.

*New in version 3.11.*

`wchar_t *base_exec_prefix`

`sys.base_exec_prefix`.

Default: `NULL`.

Part of the [Python Path Configuration](#) output.

`wchar_t *base_executable`

Python base executable: `sys._base_executable`.

Set by the `__PYENVV_LAUNCHER__` environment variable.

Set from `PyConfig.executable` if `NULL`.

Default: `NULL`.

Part of the [Python Path Configuration](#) output.

`wchar_t *base_prefix`  
[`sys.base\_prefix`](#).

Default: `NULL`.

Part of the [Python Path Configuration](#) output.

`int buffered_stdio`

If equals to `0` and [`configure\_c\_stdio`](#) is non-zero, disable buffering on the C streams `stdout` and `stderr`.

Set to `0` by the [`-u`](#) command line option and the [`PYTHONUNBUFFERED`](#) environment variable.

`stdin` is always opened in buffered mode.

Default: `1`.

`int bytes_warning`

If equals to `1`, issue a warning when comparing [`bytes`](#) or [`bytearray`](#) with [`str`](#), or comparing [`bytes`](#) with [`int`](#).

If equal or greater to `2`, raise a [`BytesWarning`](#) exception in these cases.

Incremented by the [`-b`](#) command line option.

Default: `0`.

`int warn_default_encoding`

If non-zero, emit a [`EncodingWarning`](#) warning when [`io.TextIOWrapper`](#) uses its default encoding. See [Opt-in EncodingWarning](#) for details.

Default: `0`.

*New in version 3.10.*

`int code_debug_ranges`

If equals to 0, disables the inclusion of the end line and column mappings in code objects. Also disables traceback printing carets to specific error locations.

Set to 0 by the `PYTHONNODEBUGRANGES` environment variable and by the `-X no_debug_ranges` command line option.

Default: 1.

*New in version 3.11.*

`wchar_t *check_hash_pycs_mode`

Control the validation behavior of hash-based .pyc files: value of the `--check-hash-based-pycs` command line option.

Valid values:

- `L"always"`: Hash the source file for invalidation regardless of value of the ‘check\_source’ flag.
- `L"never"`: Assume that hash-based pycs always are valid.
- `L"default"`: The ‘check\_source’ flag in hash-based pycs determines invalidation.

Default: `L"default"`.

See also [PEP 552](https://peps.python.org/pep-0552/) [https://peps.python.org/pep-0552/] “Deterministic pycs”.

`int configure_c_stdio`

If non-zero, configure C standard streams:

- On Windows, set the binary mode (`O_BINARY`) on stdin, stdout and stderr.
- If `buffered_stdio` equals zero, disable

- buffering of stdin, stdout and stderr streams.
- If **interactive** is non-zero, enable stream buffering on stdin and stdout (only stdout on Windows).

Default: 1 in Python config, 0 in isolated config.

int dev\_mode

If non-zero, enable the **Python Development Mode**.

Set to 1 by the **-X dev** option and the **PYTHONDEVMODE** environment variable.

Default: -1 in Python mode, 0 in isolated mode.

int dump\_refs

Dump Python references?

If non-zero, dump all objects which are still alive at exit.

Set to 1 by the **PYTHONDUMPREFS** environment variable.

Need a special build of Python with the **Py\_TRACE\_REFS** macro defined: see the **configure --with-trace-refs option**.

Default: 0.

wchar\_t \*exec\_prefix

The site-specific directory prefix where the platform-dependent Python files are installed:  
**sys.exec\_prefix**.

Default: NULL.

Part of the **Python Path Configuration** output.

wchar\_t \*executable

The absolute path of the executable binary for the Python interpreter: `sys.executable`.

Default: NULL.

Part of the [Python Path Configuration](#) output.

int `faulthandler`

Enable `faulthandler`?

If non-zero, call `faulthandler.enable()` at startup.

Set to 1 by `-X faulthandler` and the `PYTHONFAULTHANDLER` environment variable.

Default: -1 in Python mode, 0 in isolated mode.

wchar\_t \*`filesystem_encoding`

[Filesystem encoding](#):

`sys.getfilesystemencoding()`.

On macOS, Android and VxWorks: use "utf-8" by default.

On Windows: use "utf-8" by default, or "mbcs" if [legacy\\_windows\\_fs\\_encoding](#) of `PyPreConfig` is non-zero.

Default encoding on other platforms:

- "utf-8" if `PyPreConfig.utf8_mode` is non-zero.
- "ascii" if Python detects that `nl_langinfo(CODESET)` announces the ASCII encoding, whereas the `mbstowcs()` function decodes from a different encoding (usually Latin1).
- "utf-8" if `nl_langinfo(CODESET)` returns an empty string.
- Otherwise, use the [locale encoding](#):

`nl_langinfo(CODESET)` result.

At Python startup, the encoding name is normalized to the Python codec name. For example, "ANSI\_X3.4-1968" is replaced with "ascii".

See also the `filesystem_errors` member.

`wchar_t *filesystem_errors`

Filesystem error handler:

`sys.getfilesystemencodeerrors()`.

On Windows: use "surrogatepass" by default, or "replace" if `legacy_windows_fs_encoding` of `PyPreConfig` is non-zero.

On other platforms: use "surrogateescape" by default.

Supported error handlers:

- "strict"
- "surrogateescape"
- "surrogatepass" (only supported with the UTF-8 encoding)

See also the `filesystem_encoding` member.

`unsigned long hash_seed`

`int use_hash_seed`

Randomized hash function seed.

If `use_hash_seed` is zero, a seed is chosen randomly at Python startup, and `hash_seed` is ignored.

Set by the `PYTHONHASHSEED` environment variable.

Default `use_hash_seed` value: -1 in Python mode, 0 in isolated mode.

wchar\_t \*home

Python home directory.

If `Py_SetPythonHome()` has been called, use its argument if it is not `NULL`.

Set by the `PYTHONHOME` environment variable.

Default: `NULL`.

Part of the [Python Path Configuration](#) input.

int import\_time

If non-zero, profile import time.

Set the `1` by the `-X importtime` option and the `PYTHONPROFILEIMPORTTIME` environment variable.

Default: `0`.

int inspect

Enter interactive mode after executing a script or a command.

If greater than `0`, enable inspect: when a script is passed as first argument or the `-c` option is used, enter interactive mode after executing the script or the command, even when `sys.stdin` does not appear to be a terminal.

Incremented by the `-i` command line option. Set to `1` if the `PYTHONINSPECT` environment variable is non-empty.

Default: `0`.

int install\_signal\_handlers

Install Python signal handlers?

Default: `1` in Python mode, `0` in isolated mode.

## int interactive

If greater than 0, enable the interactive mode (REPL).

Incremented by the `-i` command line option.

Default: 0.

## int isolated

If greater than 0, enable isolated mode:

- Set `safe_path` to 1: don't prepend a potentially unsafe path to `sys.path` at Python startup.
- Set `use_environment` to 0.
- Set `user_site_directory` to 0: don't add the user site directory to `sys.path`.
- Python REPL doesn't import `readline` nor enable default readline configuration on interactive prompts.

Set to 1 by the `-I` command line option.

Default: 0 in Python mode, 1 in isolated mode.

See also `PyPreConfig.isolated`.

## int legacy\_windows\_stdio

If non-zero, use `io.FileIO` instead of `io.WindowsConsoleIO` for `sys.stdin`, `sys.stdout` and `sys.stderr`.

Set to 1 if the `PYTHONLEGACYWINDOWSSTDIO` environment variable is set to a non-empty string.

Only available on Windows. `#ifdef MS_WINDOWS` macro can be used for Windows specific code.

Default: 0.

See also the [PEP 528](https://peps.python.org/pep-0528/) [https://peps.python.org/pep-0528/]  
(Change Windows console encoding to UTF-8).

int malloc\_stats

If non-zero, dump statistics on [Python pymalloc memory allocator](#) at exit.

Set to 1 by the [PYTHONMALLOCSSTATS](#) environment variable.

The option is ignored if Python is [configured using the --without-pymalloc option](#).

Default: 0.

wchar\_t \*platlibdir

Platform library directory name: [sys.platlibdir](#).

Set by the [PYTHONPLATLIBDIR](#) environment variable.

Default: value of the `PLATLIBDIR` macro which is set by the [configure --with-platlibdir option](#) (default: "lib", or "DLLs" on Windows).

Part of the [Python Path Configuration](#) input.

*New in version 3.9.*

*Changed in version 3.11:* This macro is now used on Windows to locate the standard library extension modules, typically under `DLLs`. However, for compatibility, note that this value is ignored for any non-standard layouts, including in-tree builds and virtual environments.

wchar\_t \*pythonpath\_env

Module search paths ([sys.path](#)) as a string separated by `DELIM` ([os.path.pathsep](#)).

Set by the [PYTHONPATH](#) environment variable.

Default: `NULL`.

Part of the [Python Path Configuration](#) input.

## PyWideStringList module\_search\_paths

int module\_search\_paths\_set

Module search paths: `sys.path`.

If `module_search_paths_set` is equal to 0, `Py_InitializeFromConfig()` will replace `module_search_paths` and sets `module_search_paths_set` to 1.

Default: empty list (`module_search_paths`) and 0 (`module_search_paths_set`).

Part of the [Python Path Configuration](#) output.

int optimization\_level

Compilation optimization level:

- 0: Peephole optimizer, set `__debug__` to True.
- 1: Level 0, remove assertions, set `__debug__` to False.
- 2: Level 1, strip docstrings.

Incremented by the `-O` command line option. Set to the `PYTHONOPTIMIZE` environment variable value.

Default: 0.

## PyWideStringList orig\_argv

The list of the original command line arguments passed to the Python executable: `sys.orig_argv`.

If `orig_argv` list is empty and `argv` is not a list only containing an empty string, `PyConfig_Read()` copies `argv` into `orig_argv` before modifying `argv` (if `parse_argv` is non-zero).

See also the `argv` member and the `Py_GetArgcArgv()` function.

Default: empty list.

*New in version 3.10.*

`int parse_argv`

Parse command line arguments?

If equals to `1`, parse `argv` the same way the regular Python parses `command line arguments`, and strip Python arguments from `argv`.

The `PyConfig_Read()` function only parses `PyConfig.argv` arguments once: `PyConfig.parse_argv` is set to `2` after arguments are parsed. Since Python arguments are stripped from `PyConfig.argv`, parsing arguments twice would parse the application options as Python options.

Default: `1` in Python mode, `0` in isolated mode.

*Changed in version 3.10:* The `PyConfig.argv` arguments are now only parsed if `PyConfig.parse_argv` equals to `1`.

`int parser_debug`

Parser debug mode. If greater than `0`, turn on parser debugging output (for expert only, depending on compilation options).

Incremented by the `-d` command line option. Set to the `PYTHONDEBUG` environment variable value.

Default: `0`.

`int pathconfig_warnings`

If non-zero, calculation of path configuration is allowed to log warnings into `stderr`. If equals to `0`, suppress these warnings.

Default: `1` in Python mode, `0` in isolated mode.

Part of the [Python Path Configuration](#) input.

*Changed in version 3.11:* Now also applies on Windows.

wchar\_t \*prefix

The site-specific directory prefix where the platform independent Python files are installed: [sys.prefix](#).

Default: NULL.

Part of the [Python Path Configuration](#) output.

wchar\_t \*program\_name

Program name used to initialize [executable](#) and in early error messages during Python initialization.

- If **Py\_SetProgramName()** has been called, use its argument.
- On macOS, use [PYTHONEXECUTABLE](#) environment variable if set.
- If the `WITH_NEXT_FRAMEWORK` macro is defined, use [\\_\\_PYENV\\_LAUNCHER\\_\\_](#) environment variable if set.
- Use `argv[0]` of [argv](#) if available and non-empty.
- Otherwise, use `L"python"` on Windows, or `L"python3"` on other platforms.

Default: NULL.

Part of the [Python Path Configuration](#) input.

wchar\_t \*pycache\_prefix

Directory where cached `.pyc` files are written: [sys.pycache\\_prefix](#).

Set by the `-X pycache_prefix=PATH` command line option and the [PYTHONPYCACHEPREFIX](#) environment variable.

If `NULL`, `sys.pycache_prefix` is set to `None`.

Default: `NULL`.

`int quiet`

Quiet mode. If greater than `0`, don't display the copyright and version at Python startup in interactive mode.

Incremented by the `-q` command line option.

Default: `0`.

`wchar_t *run_command`

Value of the `-c` command line option.

Used by `Py_RunMain()`.

Default: `NULL`.

`wchar_t *run_filename`

Filename passed on the command line: trailing command line argument without `-c` or `-m`. It is used by the `Py_RunMain()` function.

For example, it is set to `script.py` by the `python3 script.py arg` command line.

See also the `PyConfig.skip_source_first_line` option.

Default: `NULL`.

`wchar_t *run_module`

Value of the `-m` command line option.

Used by `Py_RunMain()`.

Default: `NULL`.

int show\_ref\_count

Show total reference count at exit?

Set to 1 by **-X showrefcount** command line option.

Need a **debug build of Python** (the `Py_REF_DEBUG` macro must be defined).

Default: 0.

int site\_import

Import the **site** module at startup?

If equal to zero, disable the import of the module `site` and the site-dependent manipulations of **`sys.path`** that it entails.

Also disable these manipulations if the **site** module is explicitly imported later (call **`site.main()`** if you want them to be triggered).

Set to 0 by the **-S** command line option.

**`sys.flags.no_site`** is set to the inverted value of **`site_import`**.

Default: 1.

int skip\_source\_first\_line

If non-zero, skip the first line of the **`PyConfig.run_filename`** source.

It allows the usage of non-Unix forms of `#!cmd`. This is intended for a DOS specific hack only.

Set to 1 by the **-x** command line option.

Default: 0.

wchar\_t \*stdio\_encoding

wchar\_t \*stdio\_errors

Encoding and encoding errors of `sys.stdin`, `sys.stdout` and `sys.stderr` (but `sys.stderr` always uses "backslashreplace" error handler).

If `Py_SetStandardStreamEncoding()` has been called, use its *error* and *errors* arguments if they are not NULL.

Use the `PYTHONIOENCODING` environment variable if it is non-empty.

Default encoding:

- "UTF-8" if `PyPreConfig.utf8_mode` is non-zero.
- Otherwise, use the [locale encoding](#).

Default error handler:

- On Windows: use "surrogateescape".
- "surrogateescape" if `PyPreConfig.utf8_mode` is non-zero, or if the LC\_CTYPE locale is "C" or "POSIX".
- "strict" otherwise.

int tracemalloc

Enable tracemalloc?

If non-zero, call `tracemalloc.start()` at startup.

Set by `-X tracemalloc=N` command line option and by the `PYTHONTRACEMALLOC` environment variable.

Default: -1 in Python mode, 0 in isolated mode.

int use\_environment

Use [environment variables](#)?

If equals to zero, ignore the [environment variables](#).

Set to 0 by the **-E** environment variable.

Default: 1 in Python config and 0 in isolated config.

`int user_site_directory`

If non-zero, add the user site directory to **sys.path**.

Set to 0 by the **-s** and **-I** command line options.

Set to 0 by the **PYTHONNOUSERSITE** environment variable.

Default: 1 in Python mode, 0 in isolated mode.

`int verbose`

Verbose mode. If greater than 0, print a message each time a module is imported, showing the place (filename or built-in module) from which it is loaded.

If greater or equal to 2, print a message for each file that is checked for when searching for a module. Also provides information on module cleanup at exit.

Incremented by the **-v** command line option.

Set to the **PYTHONVERBOSE** environment variable value.

Default: 0.

**PyWideStringList** `warnoptions`

Options of the **warnings** module to build warnings filters, lowest to highest priority: **sys.warnoptions**.

The **warnings** module adds **sys.warnoptions** in the reverse order: the last **PyConfig.warnoptions** item becomes the first item of **warnings.filters** which is checked first (highest priority).

The **-W** command line options adds its value to **warnoptions**, it can be used multiple times.

The `PYTHONWARNINGS` environment variable can also be used to add warning options. Multiple options can be specified, separated by commas (, ).

Default: empty list.

`int write_bytecode`

If equal to 0, Python won't try to write `.pyc` files on the import of source modules.

Set to 0 by the `-B` command line option and the `PYTHONDONTWRITEBYTECODE` environment variable.

`sys.dont_write_bytecode` is initialized to the inverted value of `write_bytecode`.

Default: 1.

`PyWideStringList xoptions`

Values of the `-X` command line options:

`sys._xoptions`.

Default: empty list.

If `parse_argv` is non-zero, `argv` arguments are parsed the same way the regular Python parses [command line arguments](#), and Python arguments are stripped from `argv`.

The `xoptions` options are parsed to set other options: see the `-X` command line option.

*Changed in version 3.9:* The `show_alloc_count` field has been removed.

## Initialization with PyConfig

Function to initialize Python:

`PyStatus Py_InitializeFromConfig(const PyConfig *config)`

Initialize Python from *config* configuration.

The caller is responsible to handle exceptions (error or exit) using `PyStatus_Exception()` and `Py_ExitStatusException()`.

If `PyImport_FrozenModules()`, `PyImport_AppendInittab()` or `PyImport_ExtendInittab()` are used, they must be set or called after Python preinitialization and before the Python initialization. If Python is initialized multiple times, `PyImport_AppendInittab()` or `PyImport_ExtendInittab()` must be called before each Python initialization.

The current configuration (`PyConfig` type) is stored in `PyInterpreterState.config`.

Example setting the program name:

```
void init_python(void)
{
    PyStatus status;

    PyConfig config;
    PyConfig_InitPythonConfig(&config);

    /* Set the program name. Implicitly preinitialize Py
    status = PyConfig_SetString(&config, &config.program_name,
                                L"/path/to/my_program");
    if (PyStatus_Exception(status)) {
        goto exception;
    }

    status = Py_InitializeFromConfig(&config);
    if (PyStatus_Exception(status)) {
        goto exception;
    }
    PyConfig_Clear(&config);
    return;
```

```

exception:
    PyConfig_Clear(&config);
    Py_ExitStatusException(status);
}

```

More complete example modifying the default configuration, read the configuration, and then override some parameters. Note that since 3.11, many parameters are not calculated until initialization, and so values cannot be read from the configuration structure. Any values set before initialize is called will be left unchanged by initialization:

```

PyStatus init_python(const char *program_name)
{
    PyStatus status;

    PyConfig config;
    PyConfig_InitPythonConfig(&config);

    /* Set the program name before reading the configuration
       (decode byte string from the locale encoding).

       Implicitly preinitialize Python. */
    status = PyConfig_SetBytesString(&config, &config.program_name,
                                     program_name);
    if (PyStatus_Exception(status)) {
        goto done;
    }

    /* Read all configuration at once */
    status = PyConfig_Read(&config);
    if (PyStatus_Exception(status)) {
        goto done;
    }

    /* Specify sys.path explicitly */
    /* If you want to modify the default set of paths, first do
       initialization first and then use PySys_GetObject
       config.module_search_paths_set = 1;

```

```

        status = PyWideStringList_Append(&config.module_search_path,
   L"/path/to/stdlib")
    if (PyStatus_Exception(status)) {
        goto done;
    }
    status = PyWideStringList_Append(&config.module_search_path,
                                     L"/path/to/more/modules")
    if (PyStatus_Exception(status)) {
        goto done;
    }

    /* Override executable computed by PyConfig_Read() */
    status = PyConfig_SetString(&config, &config.executable,
                               L"/path/to/my_executable")
    if (PyStatus_Exception(status)) {
        goto done;
    }

    status = Py_InitializeFromConfig(&config);

done:
    PyConfig_Clear(&config);
    return status;
}

```

## Isolated Configuration

**PyPreConfig\_InitIsolatedConfig()** and **PyConfig\_InitIsolatedConfig()** functions create a configuration to isolate Python from the system. For example, to embed Python into an application.

This configuration ignores global configuration variables, environment variables, command line arguments (**PyConfig.argv** is not parsed) and user site directory. The C standard streams (ex: stdout) and the LC\_CTYPE locale are left unchanged. Signal handlers are not installed.

Configuration files are still used with this configuration to

determine paths that are unspecified. Ensure `PyConfig.home` is specified to avoid computing the default path configuration.

## Python Configuration

`PyPreConfig_InitPythonConfig()` and `PyConfig_InitPythonConfig()` functions create a configuration to build a customized Python which behaves as the regular Python.

Environments variables and command line arguments are used to configure Python, whereas global configuration variables are ignored.

This function enables C locale coercion ([PEP 538](https://peps.python.org/pep-0538/) [https://peps.python.org/pep-0538/]) and [Python UTF-8 Mode](https://peps.python.org/pep-0540/) ([PEP 540](https://peps.python.org/pep-0540/) [https://peps.python.org/pep-0540/]) depending on the `LC_CTYPE` locale, `PYTHONUTF8` and `PYTHONCOERCECLOCALE` environment variables.

## Python Path Configuration

`PyConfig` contains multiple fields for the path configuration:

- Path configuration inputs:
  - `PyConfig.home`
  - `PyConfig.platlibdir`
  - `PyConfig.pathconfig_warnings`
  - `PyConfig.program_name`
  - `PyConfig.pythonpath_env`
  - current working directory: to get absolute paths
  - `PATH` environment variable to get the program full path (from `PyConfig.program_name`)
  - `__PYENV_LAUNCHER__` environment variable
  - (Windows only) Application paths in the registry under “SoftwarePythonPythonCoreX.YPythonPath” of `HKEY_CURRENT_USER` and `HKEY_LOCAL_MACHINE` (where X.Y is the Python version).
- Path configuration output fields:

- `PyConfig.base_exec_prefix`
- `PyConfig.base_executable`
- `PyConfig.base_prefix`
- `PyConfig.exec_prefix`
- `PyConfig.executable`
- `PyConfig.module_search_paths_set,`  
`PyConfig.module_search_paths`
- `PyConfig.prefix`

If at least one “output field” is not set, Python calculates the path configuration to fill unset fields. If `module_search_paths_set` is equal to 0, `module_search_paths` is overridden and `module_search_paths_set` is set to 1.

It is possible to completely ignore the function calculating the default path configuration by setting explicitly all path configuration output fields listed above. A string is considered as set even if it is non-empty. `module_search_paths` is considered as set if `module_search_paths_set` is set to 1. In this case, `module_search_paths` will be used without modification.

Set `pathconfig_warnings` to 0 to suppress warnings when calculating the path configuration (Unix only, Windows does not log any warning).

If `base_prefix` or `base_exec_prefix` fields are not set, they inherit their value from `prefix` and `exec_prefix` respectively.

`Py_RunMain()` and `Py_Main()` modify `sys.path`:

- If `run_filename` is set and is a directory which contains a `__main__.py` script, prepend `run_filename` to `sys.path`.
- If `isolated` is zero:
  - If `run_module` is set, prepend the current directory to `sys.path`. Do nothing if the current directory cannot be read.
  - If `run_filename` is set, prepend the directory of the filename to `sys.path`.
  - Otherwise, prepend an empty string to `sys.path`.

If `site_import` is non-zero, `sys.path` can be modified by the `site` module. If `user_site_directory` is non-zero and the user's site-package directory exists, the `site` module appends the user's site-package directory to `sys.path`.

The following configuration files are used by the path configuration:

- `pyvenv.cfg`
- `._pth` file (ex: `python._pth`)
- `pybuilddir.txt` (Unix only)

If a `._pth` file is present:

- Set `isolated` to 1.
- Set `use_environment` to 0.
- Set `site_import` to 0.
- Set `safe_path` to 1.

The `__PYENVN__LAUNCHER__` environment variable is used to set `PyConfig.base_executable`

## Py\_RunMain()

`int Py_RunMain(void)`

Execute the command (`PyConfig.run_command`), the script (`PyConfig.run_filename`) or the module (`PyConfig.run_module`) specified on the command line or in the configuration.

By default and when if `-i` option is used, run the REPL.

Finally, finalizes Python and returns an exit status that can be passed to the `exit()` function.

See [Python Configuration](#) for an example of customized Python always running in isolated mode using `Py_RunMain()`.

## Py\_GetArgcArgv()

```
void Py_GetArgvArgv(int *argc, wchar_t ***argv)
```

Get the original command line arguments, before Python modified them.

See also [PyConfig.orig\\_argv](#) member.

## Multi-Phase Initialization Private Provisional API

This section is a private provisional API introducing multi-phase initialization, the core feature of [PEP 432](#) [<https://peps.python.org/pep-0432/>]:

- “Core” initialization phase, “bare minimum Python”:
  - Builtin types;
  - Builtin exceptions;
  - Builtin and frozen modules;
  - The `sys` module is only partially initialized (ex: `sys.path` doesn’t exist yet).
- “Main” initialization phase, Python is fully initialized:
  - Install and configure `importlib`;
  - Apply the [Path Configuration](#);
  - Install signal handlers;
  - Finish `sys` module initialization (ex: create `sys.stdout` and `sys.path`);
  - Enable optional features like [faulthandler](#) and [tracemalloc](#);
  - Import the `site` module;
  - etc.

Private provisional API:

- `PyConfig._init_main`: if set to 0, `Py_InitializeFromConfig()` stops at the “Core” initialization phase.
- `PyConfig._isolated_interpreter`: if non-zero, disallow threads, subprocesses and fork.

[PyStatus](#) `_Py_InitializeMain(void)`

Move to the “Main” initialization phase, finish the Python initialization.

No module is imported during the “Core” phase and the `importlib` module is not configured: the [Path Configuration](#) is only applied during the “Main” phase. It may allow to customize Python in Python to override or tune the [Path Configuration](#), maybe install a custom `sys.meta_path` importer or an import hook, etc.

It may become possible to calculate the [Path Configuration](#) in Python, after the Core phase and before the Main phase, which is one of the [PEP 432](#) [<https://peps.python.org/pep-0432/>] motivation.

The “Core” phase is not properly defined: what should be and what should not be available at this phase is not specified yet. The API is marked as private and provisional: the API can be modified or even be removed anytime until a proper public API is designed.

Example running Python code between “Core” and “Main” initialization phases:

```
void init_python(void)
{
    PyStatus status;

    PyConfig config;
    PyConfig_InitPythonConfig(&config);
    config._init_main = 0;

    /* ... customize 'config' configuration ... */

    status = Py_InitializeFromConfig(&config);
    PyConfig_Clear(&config);
    if (PyStatus_Exception(status)) {
        Py_ExitStatusException(status);
    }

    /* Use sys.stderr because sys.stdout is only created
       by _Py_InitializeMain() */
    int res = PyRun_SimpleString(
```

```
    "import sys; "  
    "print('Run Python code before _Py_InitializeMain()  
        "file=sys.stderr)");  
if (res < 0) {  
    exit(1);  
}  
  
/* ... put more configuration code here ... */  
  
status = _Py_InitializeMain();  
if (PyStatus_Exception(status)) {  
    Py_ExitStatusException(status);  
}  
}
```

# Memory Management

## Overview

Memory management in Python involves a private heap containing all Python objects and data structures. The management of this private heap is ensured internally by the *Python memory manager*. The Python memory manager has different components which deal with various dynamic storage management aspects, like sharing, segmentation, preallocation or caching.

At the lowest level, a raw memory allocator ensures that there is enough room in the private heap for storing all Python-related data by interacting with the memory manager of the operating system. On top of the raw memory allocator, several object-specific allocators operate on the same heap and implement distinct memory management policies adapted to the peculiarities of every object type. For example, integer objects are managed differently within the heap than strings, tuples or dictionaries because integers imply different storage requirements and speed/space tradeoffs. The Python memory manager thus delegates some of the work to the object-specific allocators, but ensures that the latter operate within the bounds of the private heap.

It is important to understand that the management of the Python heap is performed by the interpreter itself and that the user has no control over it, even if they regularly manipulate object pointers to memory blocks inside that heap. The allocation of heap space for Python objects and other internal buffers is performed on demand by the Python memory manager through the Python/C API functions listed in this document.

To avoid memory corruption, extension writers should never try to operate on Python objects with the functions exported by the C library: `malloc()`, `calloc()`, `realloc()` and `free()`. This will result in mixed calls between the C allocator and the Python

memory manager with fatal consequences, because they implement different algorithms and operate on different heaps. However, one may safely allocate and release memory blocks with the C library allocator for individual purposes, as shown in the following example:

```
PyObject *res;
char *buf = (char *) malloc(BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
...Do some I/O operation involving buf...
res = PyBytes_FromString(buf);
free(buf); /* malloc'ed */
return res;
```

In this example, the memory request for the I/O buffer is handled by the C library allocator. The Python memory manager is involved only in the allocation of the bytes object returned as a result.

In most situations, however, it is recommended to allocate memory from the Python heap specifically because the latter is under control of the Python memory manager. For example, this is required when the interpreter is extended with new object types written in C. Another reason for using the Python heap is the desire to *inform* the Python memory manager about the memory needs of the extension module. Even when the requested memory is used exclusively for internal, highly specific purposes, delegating all memory requests to the Python memory manager causes the interpreter to have a more accurate image of its memory footprint as a whole. Consequently, under certain circumstances, the Python memory manager may or may not trigger appropriate actions, like garbage collection, memory compaction or other preventive procedures. Note that by using the C library allocator as shown in the previous example, the allocated memory for the I/O buffer escapes completely the Python memory manager.

## See also

The [PYTHONMALLOC](#) environment variable can be used to

configure the memory allocators used by Python.

The `PYTHONMALLOCSTATS` environment variable can be used to print statistics of the `pymalloc` memory allocator every time a new `pymalloc` object arena is created, and on shutdown.

## Allocator Domains

All allocating functions belong to one of three different “domains” (see also `PyMemAllocatorDomain`). These domains represent different allocation strategies and are optimized for different purposes. The specific details on how every domain allocates memory or what internal functions each domain calls is considered an implementation detail, but for debugging purposes a simplified table can be found at [here](#). There is no hard requirement to use the memory returned by the allocation functions belonging to a given domain for only the purposes hinted by that domain (although this is the recommended practice). For example, one could use the memory returned by `PyMem_RawMalloc()` for allocating Python objects or the memory returned by `PyObject_Malloc()` for allocating memory for buffers.

The three allocation domains are:

- Raw domain: intended for allocating memory for general-purpose memory buffers where the allocation *must* go to the system allocator or where the allocator can operate without the `GIL`. The memory is requested directly to the system.
- “Mem” domain: intended for allocating memory for Python buffers and general-purpose memory buffers where the allocation must be performed with the `GIL` held. The memory is taken from the Python private heap.
- Object domain: intended for allocating memory belonging to Python objects. The memory is taken from the Python private heap.

When freeing memory previously allocated by the allocating functions belonging to a given domain, the matching specific deallocating functions must be used. For example, `PyMem_Free()` must be used to free memory allocated using `PyMem_Malloc()`.

# Raw Memory Interface

The following function sets are wrappers to the system allocator. These functions are thread-safe, the [GIL](#) does not need to be held.

The [default raw memory allocator](#) uses the following functions:

**malloc()**, **calloc()**, **realloc()** and **free()**; call `malloc(1)` (or `calloc(1, 1)`) when requesting zero bytes.

*New in version 3.4.*

`void *PyMem_RawMalloc(size_t n)`

Allocates *n* bytes and returns a pointer of type `void*` to the allocated memory, or `NULL` if the request fails.

Requesting zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyMem_RawMalloc(1)` had been called instead. The memory will not have been initialized in any way.

`void *PyMem_RawCalloc(size_t nelem, size_t elsize)`

Allocates *nelem* elements each whose size in bytes is *elsize* and returns a pointer of type `void*` to the allocated memory, or `NULL` if the request fails. The memory is initialized to zeros.

Requesting zero elements or elements of size zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyMem_RawCalloc(1, 1)` had been called instead.

*New in version 3.5.*

`void *PyMem_RawRealloc(void *p, size_t n)`

Resizes the memory block pointed to by *p* to *n* bytes. The contents will be unchanged to the minimum of the old and the new sizes.

If *p* is `NULL`, the call is equivalent to `PyMem_RawMalloc(n)`; else if *n* is equal to zero, the memory block is resized but is not freed, and the returned

pointer is non-NULL.

Unless *p* is NULL, it must have been returned by a previous call to `PyMem_RawMalloc()`, `PyMem_RawRealloc()` or `PyMem_RawCalloc()`.

If the request fails, `PyMem_RawRealloc()` returns NULL and *p* remains a valid pointer to the previous memory area.

`void PyMem_RawFree(void *p)`

Frees the memory block pointed to by *p*, which must have been returned by a previous call to `PyMem_RawMalloc()`, `PyMem_RawRealloc()` or `PyMem_RawCalloc()`.

Otherwise, or if `PyMem_RawFree(p)` has been called before, undefined behavior occurs.

If *p* is NULL, no operation is performed.

## Memory Interface

The following function sets, modeled after the ANSI C standard, but specifying behavior when requesting zero bytes, are available for allocating and releasing memory from the Python heap.

The [default memory allocator](#) uses the [pymalloc memory allocator](#).

### Warning

The [GIL](#) must be held when using these functions.

*Changed in version 3.6:* The default allocator is now `pymalloc` instead of system `malloc()`.

`void *PyMem_Malloc(size_t n)`

*Part of the [Stable ABI](#).*

Allocates *n* bytes and returns a pointer of type `void*` to the allocated memory, or NULL if the request fails.

Requesting zero bytes returns a distinct non-NULL pointer if

possible, as if `PyMem_Malloc(1)` had been called instead. The memory will not have been initialized in any way.

`void *PyMem_Calloc(size_t nelem, size_t elsize)`

*Part of the [Stable ABI](#) since version 3.7.*

Allocates *nelem* elements each whose size in bytes is *elsize* and returns a pointer of type `void*` to the allocated memory, or `NULL` if the request fails. The memory is initialized to zeros.

Requesting zero elements or elements of size zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyMem_Calloc(1, 1)` had been called instead.

*New in version 3.5.*

`void *PyMem_Realloc(void *p, size_t n)`

*Part of the [Stable ABI](#).*

Resizes the memory block pointed to by *p* to *n* bytes. The contents will be unchanged to the minimum of the old and the new sizes.

If *p* is `NULL`, the call is equivalent to `PyMem_Malloc(n)`; else if *n* is equal to zero, the memory block is resized but is not freed, and the returned pointer is non-`NULL`.

Unless *p* is `NULL`, it must have been returned by a previous call to [PyMem\\_Malloc\(\)](#), [PyMem\\_Realloc\(\)](#) or [PyMem\\_Calloc\(\)](#).

If the request fails, [PyMem\\_Realloc\(\)](#) returns `NULL` and *p* remains a valid pointer to the previous memory area.

`void PyMem_Free(void *p)`

*Part of the [Stable ABI](#).*

Frees the memory block pointed to by *p*, which must have been returned by a previous call to [PyMem\\_Malloc\(\)](#), [PyMem\\_Realloc\(\)](#) or [PyMem\\_Calloc\(\)](#). Otherwise, or if `PyMem_Free(p)` has been called before, undefined behavior occurs.

If *p* is `NULL`, no operation is performed.

The following type-oriented macros are provided for convenience. Note that *TYPE* refers to any C type.

`TYPE *PyMem_New(TYPE, size_t n)`

Same as `PyMem_Malloc()`, but allocates  $(n * \text{sizeof}(TYPE))$  bytes of memory. Returns a pointer cast to `TYPE*`. The memory will not have been initialized in any way.

`TYPE *PyMem_Resize(void *p, TYPE, size_t n)`

Same as `PyMem_Realloc()`, but the memory block is resized to  $(n * \text{sizeof}(TYPE))$  bytes. Returns a pointer cast to `TYPE*`. On return, *p* will be a pointer to the new memory area, or `NULL` in the event of failure.

This is a C preprocessor macro; *p* is always reassigned. Save the original value of *p* to avoid losing memory when handling errors.

`void PyMem_Del(void *p)`

Same as `PyMem_Free()`.

In addition, the following macro sets are provided for calling the Python memory allocator directly, without involving the C API functions listed above. However, note that their use does not preserve binary compatibility across Python versions and is therefore deprecated in extension modules.

- `PyMem_MALLOC(size)`
- `PyMem_NEW(type, size)`
- `PyMem_REALLOC(ptr, size)`
- `PyMem_RESIZE(ptr, type, size)`
- `PyMem_FREE(ptr)`
- `PyMem_DEL(ptr)`

## Object allocators

The following function sets, modeled after the ANSI C standard, but specifying behavior when requesting zero bytes, are available for allocating and releasing memory from the Python heap.

## Note

There is no guarantee that the memory returned by these allocators can be successfully cast to a Python object when intercepting the allocating functions in this domain by the methods described in the [Customize Memory Allocators](#) section.

The [default object allocator](#) uses the [pymalloc memory allocator](#).

## Warning

The [GIL](#) must be held when using these functions.

`void *PyObject_Malloc(size_t n)`

*Part of the [Stable ABI](#).*

Allocates *n* bytes and returns a pointer of type `void*` to the allocated memory, or `NULL` if the request fails.

Requesting zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyObject_Malloc(1)` had been called instead. The memory will not have been initialized in any way.

`void *PyObject_Calloc(size_t nelem, size_t elsize)`

*Part of the [Stable ABI](#) since version 3.7.*

Allocates *nelem* elements each whose size in bytes is *elsize* and returns a pointer of type `void*` to the allocated memory, or `NULL` if the request fails. The memory is initialized to zeros.

Requesting zero elements or elements of size zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyObject_Calloc(1, 1)` had been called instead.

*New in version 3.5.*

`void *PyObject_Realloc(void *p, size_t n)`

*Part of the [Stable ABI](#).*

Resizes the memory block pointed to by *p* to *n* bytes. The contents will be unchanged to the minimum of the old and the new sizes.

If *p* is `NULL`, the call is equivalent to `PyObject_Malloc(n)`; else if *n* is equal to zero, the memory block is resized but is not freed, and the returned pointer is non-`NULL`.

Unless *p* is `NULL`, it must have been returned by a previous call to `PyObject_Malloc()`, `PyObject_Realloc()` or `PyObject_Calloc()`.

If the request fails, `PyObject_Realloc()` returns `NULL` and *p* remains a valid pointer to the previous memory area.

`void PyObject_Free(void *p)`

*Part of the [Stable ABI](#).*

Frees the memory block pointed to by *p*, which must have been returned by a previous call to `PyObject_Malloc()`, `PyObject_Realloc()` or `PyObject_Calloc()`.

Otherwise, or if `PyObject_Free(p)` has been called before, undefined behavior occurs.

If *p* is `NULL`, no operation is performed.

## Default Memory Allocators

Default memory allocators:

<code>PyConfig_Malloc</code>
Release build
Debug build
Debug build with debug
Release build, without pymalloc
Debug build, without pymalloc

Legend:

- Name: value for `PYTHONMALLOC` environment variable.
- malloc: system allocators from the standard C library, C functions: `malloc()`, `calloc()`, `realloc()` and `free()`.
- pymalloc: [pymalloc memory allocator](#).
- “+ debug”: with [debug hooks on the Python memory allocators](#).
- “Debug build”: [Python build in debug mode](#).

## Customize Memory Allocators

*New in version 3.4.*

type `PyMemAllocatorEx`

Structure used to describe a memory block allocator. The structure has the following fields:

### Members

`user_context` passed as first argument

`allocate_a_memory_block*ctx, size_t size)`

`allocate_a_memory_block*initialized with zeros, size_t  
elsize)`

`allocate or resize a memory blockvoid *ptr, size_t  
new_size)`

`free a memory block*ctx, void *ptr)`

*Changed in version 3.5:* The `PyMemAllocator` structure was renamed to `PyMemAllocatorEx` and a new `calloc` field was added.

type `PyMemAllocatorDomain`

Enum used to identify an allocator domain. Domains:

`PYMEM_DOMAIN_RAW`

Functions:

- `PyMem_RawMalloc()`
- `PyMem_RawRealloc()`
- `PyMem_RawCalloc()`

- `PyMem_RawFree()`

## PYMEM\_DOMAIN\_MEM

Functions:

- `PyMem_Malloc()`,
- `PyMem_Realloc()`
- `PyMem_Calloc()`
- `PyMem_Free()`

## PYMEM\_DOMAIN\_OBJ

Functions:

- `PyObject_Malloc()`
- `PyObject_Realloc()`
- `PyObject_Calloc()`
- `PyObject_Free()`

`void PyMem_GetAllocator(PyMemAllocatorDomain domain, PyMemAllocatorEx *allocator)`

Get the memory block allocator of the specified domain.

`void PyMem_SetAllocator(PyMemAllocatorDomain domain, PyMemAllocatorEx *allocator)`

Set the memory block allocator of the specified domain.

The new allocator must return a distinct non-NULL pointer when requesting zero bytes.

For the **PYMEM\_DOMAIN\_RAW** domain, the allocator must be thread-safe: the [GIL](#) is not held when the allocator is called.

If the new allocator is not a hook (does not call the previous allocator), the `PyMem_SetupDebugHooks()` function must be called to reinstall the debug hooks on top on the new allocator.

See also `PyPreConfig.allocator` and [Preinitialize Python with PyPreConfig](#).

## Warning

`PyMem_SetAllocator()` does have the following contract:

- It can be called after `Py_PreInitialize()` and before `Py_InitializeFromConfig()` to install a custom memory allocator. There are no restrictions over the installed allocator other than the ones imposed by the domain (for instance, the Raw Domain allows the allocator to be called without the GIL held). See [the section on allocator domains](#) for more information.
- If called after Python has finish initializing (after `Py_InitializeFromConfig()` has been called) the allocator **must** wrap the existing allocator. Substituting the current allocator for some other arbitrary one is **not supported**.

`void PyMem_SetupDebugHooks(void)`

Setup [debug hooks in the Python memory allocators](#) to detect memory errors.

## Debug hooks on the Python memory allocators

When [Python is built in debug mode](#), the `PyMem_SetupDebugHooks()` function is called at the [Python preinitialization](#) to setup debug hooks on Python memory allocators to detect memory errors.

The `PYTHONMALLOC` environment variable can be used to install debug hooks on a Python compiled in release mode (ex: `PYTHONMALLOC=debug`).

The `PyMem_SetupDebugHooks()` function can be used to set debug hooks after calling `PyMem_SetAllocator()`.

These debug hooks fill dynamically allocated memory blocks with special, recognizable bit patterns. Newly allocated memory is filled with the byte `0xCD` (`PYMEM_CLEANBYTE`), freed memory is filled with the byte `0xDD` (`PYMEM_DEADBYTE`). Memory blocks are surrounded by “forbidden bytes” filled with the byte `0xFD` (`PYMEM_FORBIDDENBYTE`). Strings of these bytes are unlikely to be valid addresses, floats, or ASCII strings.

Runtime checks:

- Detect API violations. For example, detect if `PyObject_Free()` is called on a memory block allocated by `PyMem_Malloc()`.
- Detect write before the start of the buffer (buffer underflow).
- Detect write after the end of the buffer (buffer overflow).
- Check that the `GIL` is held when allocator functions of `PYMEM_DOMAIN_OBJ` (ex: `PyObject_Malloc()`) and `PYMEM_DOMAIN_MEM` (ex: `PyMem_Malloc()`) domains are called.

On error, the debug hooks use the `tracemalloc` module to get the traceback where a memory block was allocated. The traceback is only displayed if `tracemalloc` is tracing Python memory allocations and the memory block was traced.

Let  $S = \text{sizeof}(\text{size\_t})$ .  $2 \cdot S$  bytes are added at each end of each block of  $N$  bytes requested. The memory layout is like so, where  $p$  represents the address returned by a malloc-like or realloc-like function ( $p[i:j]$  means the slice of bytes from  $*(p+i)$  inclusive up to  $*(p+j)$  exclusive; note that the treatment of negative indices differs from a Python slice):

$p[-2 \cdot S:-S]$

Number of bytes originally asked for. This is a `size_t`, big-

endian (easier to read in a memory dump).

`p[-S]`

API identifier (ASCII character):

- 'r' for **PYMEM\_DOMAIN\_RAW**.
- 'm' for **PYMEM\_DOMAIN\_MEM**.
- 'o' for **PYMEM\_DOMAIN\_OBJ**.

`p[-S+1:0]`

Copies of **PYMEM\_FORBIDDENBYTE**. Used to catch underwrites and reads.

`p[0:N]`

The requested memory, filled with copies of **PYMEM\_CLEANBYTE**, used to catch reference to uninitialized memory. When a `realloc`-like function is called requesting a larger memory block, the new excess bytes are also filled with **PYMEM\_CLEANBYTE**. When a `free`-like function is called, these are overwritten with **PYMEM\_DEADBYTE**, to catch reference to freed memory. When a `realloc`-like function is called requesting a smaller memory block, the excess old bytes are also filled with **PYMEM\_DEADBYTE**.

`p[N:N+S]`

Copies of **PYMEM\_FORBIDDENBYTE**. Used to catch overwrites and reads.

`p[N+S:N+2*S]`

Only used if the **PYMEM\_DEBUG\_SERIALNO** macro is defined (not defined by default).

A serial number, incremented by 1 on each call to a `malloc`-like or `realloc`-like function. Big-endian `size_t`. If “bad memory” is detected later, the serial number gives an excellent way to set a breakpoint on the next run, to capture the instant at which this block was passed out. The static function `bumpserialno()` in `obmalloc.c` is the only place the serial number is incremented, and exists so you can set such a breakpoint easily.

A realloc-like or free-like function first checks that the `PYMEM_FORBIDDENBYTE` bytes at each end are intact. If they've been altered, diagnostic output is written to `stderr`, and the program is aborted via `Py_FatalError()`. The other main failure mode is provoking a memory error when a program reads up one of the special bit patterns and tries to use it as an address. If you get in a debugger then and look at the object, you're likely to see that it's entirely filled with `PYMEM_DEADBYTE` (meaning freed memory is getting used) or `PYMEM_CLEANBYTE` (meaning uninitialized memory is getting used).

*Changed in version 3.6:* The `PyMem_SetupDebugHooks()` function now also works on Python compiled in release mode. On error, the debug hooks now use `tracemalloc` to get the traceback where a memory block was allocated. The debug hooks now also check if the GIL is held when functions of `PYMEM_DOMAIN_OBJ` and `PYMEM_DOMAIN_MEM` domains are called.

*Changed in version 3.8:* Byte patterns `0xCB` (`PYMEM_CLEANBYTE`), `0xDB` (`PYMEM_DEADBYTE`) and `0xFB` (`PYMEM_FORBIDDENBYTE`) have been replaced with `0xCD`, `0xDD` and `0xFD` to use the same values than Windows CRT debug `malloc()` and `free()`.

## The pymalloc allocator

Python has a *pymalloc* allocator optimized for small objects (smaller or equal to 512 bytes) with a short lifetime. It uses memory mappings called “arenas” with a fixed size of 256 KiB. It falls back to `PyMem_RawMalloc()` and `PyMem_RawRealloc()` for allocations larger than 512 bytes.

*pymalloc* is the *default allocator* of the `PYMEM_DOMAIN_MEM` (ex: `PyMem_Malloc()`) and `PYMEM_DOMAIN_OBJ` (ex: `PyObject_Malloc()`) domains.

The arena allocator uses the following functions:

- `VirtualAlloc()` and `VirtualFree()` on Windows,
- `mmap()` and `munmap()` if available,
- `malloc()` and `free()` otherwise.

This allocator is disabled if Python is configured with the `--without-pymalloc` option. It can also be disabled at runtime using the `PYTHONMALLOC` environment variable (ex: `PYTHONMALLOC=malloc`).

## Customize pymalloc Arena Allocator

*New in version 3.4.*

type PyObjectArenaAllocator

Structure used to describe an arena allocator. The structure has three fields:

### Members

---

`user context` passed as first argument

---

`allocate an arena of size bytes` `size_t size)`

---

`free an arena` `(void *ctx, void *ptr, size_t size)`

---

`void PyObject_GetArenaAllocator(PyObjectArenaAllocator  
*allocator)`

Get the arena allocator.

`void PyObject_SetArenaAllocator(PyObjectArenaAllocator  
*allocator)`

Set the arena allocator.

## tracemalloc C API

*New in version 3.7.*

`int PyTraceMalloc_Track(unsigned int domain, uintptr_t ptr, size_t  
size)`

Track an allocated memory block in the `tracemalloc` module.

Return 0 on success, return -1 on error (failed to allocate memory to store the trace). Return -2 if tracemalloc is

disabled.

If memory block is already tracked, update the existing trace.

`int PyTraceMalloc_Untrack(unsigned int domain, uintptr_t ptr)`

Untrack an allocated memory block in the `tracemalloc` module. Do nothing if the block was not tracked.

Return `-2` if `tracemalloc` is disabled, otherwise return `0`.

## Examples

Here is the example from section [Overview](#), rewritten so that the I/O buffer is allocated from the Python heap by using the first function set:

```
PyObject *res;
char *buf = (char *) PyMem_Malloc(BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyBytes_FromString(buf);
PyMem_Free(buf); /* allocated with PyMem_Malloc */
return res;
```

The same code using the type-oriented function set:

```
PyObject *res;
char *buf = PyMem_New(char, BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyBytes_FromString(buf);
PyMem_Del(buf); /* allocated with PyMem_New */
return res;
```

Note that in the two examples above, the buffer is always

manipulated via functions belonging to the same set. Indeed, it is required to use the same memory API family for a given memory block, so that the risk of mixing different allocators is reduced to a minimum. The following code sequence contains two errors, one of which is labeled as *fatal* because it mixes two different allocators operating on different heaps.

```
char *buf1 = PyMem_New(char, BUFSIZ);
char *buf2 = (char *) malloc(BUFSIZ);
char *buf3 = (char *) PyMem_Malloc(BUFSIZ);
...
PyMem_Del(buf3); /* Wrong -- should be PyMem_Free() */
free(buf2);      /* Right -- allocated via malloc() */
free(buf1);      /* Fatal -- should be PyMem_Del() */
```

In addition to the functions aimed at handling raw memory blocks from the Python heap, objects in Python are allocated and released with `PyObject_New()`, `PyObject_NewVar()` and `PyObject_Del()`.

These will be explained in the next chapter on defining and implementing new object types in C.

# Object Implementation Support

This chapter describes the functions, types, and macros used when defining new object types.

# Allocating Objects on the Heap

`PyObject *_PyObject_New(PyTypeObject *type)`

*Return value: New reference.*

`PyVarObject *_PyObject_NewVar(PyTypeObject *type, Py_ssize_t size)`

*Return value: New reference.*

`PyObject *PyObject_Init(PyObject *op, PyTypeObject *type)`

*Return value: Borrowed reference. Part of the [Stable ABI](#).*

Initialize a newly allocated object `op` with its type and initial reference. Returns the initialized object. If `type` indicates that the object participates in the cyclic garbage detector, it is added to the detector's set of observed objects. Other fields of the object are not affected.

`PyVarObject *PyObject_InitVar(PyVarObject *op, PyTypeObject *type, Py_ssize_t size)`

*Return value: Borrowed reference. Part of the [Stable ABI](#).*

This does everything `PyObject_Init()` does, and also initializes the length information for a variable-size object.

`TYPE *PyObject_New(TYPE, PyTypeObject *type)`

*Return value: New reference.*

Allocate a new Python object using the C structure type `TYPE` and the Python type object `type`. Fields not defined by the Python object header are not initialized; the object's reference count will be one. The size of the memory allocation is determined from the `tp_basicsize` field of the type object.

`TYPE *PyObject_NewVar(TYPE, PyTypeObject *type, Py_ssize_t`

size)

*Return value: New reference.*

Allocate a new Python object using the C structure type *TYPE* and the Python type object *type*. Fields not defined by the Python object header are not initialized. The allocated memory allows for the *TYPE* structure plus *size* fields of the size given by the `tp_itemsize` field of *type*. This is useful for implementing objects like tuples, which are able to determine their size at construction time. Embedding the array of fields into the same allocation decreases the number of allocations, improving the memory management efficiency.

`void PyObject_Del(void *op)`

Releases memory allocated to an object using `PyObject_New()` or `PyObject_NewVar()`. This is normally called from the `tp_dealloc` handler specified in the object's type. The fields of the object should not be accessed after this call as the memory is no longer a valid Python object.

`PyObject_PyNoneStruct`

Object which is visible in Python as `None`. This should only be accessed using the `Py_None` macro, which evaluates to a pointer to this object.

**See also**

`PyModule_Create()`

To allocate and create extension modules.

# Common Object Structures

There are a large number of structures which are used in the definition of object types for Python. This section describes these structures and how they are used.

## Base object types and macros

All Python objects ultimately share a small number of fields at the beginning of the object's representation in memory. These are represented by the `PyObject` and `PyVarObject` types, which are defined, in turn, by the expansions of some macros also used, whether directly or indirectly, in the definition of all other Python objects.

type `PyObject`

*Part of the [Limited API](#). (Only some members are part of the stable ABI.)*

All object types are extensions of this type. This is a type which contains the information Python needs to treat a pointer to an object as an object. In a normal “release” build, it contains only the object's reference count and a pointer to the corresponding type object. Nothing is actually declared to be a `PyObject`, but every pointer to a Python object can be cast to a `PyObject*`. Access to the members must be done by using the macros `Py_REFCNT` and `Py_TYPE`.

type `PyVarObject`

*Part of the [Limited API](#). (Only some members are part of the stable ABI.)*

This is an extension of `PyObject` that adds the `ob_size` field. This is only used for objects that have some notion of *length*. This type does not often appear in the Python/C API. Access to the members must be done by using the macros `Py_REFCNT`, `Py_TYPE`, and `Py_SIZE`.

## PyObject\_HEAD

This is a macro used when declaring new types which represent objects without a varying length. The PyObject\_HEAD macro expands to:

```
PyObject ob_base;
```

See documentation of [PyObject](#) above.

## PyObject\_VAR\_HEAD

This is a macro used when declaring new types which represent objects with a length that varies from instance to instance. The PyObject\_VAR\_HEAD macro expands to:

```
PyVarObject ob_base;
```

See documentation of [PyVarObject](#) above.

## int Py\_Is(PyObject \*x, PyObject \*y)

*Part of the [Stable ABI](#) since version 3.10.*

Test if the `x` object is the `y` object, the same as `x is y` in Python.

*New in version 3.10.*

## int Py\_IsNone(PyObject \*x)

*Part of the [Stable ABI](#) since version 3.10.*

Test if an object is the `None` singleton, the same as `x is None` in Python.

*New in version 3.10.*

## int Py\_IsTrue(PyObject \*x)

*Part of the [Stable ABI](#) since version 3.10.*

Test if an object is the `True` singleton, the same as `x is True` in Python.

*New in version 3.10.*

`int Py_IsFalse(PyObject *x)`

*Part of the [Stable ABI](#) since version 3.10.*

Test if an object is the `False` singleton, the same as `x is False` in Python.

*New in version 3.10.*

`PyTypeObject *Py_TYPE(PyObject *o)`

Get the type of the Python object `o`.

Return a [borrowed reference](#).

Use the [Py\\_SET\\_TYPE\(\)](#) function to set an object type.

*Changed in version 3.11:* [Py\\_TYPE\(\)](#) is changed to an inline static function. The parameter type is no longer `const PyObject*`.

`int Py_IS_TYPE(PyObject *o, PyTypeObject *type)`

Return non-zero if the object `o` type is `type`. Return zero otherwise. Equivalent to: `Py_TYPE(o) == type`.

*New in version 3.9.*

`void Py_SET_TYPE(PyObject *o, PyTypeObject *type)`

Set the object `o` type to `type`.

*New in version 3.9.*

`Py_ssize_t Py_REFCNT(PyObject *o)`

Get the reference count of the Python object `o`.

Use the [Py\\_SET\\_REFCNT\(\)](#) function to set an object reference count.

*Changed in version 3.11:* The parameter type is no longer `const PyObject*`.

*Changed in version 3.10:* [Py\\_REFCNT\(\)](#) is changed to the

inline static function.

void Py\_SET\_REFCNT(PyObject \*o, Py\_ssize\_t refcnt)

Set the object *o* reference counter to *refcnt*.

*New in version 3.9.*

Py\_ssize\_t Py\_SIZE(PyVarObject \*o)

Get the size of the Python object *o*.

Use the `Py_SET_SIZE()` function to set an object size.

*Changed in version 3.11:* `Py_SIZE()` is changed to an inline static function. The parameter type is no longer `const PyVarObject*`.

void Py\_SET\_SIZE(PyVarObject \*o, Py\_ssize\_t size)

Set the object *o* size to *size*.

*New in version 3.9.*

PyObject\_HEAD\_INIT(type)

This is a macro which expands to initialization values for a new `PyObject` type. This macro expands to:

```
_PyObject_EXTRA_INIT  
1, type,
```

PyVarObject\_HEAD\_INIT(type, size)

This is a macro which expands to initialization values for a new `PyVarObject` type, including the `ob_size` field. This macro expands to:

```
_PyObject_EXTRA_INIT  
1, type, size,
```

## Implementing functions and methods

## type PyCFunction

*Part of the [Stable ABI](#).*

Type of the functions used to implement most Python callables in C. Functions of this type take two [PyObject\\*](#) parameters and return one such value. If the return value is NULL, an exception shall have been set. If not NULL, the return value is interpreted as the return value of the function as exposed in Python. The function must return a new reference.

The function signature is:

```
PyObject *PyCFunction(PyObject *self,  
                      PyObject *args);
```

## type PyCFunctionWithKeywords

*Part of the [Stable ABI](#).*

Type of the functions used to implement Python callables in C with signature **METH\_VARARGS | METH\_KEYWORDS**. The function signature is:

```
PyObject *PyCFunctionWithKeywords(PyObject *self,  
                                   PyObject *args,  
                                   PyObject *kwargs)
```

## type \_PyCFunctionFast

Type of the functions used to implement Python callables in C with signature **METH\_FASTCALL**. The function signature is:

```
PyObject *_PyCFunctionFast(PyObject *self,  
                           PyObject *const *args,  
                           Py_ssize_t nargs);
```

## type \_PyCFunctionFastWithKeywords

Type of the functions used to implement Python callables in C with signature **METH\_FASTCALL | METH\_KEYWORDS**. The function signature is:

```
PyObject *_PyCFunctionFastWithKeywords(PyObject *self,
```

```
PyObject *co
Py_ssize_t n
PyObject *kw
```

## type PyCMethod

Type of the functions used to implement Python callables in C with signature **METH\_METHOD** | **METH\_FASTCALL** | **METH\_KEYWORDS**. The function signature is:

```
PyObject *PyCMethod(PyObject *self,
                    PyTypeObject *defining_class,
                    PyObject *const *args,
                    Py_ssize_t nargs,
                    PyObject *kwnames)
```

*New in version 3.9.*

## type PyMethodDef

Part of the [Stable ABI](#) (including all members).

Structure used to describe a method of an extension type.

This structure has four fields:

const char \*ml\_name

name of the method

[PyCFunction](#) ml\_meth

pointer to the C implementation

int ml\_flags

flags bits indicating how the call should be constructed

const char \*ml\_doc

points to the contents of the docstring

The **ml\_meth** is a C function pointer. The functions may be of different types, but they always return [PyObject\\*](#). If the function is not of the [PyCFunction](#), the compiler will require a cast in the method table. Even though [PyCFunction](#) defines the first

parameter as `PyObject*`, it is common that the method implementation uses the specific C type of the *self* object.

The `ml_flags` field is a bitfield which can include the following flags. The individual flags indicate either a calling convention or a binding convention.

There are these calling conventions:

#### METH\_VARARGS

This is the typical calling convention, where the methods have the type `PyCFunction`. The function expects two `PyObject*` values. The first one is the *self* object for methods; for module functions, it is the module object. The second parameter (often called *args*) is a tuple object representing all arguments. This parameter is typically processed using `PyArg_ParseTuple()` or `PyArg_UnpackTuple()`.

#### METH\_VARARGS | METH\_KEYWORDS

Methods with these flags must be of type `PyCFunctionWithKeywords`. The function expects three parameters: *self*, *args*, *kwargs* where *kwargs* is a dictionary of all the keyword arguments or possibly `NULL` if there are no keyword arguments. The parameters are typically processed using `PyArg_ParseTupleAndKeywords()`.

#### METH\_FASTCALL

Fast calling convention supporting only positional arguments. The methods have the type `_PyCFunctionFast`. The first parameter is *self*, the second parameter is a C array of `PyObject*` values indicating the arguments and the third parameter is the number of arguments (the length of the array).

*New in version 3.7.*

*Changed in version 3.10:* `METH_FASTCALL` is now part of the stable ABI.

#### METH\_FASTCALL | METH\_KEYWORDS

Extension of **METH\_FASTCALL** supporting also keyword arguments, with methods of type **\_PyCFunctionFastWithKeywords**. Keyword arguments are passed the same way as in the **vectorcall protocol**: there is an additional fourth **PyObject\*** parameter which is a tuple representing the names of the keyword arguments (which are guaranteed to be strings) or possibly **NULL** if there are no keywords. The values of the keyword arguments are stored in the **args** array, after the positional arguments.

*New in version 3.7.*

## METH\_METHOD | METH\_FASTCALL | METH\_KEYWORDS

Extension of **METH\_FASTCALL** | **METH\_KEYWORDS** supporting the *defining class*, that is, the class that contains the method in question. The defining class might be a superclass of **Py\_TYPE(self)**.

The method needs to be of type **PyCMethod**, the same as for **METH\_FASTCALL** | **METH\_KEYWORDS** with **defining\_class** argument added after **self**.

*New in version 3.9.*

## METH\_NOARGS

Methods without parameters don't need to check whether arguments are given if they are listed with the **METH\_NOARGS** flag. They need to be of type **PyCFunction**. The first parameter is typically named *self* and will hold a reference to the module or object instance. In all cases the second parameter will be **NULL**.

The function must have 2 parameters. Since the second parameter is unused, **Py\_UNUSED** can be used to prevent a compiler warning.

## METH\_O

Methods with a single object argument can be listed with the **METH\_O** flag, instead of invoking **PyArg\_ParseTuple()** with a "O" argument. They have the type **PyCFunction**,

with the *self* parameter, and a `PyObject*` parameter representing the single argument.

These two constants are not used to indicate the calling convention but the binding when use with methods of classes. These may not be used for functions defined for modules. At most one of these flags may be set for any given method.

#### METH\_CLASS

The method will be passed the type object as the first parameter rather than an instance of the type. This is used to create *class methods*, similar to what is created when using the `classmethod()` built-in function.

#### METH\_STATIC

The method will be passed `NULL` as the first parameter rather than an instance of the type. This is used to create *static methods*, similar to what is created when using the `staticmethod()` built-in function.

One other constant controls whether a method is loaded in place of another definition with the same method name.

#### METH\_COEXIST

The method will be loaded in place of existing definitions. Without *METH\_COEXIST*, the default is to skip repeated definitions. Since slot wrappers are loaded before the method table, the existence of a *sq\_contains* slot, for example, would generate a wrapped method named `__contains__()` and preclude the loading of a corresponding `PyCFunction` with the same name. With the flag defined, the `PyCFunction` will be loaded in place of the wrapper object and will co-exist with the slot. This is helpful because calls to `PyCFunctions` are optimized more than wrapper object calls.

## Accessing attributes of extension types

type `PyMemberDef`

Part of the [Stable ABI](#) (including all members).

Structure which describes an attribute of a type which corresponds to a C struct member. Its fields are:

### Mapping

**name** of the member

**type** type of the member in the C struct

**offset** in bytes that the member is located on the type's object struct

**flags** indicating if the field should be read-only or writable

**docstring** the contents of the docstring

**type** can be one of many `T_` macros corresponding to various C types. When the member is accessed in Python, it will be converted to the equivalent Python type.

### Macro name

`T_SHORT`

`T_INT`

`T_LONG`

`T_FLOAT`

`T_DOUBLE`

`T_STRING *`

`T_OBJECT *`

`T_OBJECT_EX`

`T_CHAR`

`T_BYTE`

`T_SIGNED char`

`T_SIGNED int`

`T_SIGNED short`

`T_SIGNED long`

`T_BOOL`

`T_LONG long`

`T_SIGNED long long`

`T_PYSSIZE_T`

`T_OBJECT` and `T_OBJECT_EX` differ in that `T_OBJECT` returns `None` if the member is `NULL` and `T_OBJECT_EX` raises an [AttributeError](#). Try to use `T_OBJECT_EX` over `T_OBJECT` because `T_OBJECT_EX` handles use of the [del](#)

statement on that attribute more correctly than `T_OBJECT`.

**flags** can be 0 for write and read access or **READONLY** for read-only access. Using **T\_STRING** for **type** implies **READONLY**. **T\_STRING** data is interpreted as UTF-8. Only **T\_OBJECT** and **T\_OBJECT\_EX** members can be deleted. (They are set to `NULL`).

Heap allocated types (created using `PyType_FromSpec()` or similar), `PyMemberDef` may contain definitions for the special members `__dictoffset__`, `__weaklistoffset__` and `__vectorcalloffset__`, corresponding to `tp_dictoffset`, `tp_weaklistoffset` and `tp_vectorcall_offset` in type objects. These must be defined with `T_PYSSIZET` and `READONLY`, for example:

```
static PyMemberDef spam_type_members[] = {
    {"__dictoffset__", T_PYSSIZET, offsetof(Spam_obj,
    {NULL} /* Sentinel */
};
```

`PyObject *``PyMember_GetOne`(const char \*obj\_addr, struct `PyMemberDef` \*m)

Get an attribute belonging to the object at address *obj\_addr*. The attribute is described by `PyMemberDef` *m*. Returns `NULL` on error.

int `PyMember_SetOne`(char \*obj\_addr, struct `PyMemberDef` \*m, `PyObject` \*o)

Set an attribute belonging to the object at address *obj\_addr* to object *o*. The attribute to set is described by `PyMemberDef` *m*. Returns 0 if successful and a negative value on failure.

type `PyGetSetDef`

Part of the *Stable ABI* (including all members).

Structure to define property-like access for a type. See also description of the `PyTypeObject.tp_getset` slot.

---

## Typing

---

<b>attribute name</b>	
<b>getter</b>	function to get the attribute
<b>setter</b>	optional C function to set or delete the attribute, if omitted the attribute is readonly
<b>docstring</b>	optional docstring
<b>optional</b>	optional function pointer, providing additional data for getter and setter

The `get` function takes one `PyObject*` parameter (the instance) and a function pointer (the associated `closure`):

```
typedef PyObject *(*getter)(PyObject *, void *);
```

It should return a new reference on success or `NULL` with a set exception on failure.

`set` functions take two `PyObject*` parameters (the instance and the value to be set) and a function pointer (the associated `closure`):

```
typedef int (*setter)(PyObject *, PyObject *, void *
```

In case the attribute should be deleted the second parameter is `NULL`. Should return `0` on success or `-1` with a set exception on failure.

# Type Objects

Perhaps one of the most important structures of the Python object system is the structure that defines a new type: the `PyTypeObject` structure. Type objects can be handled using any of the `PyObject_*` or `PyType_*` functions, but do not offer much that's interesting to most Python applications. These objects are fundamental to how objects behave, so they are very important to the interpreter itself and to any extension module that implements new types.

Type objects are fairly large compared to most of the standard types. The reason for the size is that each type object stores a large number of values, mostly C function pointers, each of which implements a small part of the type's functionality. The fields of the type object are examined in detail in this section. The fields will be described in the order in which they occur in the structure.

In addition to the following quick reference, the [Examples](#) section provides at-a-glance insight into the meaning and use of `PyTypeObject`.

1

**Q**: A slot name in parentheses indicates it is (effectively) deprecated.

**<>**: Names in angle brackets should be initially set to `NULL` and treated as read-only.

**[]**: Names in square brackets are for internal use only.

**<R>** (as a prefix) means the field is required (must be non-`NULL`).

2

Columns:

**“O”**: set on `PyBaseObject_Type`

**“T”**: set on `PyType_Type`

**“D”**: default (if slot is set to `NULL`)

X - `PyType_Ready` sets this value if it is `NULL`

~ - `PyType_Ready` always sets this value (it should be)

? - `PyType_Ready` may set this value depending on other

Also see the inheritance column ("I").

**“I”**: inheritance

X - type slot is inherited via `*PyType_Ready*` if def.

% - the slots of the sub-struct are inherited individually

G - inherited, but only in combination with other slots

? - it's complicated; see the slot's description

Note that some slots are effectively inherited through the normal attribute lookup chain.

## PyObject Slots

The type object structure extends the [PyVarObject](#) structure. The **ob\_size** field is used for dynamic types (created by `type_new()`, usually called from a class statement). Note that [PyType\\_Type](#) (the metatype) initializes [tp\\_itemsize](#), which means that its instances (i.e. type objects) *must* have the **ob\_size** field.

[Py\\_ssize\\_t PyObject.ob\\_refcnt](#)

*Part of the [Stable ABI](#).*

This is the type object's reference count, initialized to 1 by the `PyObject_HEAD_INIT` macro. Note that for [statically allocated type objects](#), the type's instances (objects whose **ob\_type** points back to the type) do *not* count as references. But for [dynamically allocated type objects](#), the instances do count as references.

### Inheritance:

This field is not inherited by subtypes.

[PyTypeObject \\*PyObject.ob\\_type](#)

*Part of the [Stable ABI](#).*

This is the type's type, in other words its metatype. It is initialized by the argument to the `PyObject_HEAD_INIT` macro, and its value should normally be `&PyType_Type`. However, for dynamically loadable extension modules that must be usable on Windows (at least), the compiler complains

that this is not a valid initializer. Therefore, the convention is to pass `NULL` to the `PyObject_HEAD_INIT` macro and to initialize this field explicitly at the start of the module's initialization function, before doing anything else. This is typically done like this:

```
Foo_Type.ob_type = &PyType_Type;
```

This should be done before any instances of the type are created. `PyType_Ready()` checks if `ob_type` is `NULL`, and if so, initializes it to the `ob_type` field of the base class. `PyType_Ready()` will not change this field if it is non-zero.

### Inheritance:

This field is inherited by subtypes.

`PyObject *PyObject._ob_next`

`PyObject *PyObject._ob_prev`

These fields are only present when the macro `Py_TRACE_REFS` is defined (see the [configure --with-trace-refs option](#)).

Their initialization to `NULL` is taken care of by the `PyObject_HEAD_INIT` macro. For [statically allocated objects](#), these fields always remain `NULL`. For [dynamically allocated objects](#), these two fields are used to link the object into a doubly linked list of *all* live objects on the heap.

This could be used for various debugging purposes; currently the only uses are the `sys.getobjects()` function and to print the objects that are still alive at the end of a run when the environment variable `PYTHONDUMPREFS` is set.

### Inheritance:

These fields are not inherited by subtypes.

## PyVarObject Slots

`Py_ssize_t PyVarObject.ob_size`

Part of the *Stable ABI*.

For [statically allocated type objects](#), this should be initialized to zero. For [dynamically allocated type objects](#), this field has a special internal meaning.

### Inheritance:

This field is not inherited by subtypes.

## PyTypeObject Slots

Each slot has a section describing inheritance. If `PyType_Ready()` may set a value when the field is set to `NULL` then there will also be a “Default” section. (Note that many fields set on `PyBaseObject_Type` and `PyType_Type` effectively act as defaults.)

`const char *PyTypeObject.tp_name`

Pointer to a NUL-terminated string containing the name of the type. For types that are accessible as module globals, the string should be the full module name, followed by a dot, followed by the type name; for built-in types, it should be just the type name. If the module is a submodule of a package, the full package name is part of the full module name. For example, a type named `T` defined in module `M` in subpackage `Q` in package `P` should have the `tp_name` initializer `"P.Q.M.T"`.

For [dynamically allocated type objects](#), this should just be the type name, and the module name explicitly stored in the type dict as the value for key `'__module__'`.

For [statically allocated type objects](#), the `tp_name` field should contain a dot. Everything before the last dot is made accessible as the `__module__` attribute, and everything after the last dot is made accessible as the `__name__` attribute.

If no dot is present, the entire `tp_name` field is made accessible as the `__name__` attribute, and the `__module__`

attribute is undefined (unless explicitly set in the dictionary, as explained above). This means your type will be impossible to pickle. Additionally, it will not be listed in module documentations created with pydoc.

This field must not be `NULL`. It is the only required field in `PyObject()` (other than potentially `tp_itemsize`).

### Inheritance:

This field is not inherited by subtypes.

`Py_ssize_t PyObject.tp_basicsize`

`Py_ssize_t PyObject.tp_itemsize`

These fields allow calculating the size in bytes of instances of the type.

There are two kinds of types: types with fixed-length instances have a zero `tp_itemsize` field, types with variable-length instances have a non-zero `tp_itemsize` field. For a type with fixed-length instances, all instances have the same size, given in `tp_basicsize`.

For a type with variable-length instances, the instances must have an `ob_size` field, and the instance size is `tp_basicsize` plus N times `tp_itemsize`, where N is the “length” of the object. The value of N is typically stored in the instance’s `ob_size` field. There are exceptions: for example, ints use a negative `ob_size` to indicate a negative number, and N is `abs(ob_size)` there. Also, the presence of an `ob_size` field in the instance layout doesn’t mean that the instance structure is variable-length (for example, the structure for the list type has fixed-length instances, yet those instances have a meaningful `ob_size` field).

The basic size includes the fields in the instance declared by the macro `PyObject_HEAD` or `PyObject_VAR_HEAD` (whichever is used to declare the instance struct) and this in turn includes the `_ob_prev` and `_ob_next` fields if they are present. This means that the only correct way to get an initializer for the `tp_basicsize` is to use the `sizeof`

operator on the struct used to declare the instance layout. The basic size does not include the GC header size.

A note about alignment: if the variable items require a particular alignment, this should be taken care of by the value of `tp_basicsize`. Example: suppose a type implements an array of `double`. `tp_itemsize` is `sizeof(double)`. It is the programmer's responsibility that `tp_basicsize` is a multiple of `sizeof(double)` (assuming this is the alignment requirement for `double`).

For any type with variable-length instances, this field must not be `NULL`.

### Inheritance:

These fields are inherited separately by subtypes. If the base type has a non-zero `tp_itemsize`, it is generally not safe to set `tp_itemsize` to a different non-zero value in a subtype (though this depends on the implementation of the base type).

### destructor `PyTypeObject.tp_dealloc`

A pointer to the instance destructor function. This function must be defined unless the type guarantees that its instances will never be deallocated (as is the case for the singletons `None` and `Ellipsis`). The function signature is:

```
void tp_dealloc(PyObject *self);
```

The destructor function is called by the `Py_DECREF()` and `Py_XDECREF()` macros when the new reference count is zero. At this point, the instance is still in existence, but there are no references to it. The destructor function should free all references which the instance owns, free all memory buffers owned by the instance (using the freeing function corresponding to the allocation function used to allocate the buffer), and call the type's `tp_free` function. If the type is not subtypable (doesn't have the `Py_TPFLAGS_BASETYPE` flag bit set), it is permissible to call the object deallocator directly instead of via `tp_free`. The object deallocator

should be the one used to allocate the instance; this is normally `PyObject_Del()` if the instance was allocated using `PyObject_New()` or `PyObject_VarNew()`, or `PyObject_GC_Del()` if the instance was allocated using `PyObject_GC_New()` or `PyObject_GC_NewVar()`.

If the type supports garbage collection (has the `Py_TPFLAGS_HAVE_GC` flag bit set), the destructor should call `PyObject_GC_UnTrack()` before clearing any member fields.

```
static void foo_dealloc(foo_object *self) {
    PyObject_GC_UnTrack(self);
    Py_CLEAR(self->ref);
    Py_TYPE(self)->tp_free((PyObject *)self);
}
```

Finally, if the type is heap allocated (`Py_TPFLAGS_HEAPTYPE`), the deallocator should decrement the reference count for its type object after calling the type deallocator. In order to avoid dangling pointers, the recommended way to achieve this is:

```
static void foo_dealloc(foo_object *self) {
    PyTypeObject *tp = Py_TYPE(self);
    // free references and buffers here
    tp->tp_free(self);
    Py_DECREF(tp);
}
```

### **Inheritance:**

This field is inherited by subtypes.

`Py_ssize_t PyTypeObject.tp_vectorcall_offset`

An optional offset to a per-instance function that implements calling the object using the [vectorcall protocol](#), a more efficient alternative of the simpler [tp\\_call](#).

This field is only used if the flag

`Py_TPFLAGS_HAVE_VECTORCALL` is set. If so, this must be a positive integer containing the offset in the instance of a `vectorcallfunc` pointer.

The `vectorcallfunc` pointer may be `NULL`, in which case the instance behaves as if `Py_TPFLAGS_HAVE_VECTORCALL` was not set: calling the instance falls back to `tp_call`.

Any class that sets `Py_TPFLAGS_HAVE_VECTORCALL` must also set `tp_call` and make sure its behaviour is consistent with the `vectorcallfunc` function. This can be done by setting `tp_call` to `PyVectorcall_Call()`.

### Warning

It is not recommended for `mutable heap types` to implement the vectorcall protocol. When a user sets `__call__` in Python code, only `tp_call` is updated, likely making it inconsistent with the vectorcall function.

*Changed in version 3.8:* Before version 3.8, this slot was named `tp_print`. In Python 2.x, it was used for printing to a file. In Python 3.0 to 3.7, it was unused.

### Inheritance:

This field is always inherited. However, the `Py_TPFLAGS_HAVE_VECTORCALL` flag is not always inherited. If it's not, then the subclass won't use `vectorcall`, except when `PyVectorcall_Call()` is explicitly called. This is in particular the case for types without the `Py_TPFLAGS_IMMUTABLETYPE` flag set (including subclasses defined in Python).

`getattrfunc PyTypeObject.tp_getattr`

An optional pointer to the get-attribute-string function.

This field is deprecated. When it is defined, it should point to a function that acts the same as the `tp_getattro` function, but taking a C string instead of a Python string object to give

the attribute name.

### Inheritance:

Group: `tp_getattr`, `tp_getattro`

This field is inherited by subtypes together with `tp_getattro`: a subtype inherits both `tp_getattr` and `tp_getattro` from its base type when the subtype's `tp_getattr` and `tp_getattro` are both `NULL`.

### `setattrfunc PyTypeObject.tp_setattr`

An optional pointer to the function for setting and deleting attributes.

This field is deprecated. When it is defined, it should point to a function that acts the same as the `tp_setattro` function, but taking a C string instead of a Python string object to give the attribute name.

### Inheritance:

Group: `tp_setattr`, `tp_setattro`

This field is inherited by subtypes together with `tp_setattro`: a subtype inherits both `tp_setattr` and `tp_setattro` from its base type when the subtype's `tp_setattr` and `tp_setattro` are both `NULL`.

### `PyAsyncMethods *PyTypeObject.tp_as_async`

Pointer to an additional structure that contains fields relevant only to objects which implement `awaitable` and `asynchronous iterator` protocols at the C-level. See [Async Object Structures](#) for details.

*New in version 3.5:* Formerly known as `tp_compare` and `tp_reserved`.

### Inheritance:

The `tp_as_async` field is not inherited, but the contained

fields are inherited individually.

### `reprfunc PyObject.tp_repr`

An optional pointer to a function that implements the built-in function `repr()`.

The signature is the same as for `PyObject_Repr()`:

```
PyObject *tp_repr(PyObject *self);
```

The function must return a string or a Unicode object. Ideally, this function should return a string that, when passed to `eval()`, given a suitable environment, returns an object with the same value. If this is not feasible, it should return a string starting with `'<'` and ending with `'>'` from which both the type and the value of the object can be deduced.

### **Inheritance:**

This field is inherited by subtypes.

### **Default:**

When this field is not set, a string of the form `<%s object at %p>` is returned, where `%s` is replaced by the type name, and `%p` by the object's memory address.

### `PyNumberMethods *PyObject.tp_as_number`

Pointer to an additional structure that contains fields relevant only to objects which implement the number protocol. These fields are documented in [Number Object Structures](#).

### **Inheritance:**

The `tp_as_number` field is not inherited, but the contained fields are inherited individually.

### `PySequenceMethods *PyObject.tp_as_sequence`

Pointer to an additional structure that contains fields relevant only to objects which implement the sequence protocol.

These fields are documented in [Sequence Object Structures](#).

### Inheritance:

The `tp_as_sequence` field is not inherited, but the contained fields are inherited individually.

### `PyMappingMethods` \*`PyTypeObject`.`tp_as_mapping`

Pointer to an additional structure that contains fields relevant only to objects which implement the mapping protocol. These fields are documented in [Mapping Object Structures](#).

### Inheritance:

The `tp_as_mapping` field is not inherited, but the contained fields are inherited individually.

### `hashfunc` `PyTypeObject`.`tp_hash`

An optional pointer to a function that implements the built-in function `hash()`.

The signature is the same as for `PyObject_Hash()`:

```
Py_hash_t tp_hash(PyObject *);
```

The value `-1` should not be returned as a normal return value; when an error occurs during the computation of the hash value, the function should set an exception and return `-1`.

When this field is not set (*and* `tp_richcompare` is not set), an attempt to take the hash of the object raises `TypeError`. This is the same as setting it to `PyObject_HashNotImplemented()`.

This field can be set explicitly to `PyObject_HashNotImplemented()` to block inheritance of the hash method from a parent type. This is interpreted as the equivalent of `__hash__ = None` at the Python level, causing `isinstance(o, collections.Hashable)` to correctly return `False`. Note that the converse is also true -

setting `__hash__ = None` on a class at the Python level will result in the `tp_hash` slot being set to `PyObject_HashNotImplemented()`.

### Inheritance:

Group: `tp_hash`, `tp_richcompare`

This field is inherited by subtypes together with `tp_richcompare`: a subtype inherits both of `tp_richcompare` and `tp_hash`, when the subtype's `tp_richcompare` and `tp_hash` are both `NULL`.

`ternaryfunc PyObject.tp_call`

An optional pointer to a function that implements calling the object. This should be `NULL` if the object is not callable. The signature is the same as for `PyObject_Call()`:

```
PyObject *tp_call(PyObject *self, PyObject *args, P
```

### Inheritance:

This field is inherited by subtypes.

`reprfunc PyObject.tp_str`

An optional pointer to a function that implements the built-in operation `str()`. (Note that `str` is a type now, and `str()` calls the constructor for that type. This constructor calls `PyObject_Str()` to do the actual work, and `PyObject_Str()` will call this handler.)

The signature is the same as for `PyObject_Str()`:

```
PyObject *tp_str(PyObject *self);
```

The function must return a string or a Unicode object. It should be a “friendly” string representation of the object, as this is the representation that will be used, among other things, by the `print()` function.

### Inheritance:

This field is inherited by subtypes.

### Default:

When this field is not set, `PyObject_Repr()` is called to return a string representation.

`getattrofunc` `PyTypeObject.tp_getattro`

An optional pointer to the get-attribute function.

The signature is the same as for `PyObject_GetAttr()`:

```
PyObject *tp_getattro(PyObject *self, PyObject *att
```

It is usually convenient to set this field to `PyObject_GenericGetAttr()`, which implements the normal way of looking for object attributes.

### Inheritance:

Group: `tp_getattr`, `tp_getattro`

This field is inherited by subtypes together with `tp_getattr`: a subtype inherits both `tp_getattr` and `tp_getattro` from its base type when the subtype's `tp_getattr` and `tp_getattro` are both `NULL`.

### Default:

`PyBaseObject_Type` uses `PyObject_GenericGetAttr()`.

`setattrofunc` `PyTypeObject.tp_setattro`

An optional pointer to the function for setting and deleting attributes.

The signature is the same as for `PyObject_SetAttr()`:

```
int tp_setattro(PyObject *self, PyObject *attr, PyO
```

In addition, setting *value* to `NULL` to delete an attribute must

be supported. It is usually convenient to set this field to `PyObject_GenericSetAttr()`, which implements the normal way of setting object attributes.

### Inheritance:

Group: `tp_setattr`, `tp_setattro`

This field is inherited by subtypes together with `tp_setattr`: a subtype inherits both `tp_setattr` and `tp_setattro` from its base type when the subtype's `tp_setattr` and `tp_setattro` are both `NULL`.

### Default:

`PyBaseObject_Type` uses `PyObject_GenericSetAttr()`.

`PyBufferProcs *PyTypeObject.tp_as_buffer`

Pointer to an additional structure that contains fields relevant only to objects which implement the buffer interface. These fields are documented in [Buffer Object Structures](#).

### Inheritance:

The `tp_as_buffer` field is not inherited, but the contained fields are inherited individually.

unsigned long `PyTypeObject.tp_flags`

This field is a bit mask of various flags. Some flags indicate variant semantics for certain situations; others are used to indicate that certain fields in the type object (or in the extension structures referenced via `tp_as_number`, `tp_as_sequence`, `tp_as_mapping`, and `tp_as_buffer`) that were historically not always present are valid; if such a flag bit is clear, the type fields it guards must not be accessed and must be considered to have a zero or `NULL` value instead.

### Inheritance:

Inheritance of this field is complicated. Most flag bits are inherited individually, i.e. if the base type has a flag bit set, the subtype inherits this flag bit. The flag bits that pertain to extension structures are strictly inherited if the extension structure is inherited, i.e. the base type's value of the flag bit is copied into the subtype together with a pointer to the extension structure. The `Py_TPFLAGS_HAVE_GC` flag bit is inherited together with the `tp_traverse` and `tp_clear` fields, i.e. if the `Py_TPFLAGS_HAVE_GC` flag bit is clear in the subtype and the `tp_traverse` and `tp_clear` fields in the subtype exist and have `NULL` values.

### Default:

**PyBaseObject\_Type** uses `Py_TPFLAGS_DEFAULT` | `Py_TPFLAGS_BASETYPE`.

### Bit Masks:

The following bit masks are currently defined; these can be ORed together using the `|` operator to form the value of the `tp_flags` field. The macro `PyType_HasFeature()` takes a type and a flags value, `tp` and `f`, and checks whether `tp->tp_flags & f` is non-zero.

#### Py\_TPFLAGS\_HEAPTYPE

This bit is set when the type object itself is allocated on the heap, for example, types created dynamically using `PyType_FromSpec()`. In this case, the `ob_type` field of its instances is considered a reference to the type, and the type object is INCREf'ed when a new instance is created, and DECREf'ed when an instance is destroyed (this does not apply to instances of subtypes; only the type referenced by the instance's `ob_type` gets INCREf'ed or DECREf'ed).

### Inheritance:

???

#### Py\_TPFLAGS\_BASETYPE

This bit is set when the type can be used as the base type of another type. If this bit is clear, the type cannot be subtyped (similar to a “final” class in Java).

**Inheritance:**

???

**Py\_TPFLAGS\_READY**

This bit is set when the type object has been fully initialized by `PyType_Ready()`.

**Inheritance:**

???

**Py\_TPFLAGS\_READYING**

This bit is set while `PyType_Ready()` is in the process of initializing the type object.

**Inheritance:**

???

**Py\_TPFLAGS\_HAVE\_GC**

This bit is set when the object supports garbage collection. If this bit is set, instances must be created using `PyObject_GC_New()` and destroyed using `PyObject_GC_Del()`. More information in section [Supporting Cyclic Garbage Collection](#). This bit also implies that the GC-related fields `tp_traverse` and `tp_clear` are present in the type object.

**Inheritance:**

Group: `Py_TPFLAGS_HAVE_GC`, `tp_traverse`, `tp_clear`

The `Py_TPFLAGS_HAVE_GC` flag bit is inherited together with the `tp_traverse` and `tp_clear`

fields, i.e. if the `Py_TPFLAGS_HAVE_GC` flag bit is clear in the subtype and the `tp_traverse` and `tp_clear` fields in the subtype exist and have `NULL` values.

## Py\_TPFLAGS\_DEFAULT

This is a bitmask of all the bits that pertain to the existence of certain fields in the type object and its extension structures. Currently, it includes the following bits:

**Py\_TPFLAGS\_HAVE\_STACKLESS\_EXTENSION.**

### Inheritance:

???

## Py\_TPFLAGS\_METHOD\_DESCRIPTOR

This bit indicates that objects behave like unbound methods.

If this flag is set for `type(meth)`, then:

- `meth.__get__(obj, cls)(*args, **kwds)` (with `obj` not `None`) must be equivalent to `meth(obj, *args, **kwds)`.
- `meth.__get__(None, cls)(*args, **kwds)` must be equivalent to `meth(*args, **kwds)`.

This flag enables an optimization for typical method calls like `obj.meth()`: it avoids creating a temporary “bound method” object for `obj.meth`.

*New in version 3.8.*

### Inheritance:

This flag is never inherited by types without the `Py_TPFLAGS_IMMUTABLETYPE` flag set. For extension types, it is inherited whenever `tp_descr_get` is inherited.

Py\_TPFLAGS\_LONG\_SUBCLASS

Py\_TPFLAGS\_LIST\_SUBCLASS

Py\_TPFLAGS\_TUPLE\_SUBCLASS

Py\_TPFLAGS\_BYTES\_SUBCLASS

Py\_TPFLAGS\_UNICODE\_SUBCLASS

Py\_TPFLAGS\_DICT\_SUBCLASS

Py\_TPFLAGS\_BASE\_EXC\_SUBCLASS

Py\_TPFLAGS\_TYPE\_SUBCLASS

These flags are used by functions such as [PyLong\\_Check\(\)](#) to quickly determine if a type is a subclass of a built-in type; such specific checks are faster than a generic check, like [PyObject\\_IsInstance\(\)](#). Custom types that inherit from built-ins should have their [tp\\_flags](#) set appropriately, or the code that interacts with such types will behave differently depending on what kind of check is used.

Py\_TPFLAGS\_HAVE\_FINALIZE

This bit is set when the [tp\\_finalize](#) slot is present in the type structure.

*New in version 3.4.*

*Deprecated since version 3.8:* This flag isn't necessary anymore, as the interpreter assumes the [tp\\_finalize](#) slot is always present in the type structure.

Py\_TPFLAGS\_HAVE\_VECTORCALL

This bit is set when the class implements the [vectorcall protocol](#). See [tp\\_vectorcall\\_offset](#) for details.

### **Inheritance:**

This bit is inherited for types with the `Py_TPFLAGS_IMMUTABLETYPE` flag set, if `tp_call` is also inherited.

*New in version 3.9.*

### **Py\_TPFLAGS\_IMMUTABLETYPE**

This bit is set for type objects that are immutable: type attributes cannot be set nor deleted.

`PyType_Ready()` automatically applies this flag to static types.

### **Inheritance:**

This flag is not inherited.

*New in version 3.10.*

### **Py\_TPFLAGS\_DISALLOW\_INSTANTIATION**

Disallow creating instances of the type: set `tp_new` to NULL and don't create the `__new__` key in the type dictionary.

The flag must be set before creating the type, not after. For example, it must be set before `PyType_Ready()` is called on the type.

The flag is set automatically on static types if `tp_base` is NULL or `&PyBaseObject_Type` and `tp_new` is NULL.

### **Inheritance:**

This flag is not inherited. However, subclasses will not be instantiable unless they provide a non-NULL `tp_new` (which is only possible via the C API).

### **Note**

To disallow instantiating a class directly but allow instantiating its subclasses (e.g. for an [abstract base class](#)), do not use this flag. Instead, make `tp_new` only succeed for subclasses.

*New in version 3.10.*

## Py\_TPFLAGS\_MAPPING

This bit indicates that instances of the class may match mapping patterns when used as the subject of a [match](#) block. It is automatically set when registering or subclassing `collections.abc.Mapping`, and unset when registering `collections.abc.Sequence`.

### Note

`Py_TPFLAGS_MAPPING` and `Py_TPFLAGS_SEQUENCE` are mutually exclusive; it is an error to enable both flags simultaneously.

### Inheritance:

This flag is inherited by types that do not already set `Py_TPFLAGS_SEQUENCE`.

### See also

[PEP 634](#) [<https://peps.python.org/pep-0634/>] – Structural Pattern Matching: Specification

*New in version 3.10.*

## Py\_TPFLAGS\_SEQUENCE

This bit indicates that instances of the class may match sequence patterns when used as the subject of a [match](#) block. It is automatically set when registering or subclassing `collections.abc.Sequence`, and unset when registering `collections.abc.Mapping`.

## Note

`Py_TPFLAGS_MAPPING` and `Py_TPFLAGS_SEQUENCE` are mutually exclusive; it is an error to enable both flags simultaneously.

## Inheritance:

This flag is inherited by types that do not already set `Py_TPFLAGS_MAPPING`.

## See also

[PEP 634](https://peps.python.org/pep-0634/) [https://peps.python.org/pep-0634/] – Structural Pattern Matching: Specification

*New in version 3.10.*

const char \*`PyTypeObject.tp_doc`

An optional pointer to a NUL-terminated C string giving the docstring for this type object. This is exposed as the `__doc__` attribute on the type and instances of the type.

## Inheritance:

This field is *not* inherited by subtypes.

`traverseproc` `PyTypeObject.tp_traverse`

An optional pointer to a traversal function for the garbage collector. This is only used if the `Py_TPFLAGS_HAVE_GC` flag bit is set. The signature is:

```
int tp_traverse(PyObject *self, visitproc visit, vo
```

More information about Python's garbage collection scheme can be found in section [Supporting Cyclic Garbage Collection](#).

The `tp_traverse` pointer is used by the garbage collector to detect reference cycles. A typical implementation of a `tp_traverse` function simply calls `Py_VISIT()` on each of

the instance's members that are Python objects that the instance owns. For example, this is function `local_traverse()` from the `_thread` extension module:

```
static int
local_traverse(localobject *self, visitproc visit,
{
    Py_VISIT(self->args);
    Py_VISIT(self->kw);
    Py_VISIT(self->dict);
    return 0;
}
```

Note that `Py_VISIT()` is called only on those members that can participate in reference cycles. Although there is also a `self->key` member, it can only be `NULL` or a Python string and therefore cannot be part of a reference cycle.

On the other hand, even if you know a member can never be part of a cycle, as a debugging aid you may want to visit it anyway just so the `gc` module's `get_referents()` function will include it.

## Warning

When implementing `tp_traverse`, only the members that the instance *owns* (by having *strong references* to them) must be visited. For instance, if an object supports weak references via the `tp_weaklist` slot, the pointer supporting the linked list (what `tp_weaklist` points to) must **not** be visited as the instance does not directly own the weak references to itself (the weakreference list is there to support the weak reference machinery, but the instance has no strong reference to the elements inside it, as they are allowed to be removed even if the instance is still alive).

Note that `Py_VISIT()` requires the *visit* and *arg* parameters to `local_traverse()` to have these specific names; don't name them just anything.

Instances of [heap-allocated types](#) hold a reference to their type. Their traversal function must therefore either visit `Py_TYPE(self)`, or delegate this responsibility by calling `tp_traverse` of another heap-allocated type (such as a heap-allocated superclass). If they do not, the type object may not be garbage-collected.

*Changed in version 3.9:* Heap-allocated types are expected to visit `Py_TYPE(self)` in `tp_traverse`. In earlier versions of Python, due to [bug 40217](https://bugs.python.org/issue40217) [https://bugs.python.org/issue40217], doing this may lead to crashes in subclasses.

## Inheritance:

Group: `Py_TPFLAGS_HAVE_GC`, `tp_traverse`, `tp_clear`

This field is inherited by subtypes together with `tp_clear` and the `Py_TPFLAGS_HAVE_GC` flag bit: the flag bit, `tp_traverse`, and `tp_clear` are all inherited from the base type if they are all zero in the subtype.

## [inquiry PyTypeObject.tp\\_clear](#)

An optional pointer to a clear function for the garbage collector. This is only used if the `Py_TPFLAGS_HAVE_GC` flag bit is set. The signature is:

```
int tp_clear(PyObject *);
```

The `tp_clear` member function is used to break reference cycles in cyclic garbage detected by the garbage collector. Taken together, all `tp_clear` functions in the system must combine to break all reference cycles. This is subtle, and if in any doubt supply a `tp_clear` function. For example, the tuple type does not implement a `tp_clear` function, because it's possible to prove that no reference cycle can be composed entirely of tuples. Therefore the `tp_clear` functions of other types must be sufficient to break any cycle containing a tuple. This isn't immediately obvious, and there's rarely a good reason to avoid implementing `tp_clear`.

Implementations of `tp_clear` should drop the instance's

references to those of its members that may be Python objects, and set its pointers to those members to `NULL`, as in the following example:

```
static int
local_clear(localobject *self)
{
    Py_CLEAR(self->key);
    Py_CLEAR(self->args);
    Py_CLEAR(self->kw);
    Py_CLEAR(self->dict);
    return 0;
}
```

The `Py_CLEAR()` macro should be used, because clearing references is delicate: the reference to the contained object must not be decremented until after the pointer to the contained object is set to `NULL`. This is because decrementing the reference count may cause the contained object to become trash, triggering a chain of reclamation activity that may include invoking arbitrary Python code (due to finalizers, or weakref callbacks, associated with the contained object). If it's possible for such code to reference *self* again, it's important that the pointer to the contained object be `NULL` at that time, so that *self* knows the contained object can no longer be used. The `Py_CLEAR()` macro performs the operations in a safe order.

Note that `tp_clear` is not *always* called before an instance is deallocated. For example, when reference counting is enough to determine that an object is no longer used, the cyclic garbage collector is not involved and `tp_dealloc` is called directly.

Because the goal of `tp_clear` functions is to break reference cycles, it's not necessary to clear contained objects like Python strings or Python integers, which can't participate in reference cycles. On the other hand, it may be convenient to clear all contained Python objects, and write the type's `tp_dealloc` function to invoke `tp_clear`.

More information about Python's garbage collection scheme can be found in section [Supporting Cyclic Garbage Collection](#).

## Inheritance:

Group: `Py_TPFLAGS_HAVE_GC`, `tp_traverse`, `tp_clear`

This field is inherited by subtypes together with `tp_traverse` and the `Py_TPFLAGS_HAVE_GC` flag bit: the flag bit, `tp_traverse`, and `tp_clear` are all inherited from the base type if they are all zero in the subtype.

## `richcmpfunc` `PyTypeObject.tp_richcompare`

An optional pointer to the rich comparison function, whose signature is:

```
PyObject *tp_richcompare(PyObject *self, PyObject *
```

The first parameter is guaranteed to be an instance of the type that is defined by `PyTypeObject`.

The function should return the result of the comparison (usually `Py_True` or `Py_False`). If the comparison is undefined, it must return `Py_NotImplemented`, if another error occurred it must return `NULL` and set an exception condition.

The following constants are defined to be used as the third argument for `tp_richcompare` and for `PyObject_RichCompare()`:

### Comparison

---

`Py_LT`

---

`Py_LE`

---

`Py_EQ`

---

`Py_NE`

---

`Py_GT`

---

`Py_GE`

---

The following macro is defined to ease writing rich comparison functions:

`Py_RETURN_RICHCOMPARE(VAL_A, VAL_B, op)`

Return `Py_True` or `Py_False` from the function, depending on the result of a comparison. `VAL_A` and `VAL_B` must be orderable by C comparison operators (for example, they may be C ints or floats). The third argument specifies the requested operation, as for `PyObject_RichCompare()`.

The return value's reference count is properly incremented.

On error, sets an exception and returns `NULL` from the function.

*New in version 3.7.*

## Inheritance:

Group: `tp_hash`, `tp_richcompare`

This field is inherited by subtypes together with `tp_hash`: a subtype inherits `tp_richcompare` and `tp_hash` when the subtype's `tp_richcompare` and `tp_hash` are both `NULL`.

## Default:

`PyBaseObject_Type` provides a `tp_richcompare` implementation, which may be inherited. However, if only `tp_hash` is defined, not even the inherited function is used and instances of the type will not be able to participate in any comparisons.

`Py_ssize_t PyObject.tp_weaklistoffset`

If the instances of this type are weakly referenceable, this field is greater than zero and contains the offset in the instance structure of the weak reference list head (ignoring the GC header, if present); this offset is used by `PyObject_ClearWeakRefs()` and the `PyWeakref_*` functions. The instance structure needs to include a field of type `PyObject*` which is initialized to `NULL`.

Do not confuse this field with `tp_weaklist`; that is the list head for weak references to the type object itself.

### Inheritance:

This field is inherited by subtypes, but see the rules listed below. A subtype may override this offset; this means that the subtype uses a different weak reference list head than the base type. Since the list head is always found via `tp_weaklistoffset`, this should not be a problem.

When a type defined by a class statement has no `__slots__` declaration, and none of its base types are weakly referenceable, the type is made weakly referenceable by adding a weak reference list head slot to the instance layout and setting the `tp_weaklistoffset` of that slot's offset.

When a type's `__slots__` declaration contains a slot named `__weakref__`, that slot becomes the weak reference list head for instances of the type, and the slot's offset is stored in the type's `tp_weaklistoffset`.

When a type's `__slots__` declaration does not contain a slot named `__weakref__`, the type inherits its `tp_weaklistoffset` from its base type.

### `getiterfunc PyObject.tp_iter`

An optional pointer to a function that returns an `iterator` for the object. Its presence normally signals that the instances of this type are `iterable` (although sequences may be iterable without this function).

This function has the same signature as `PyObject_GetIter()`:

```
PyObject *tp_iter(PyObject *self);
```

### Inheritance:

This field is inherited by subtypes.

`iternextfunc` `PyTypeObject.tp_iternext`

An optional pointer to a function that returns the next item in an `iterator`. The signature is:

```
PyObject *tp_iternext(PyObject *self);
```

When the iterator is exhausted, it must return `NULL`; a `StopIteration` exception may or may not be set. When another error occurs, it must return `NULL` too. Its presence signals that the instances of this type are iterators.

Iterator types should also define the `tp_iter` function, and that function should return the iterator instance itself (not a new iterator instance).

This function has the same signature as `PyIter_Next()`.

### **Inheritance:**

This field is inherited by subtypes.

struct `PyMethodDef *PyTypeObject.tp_methods`

An optional pointer to a static `NULL`-terminated array of `PyMethodDef` structures, declaring regular methods of this type.

For each entry in the array, an entry is added to the type's dictionary (see `tp_dict` below) containing a method descriptor.

### **Inheritance:**

This field is not inherited by subtypes (methods are inherited through a different mechanism).

struct `PyMemberDef *PyTypeObject.tp_members`

An optional pointer to a static `NULL`-terminated array of `PyMemberDef` structures, declaring regular data members (fields or slots) of instances of this type.

For each entry in the array, an entry is added to the type's

dictionary (see `tp_dict` below) containing a member descriptor.

### Inheritance:

This field is not inherited by subtypes (members are inherited through a different mechanism).

struct `PyGetSetDef` \*`PyTypeObject`.`tp_getset`

An optional pointer to a static NULL-terminated array of `PyGetSetDef` structures, declaring computed attributes of instances of this type.

For each entry in the array, an entry is added to the type's dictionary (see `tp_dict` below) containing a getset descriptor.

### Inheritance:

This field is not inherited by subtypes (computed attributes are inherited through a different mechanism).

`PyTypeObject` \*`PyTypeObject`.`tp_base`

An optional pointer to a base type from which type properties are inherited. At this level, only single inheritance is supported; multiple inheritance require dynamically creating a type object by calling the metatype.

### Note

Slot initialization is subject to the rules of initializing globals. C99 requires the initializers to be “address constants”. Function designators like `PyType_GenericNew()`, with implicit conversion to a pointer, are valid C99 address constants.

However, the unary ‘&’ operator applied to a non-static variable like `PyBaseObject_Type()` is not required to produce an address constant. Compilers may support this (gcc does), MSVC does not. Both compilers are strictly

standard conforming in this particular behavior.

Consequently, `tp_base` should be set in the extension module's init function.

### Inheritance:

This field is not inherited by subtypes (obviously).

### Default:

This field defaults to `&PyBaseObject_Type` (which to Python programmers is known as the type `object`).

`PyObject *PyTypeObject.tp_dict`

The type's dictionary is stored here by `PyType_Ready()`.

This field should normally be initialized to `NULL` before `PyType_Ready` is called; it may also be initialized to a dictionary containing initial attributes for the type. Once `PyType_Ready()` has initialized the type, extra attributes for the type may be added to this dictionary only if they don't correspond to overloaded operations (like `__add__()`).

### Inheritance:

This field is not inherited by subtypes (though the attributes defined in here are inherited through a different mechanism).

### Default:

If this field is `NULL`, `PyType_Ready()` will assign a new dictionary to it.

### Warning

It is not safe to use `PyDict_SetItem()` on or otherwise modify `tp_dict` with the dictionary C-API.

### `descrgetfunc PyTypeObject.tp_descr_get`

An optional pointer to a “descriptor get” function.

The function signature is:

```
PyObject * tp_descr_get(PyObject *self, PyObject *o
```

#### **Inheritance:**

This field is inherited by subtypes.

### `descrsetfunc PyTypeObject.tp_descr_set`

An optional pointer to a function for setting and deleting a descriptor’s value.

The function signature is:

```
int tp_descr_set(PyObject *self, PyObject *obj, PyO
```

The *value* argument is set to `NULL` to delete the value.

#### **Inheritance:**

This field is inherited by subtypes.

### `Py_ssize_t PyTypeObject.tp_dictoffset`

If the instances of this type have a dictionary containing instance variables, this field is non-zero and contains the offset in the instances of the type of the instance variable dictionary; this offset is used by

`PyObject_GenericGetAttr()`.

Do not confuse this field with `tp_dict`; that is the dictionary for attributes of the type object itself.

If the value of this field is greater than zero, it specifies the offset from the start of the instance structure. If the value is less than zero, it specifies the offset from the *end* of the instance structure. A negative offset is more expensive to use, and should only be used when the instance structure contains a variable-length part. This is used for example to add an

instance variable dictionary to subtypes of `str` or `tuple`. Note that the `tp_basicsize` field should account for the dictionary added to the end in that case, even though the dictionary is not included in the basic object layout. On a system with a pointer size of 4 bytes, `tp_dictoffset` should be set to `-4` to indicate that the dictionary is at the very end of the structure.

The `tp_dictoffset` should be regarded as write-only. To get the pointer to the dictionary call `PyObject_GenericGetDict()`. Calling `PyObject_GenericGetDict()` may need to allocate memory for the dictionary, so it is may be more efficient to call `PyObject_GetAttr()` when accessing an attribute on the object.

### Inheritance:

This field is inherited by subtypes, but see the rules listed below. A subtype may override this offset; this means that the subtype instances store the dictionary at a difference offset than the base type. Since the dictionary is always found via `tp_dictoffset`, this should not be a problem.

When a type defined by a class statement has no `__slots__` declaration, and none of its base types has an instance variable dictionary, a dictionary slot is added to the instance layout and the `tp_dictoffset` is set to that slot's offset.

When a type defined by a class statement has a `__slots__` declaration, the type inherits its `tp_dictoffset` from its base type.

(Adding a slot named `__dict__` to the `__slots__` declaration does not have the expected effect, it just causes confusion. Maybe this should be added as a feature just like `__weakref__` though.)

### Default:

This slot has no default. For `static types`, if the field is `NULL`

then no `__dict__` gets created for instances.

### `initproc PyTypeObject.tp_init`

An optional pointer to an instance initialization function.

This function corresponds to the `__init__()` method of classes. Like `__init__()`, it is possible to create an instance without calling `__init__()`, and it is possible to reinitialize an instance by calling its `__init__()` method again.

The function signature is:

```
int tp_init(PyObject *self, PyObject *args, PyObject *
```

The `self` argument is the instance to be initialized; the `args` and `kws` arguments represent positional and keyword arguments of the call to `__init__()`.

The `tp_init` function, if not `NULL`, is called when an instance is created normally by calling its type, after the type's `tp_new` function has returned an instance of the type. If the `tp_new` function returns an instance of some other type that is not a subtype of the original type, no `tp_init` function is called; if `tp_new` returns an instance of a subtype of the original type, the subtype's `tp_init` is called.

Returns 0 on success, -1 and sets an exception on error.

### **Inheritance:**

This field is inherited by subtypes.

### **Default:**

For `static types` this field does not have a default.

### `allocfunc PyTypeObject.tp_alloc`

An optional pointer to an instance allocation function.

The function signature is:

```
PyObject *tp_alloc(PyTypeObject *self, Py_ssize_t n
```

## Inheritance:

This field is inherited by static subtypes, but not by dynamic subtypes (subtypes created by a class statement).

## Default:

For dynamic subtypes, this field is always set to `PyType_GenericAlloc()`, to force a standard heap allocation strategy.

For static subtypes, `PyBaseObject_Type` uses `PyType_GenericAlloc()`. That is the recommended value for all statically defined types.

## `newfunc PyTypeObject.tp_new`

An optional pointer to an instance creation function.

The function signature is:

```
PyObject *tp_new(PyTypeObject *subtype, PyObject *a
```

The *subtype* argument is the type of the object being created; the *args* and *kws* arguments represent positional and keyword arguments of the call to the type. Note that *subtype* doesn't have to equal the type whose `tp_new` function is called; it may be a subtype of that type (but not an unrelated type).

The `tp_new` function should call `subtype->tp_alloc(subtype, nitems)` to allocate space for the object, and then do only as much further initialization as is absolutely necessary. Initialization that can safely be ignored or repeated should be placed in the `tp_init` handler. A good rule of thumb is that for immutable types, all initialization should take place in `tp_new`, while for mutable types, most initialization should be deferred to `tp_init`.

Set the `Py_TPFLAGS_DISALLOW_INSTANTIATION` flag to

disallow creating instances of the type in Python.

### Inheritance:

This field is inherited by subtypes, except it is not inherited by **static types** whose **tp\_base** is `NULL` or `&PyBaseObject_Type`.

### Default:

For **static types** this field has no default. This means if the slot is defined as `NULL`, the type cannot be called to create new instances; presumably there is some other way to create instances, like a factory function.

### **freelfunc** **PyTypeObject**.tp\_free

An optional pointer to an instance deallocation function. Its signature is:

```
void tp_free(void *self);
```

An initializer that is compatible with this signature is **PyObject\_Free()**.

### Inheritance:

This field is inherited by static subtypes, but not by dynamic subtypes (subtypes created by a class statement)

### Default:

In dynamic subtypes, this field is set to a deallocator suitable to match **PyType\_GenericAlloc()** and the value of the **Py\_TPFLAGS\_HAVE\_GC** flag bit.

For static subtypes, **PyBaseObject\_Type** uses **PyObject\_Del**.

### **inquiry** **PyTypeObject**.tp\_is\_gc

An optional pointer to a function called by the garbage collector.

The garbage collector needs to know whether a particular object is collectible or not. Normally, it is sufficient to look at the object's type's `tp_flags` field, and check the `Py_TPFLAGS_HAVE_GC` flag bit. But some types have a mixture of statically and dynamically allocated instances, and the statically allocated instances are not collectible. Such types should define this function; it should return `1` for a collectible instance, and `0` for a non-collectible instance. The signature is:

```
int tp_is_gc(PyObject *self);
```

(The only example of this are types themselves. The metatype, `PyType_Type`, defines this function to distinguish between statically and dynamically allocated types.)

### Inheritance:

This field is inherited by subtypes.

### Default:

This slot has no default. If this field is `NULL`, `Py_TPFLAGS_HAVE_GC` is used as the functional equivalent.

`PyObject *PyTypeObject.tp_bases`

Tuple of base types.

This field should be set to `NULL` and treated as read-only. Python will fill it in when the type is `initialized`.

For dynamically created classes, the `Py_tp_bases` slot can be used instead of the `bases` argument of `PyType_FromSpecWithBases()`. The argument form is preferred.

### Warning

Multiple inheritance does not work well for statically defined types. If you set `tp_bases` to a tuple, Python will not raise an error, but some slots will only be inherited

from the first base.

**Inheritance:**

This field is not inherited.

`PyObject *PyTypeObject.tp_mro`

Tuple containing the expanded set of base types, starting with the type itself and ending with `object`, in Method Resolution Order.

This field should be set to `NULL` and treated as read-only. Python will fill it in when the type is `initialized`.

**Inheritance:**

This field is not inherited; it is calculated fresh by `PyType_Ready()`.

`PyObject *PyTypeObject.tp_cache`

Unused. Internal use only.

**Inheritance:**

This field is not inherited.

`PyObject *PyTypeObject.tp_subclasses`

List of weak references to subclasses. Internal use only.

**Inheritance:**

This field is not inherited.

`PyObject *PyTypeObject.tp_weaklist`

Weak reference list head, for weak references to this type object. Not inherited. Internal use only.

**Inheritance:**

This field is not inherited.

## destructor `PyTypeObject.tp_del`

This field is deprecated. Use `tp_finalize` instead.

## unsigned int `PyTypeObject.tp_version_tag`

Used to index into the method cache. Internal use only.

### **Inheritance:**

This field is not inherited.

## destructor `PyTypeObject.tp_finalize`

An optional pointer to an instance finalization function. Its signature is:

```
void tp_finalize(PyObject *self);
```

If `tp_finalize` is set, the interpreter calls it once when finalizing an instance. It is called either from the garbage collector (if the instance is part of an isolated reference cycle) or just before the object is deallocated. Either way, it is guaranteed to be called before attempting to break reference cycles, ensuring that it finds the object in a sane state.

`tp_finalize` should not mutate the current exception status; therefore, a recommended way to write a non-trivial finalizer is:

```
static void
local_finalize(PyObject *self)
{
    PyObject *error_type, *error_value, *error_traceback;

    /* Save the current exception, if any. */
    PyErr_Fetch(&error_type, &error_value, &error_traceback);

    /* ... */

    /* Restore the saved exception. */
    PyErr_Restore(error_type, error_value, error_traceback);
}
```

```
}
```

Also, note that, in a garbage collected Python, `tp_dealloc` may be called from any Python thread, not just the thread which created the object (if the object becomes part of a refcount cycle, that cycle might be collected by a garbage collection on any thread). This is not a problem for Python API calls, since the thread on which `tp_dealloc` is called will own the Global Interpreter Lock (GIL). However, if the object being destroyed in turn destroys objects from some other C or C++ library, care should be taken to ensure that destroying those objects on the thread which called `tp_dealloc` will not violate any assumptions of the library.

### **Inheritance:**

This field is inherited by subtypes.

*New in version 3.4.*

*Changed in version 3.8:* Before version 3.8 it was necessary to set the `Py_TPFLAGS_HAVE_FINALIZE` flags bit in order for this field to be used. This is no longer required.

### **See also**

“Safe object finalization” ([PEP 442](https://peps.python.org/pep-0442/) [https://peps.python.org/pep-0442/])

### **vectorcallfunc PyTypeObject.tp\_vectorcall**

Vectorcall function to use for calls of this type object. In other words, it is used to implement `vectorcall` for `type.__call__`. If `tp_vectorcall` is `NULL`, the default call implementation using `__new__` and `__init__` is used.

### **Inheritance:**

This field is never inherited.

*New in version 3.9:* (the field exists since 3.8 but it's only used

since 3.9)

## Static Types

Traditionally, types defined in C code are *static*, that is, a static `PyTypeObject` structure is defined directly in code and initialized using `PyType_Ready()`.

This results in types that are limited relative to types defined in Python:

- Static types are limited to one base, i.e. they cannot use multiple inheritance.
- Static type objects (but not necessarily their instances) are immutable. It is not possible to add or modify the type object's attributes from Python.
- Static type objects are shared across [sub-interpreters](#), so they should not include any subinterpreter-specific state.

Also, since `PyTypeObject` is only part of the [Limited API](#) as an opaque struct, any extension modules using static types must be compiled for a specific Python minor version.

## Heap Types

An alternative to [static types](#) is *heap-allocated types*, or *heap types* for short, which correspond closely to classes created by Python's `class` statement. Heap types have the `Py_TPFLAGS_HEAPTYPE` flag set.

This is done by filling a `PyType_Spec` structure and calling `PyType_FromSpec()`, `PyType_FromSpecWithBases()`, or `PyType_FromModuleAndSpec()`.

## Number Object Structures

## type PyNumberMethods

This structure holds pointers to the functions which an object uses to implement the number protocol. Each function is used by the function of similar name documented in the [Number Protocol](#) section.

Here is the structure definition:

```
typedef struct {
    binaryfunc nb_add;
    binaryfunc nb_subtract;
    binaryfunc nb_multiply;
    binaryfunc nb_remainder;
    binaryfunc nb_divmod;
    ternaryfunc nb_power;
    unaryfunc nb_negative;
    unaryfunc nb_positive;
    unaryfunc nb_absolute;
    inquiry nb_bool;
    unaryfunc nb_invert;
    binaryfunc nb_lshift;
    binaryfunc nb_rshift;
    binaryfunc nb_and;
    binaryfunc nb_xor;
    binaryfunc nb_or;
    unaryfunc nb_int;
    void *nb_reserved;
    unaryfunc nb_float;

    binaryfunc nb_inplace_add;
    binaryfunc nb_inplace_subtract;
    binaryfunc nb_inplace_multiply;
    binaryfunc nb_inplace_remainder;
    ternaryfunc nb_inplace_power;
    binaryfunc nb_inplace_lshift;
    binaryfunc nb_inplace_rshift;
    binaryfunc nb_inplace_and;
    binaryfunc nb_inplace_xor;
    binaryfunc nb_inplace_or;
```

```

    binaryfunc nb_floor_divide;
    binaryfunc nb_true_divide;
    binaryfunc nb_inplace_floor_divide;
    binaryfunc nb_inplace_true_divide;

    unaryfunc nb_index;

    binaryfunc nb_matrix_multiply;
    binaryfunc nb_inplace_matrix_multiply;
} PyNumberMethods;

```

### Note

Binary and ternary functions must check the type of all their operands, and implement the necessary conversions (at least one of the operands is an instance of the defined type). If the operation is not defined for the given operands, binary and ternary functions must return `Py_NotImplemented`, if another error occurred they must return `NULL` and set an exception.

### Note

The `nb_reserved` field should always be `NULL`. It was previously called `nb_long`, and was renamed in Python 3.0.1.

binaryfunc PyNumberMethods.nb\_inplace\_matrix\_multiply

## Mapping Object Structures

type PyMappingMethods

This structure holds pointers to the functions which an object uses to implement the mapping protocol. It has three members:

lenfunc PyMappingMethods.mp\_length

This function is used by **PyMapping\_Size()** and **PyObject\_Size()**, and has the same signature. This slot

may be set to `NULL` if the object has no defined length.

**binaryfunc** `PyMappingMethods.mp_subscript`

This function is used by `PyObject_GetItem()` and `PySequence_GetSlice()`, and has the same signature as `PyObject_GetItem()`. This slot must be filled for the `PyMapping_Check()` function to return `1`, it can be `NULL` otherwise.

**objobjargproc** `PyMappingMethods.mp_ass_subscript`

This function is used by `PyObject_SetItem()`, `PyObject_DelItem()`, `PyObject_SetSlice()` and `PyObject_DelSlice()`. It has the same signature as `PyObject_SetItem()`, but `v` can also be set to `NULL` to delete an item. If this slot is `NULL`, the object does not support item assignment and deletion.

## Sequence Object Structures

**type** `PySequenceMethods`

This structure holds pointers to the functions which an object uses to implement the sequence protocol.

**lenfunc** `PySequenceMethods.sq_length`

This function is used by `PySequence_Size()` and `PyObject_Size()`, and has the same signature. It is also used for handling negative indices via the `sq_item` and the `sq_ass_item` slots.

**binaryfunc** `PySequenceMethods.sq_concat`

This function is used by `PySequence_Concat()` and has the same signature. It is also used by the `+` operator, after trying the numeric addition via the `nb_add` slot.

**ssizeargfunc** `PySequenceMethods.sq_repeat`

This function is used by `PySequence_Repeat()` and has the same signature. It is also used by the `*` operator, after trying numeric multiplication via the `nb_multiply` slot.

#### `ssizeargfunc PySequenceMethods.sq_item`

This function is used by `PySequence_GetItem()` and has the same signature. It is also used by `PyObject_GetItem()`, after trying the subscription via the `mp_subscript` slot. This slot must be filled for the `PySequence_Check()` function to return 1, it can be `NULL` otherwise.

Negative indexes are handled as follows: if the `sq_length` slot is filled, it is called and the sequence length is used to compute a positive index which is passed to `sq_item`. If `sq_length` is `NULL`, the index is passed as is to the function.

#### `ssizeobjargproc PySequenceMethods.sq_ass_item`

This function is used by `PySequence_SetItem()` and has the same signature. It is also used by `PyObject_SetItem()` and `PyObject_DelItem()`, after trying the item assignment and deletion via the `mp_ass_subscript` slot. This slot may be left to `NULL` if the object does not support item assignment and deletion.

#### `objobjproc PySequenceMethods.sq_contains`

This function may be used by `PySequence_Contains()` and has the same signature. This slot may be left to `NULL`, in this case `PySequence_Contains()` simply traverses the sequence until it finds a match.

#### `binaryfunc PySequenceMethods.sq_inplace_concat`

This function is used by `PySequence_InPlaceConcat()` and has the same signature. It should modify its first operand, and return it. This slot may be left to `NULL`, in this case `PySequence_InPlaceConcat()` will fall back to `PySequence_Concat()`. It is also used by the augmented assignment `+=`, after trying numeric in-place addition via the `nb_inplace_add` slot.

`ssizeargfunc PySequenceMethods.sq_inplace_repeat`

This function is used by `PySequence_InPlaceRepeat()` and has the same signature. It should modify its first operand, and return it. This slot may be left to `NULL`, in this case `PySequence_InPlaceRepeat()` will fall back to `PySequence_Repeat()`. It is also used by the augmented assignment `*=`, after trying numeric in-place multiplication via the `nb_inplace_multiply` slot.

## Buffer Object Structures

`type PyBufferProcs`

This structure holds pointers to the functions required by the [Buffer protocol](#). The protocol defines how an exporter object can expose its internal data to consumer objects.

`getbufferproc PyBufferProcs.bf_getbuffer`

The signature of this function is:

```
int (PyObject *exporter, Py_buffer *view, int flags)
```

Handle a request to *exporter* to fill in *view* as specified by *flags*. Except for point (3), an implementation of this function MUST take these steps:

1. Check if the request can be met. If not, raise **PyExc\_BufferError**, set `view->obj` to `NULL` and return `-1`.
2. Fill in the requested fields.
3. Increment an internal counter for the number of exports.
4. Set `view->obj` to *exporter* and increment `view->obj`.
5. Return `0`.

If *exporter* is part of a chain or tree of buffer providers, two main schemes can be used:

- Re-export: Each member of the tree acts as the exporting object and sets `view->obj` to a new reference to itself.
- Redirect: The buffer request is redirected to the root object of the tree. Here, `view->obj` will be a new reference to the root object.

The individual fields of `view` are described in section [Buffer structure](#), the rules how an exporter must react to specific requests are in section [Buffer request types](#).

All memory pointed to in the `Py_buffer` structure belongs to the exporter and must remain valid until there are no consumers left. `format`, `shape`, `strides`, `suboffsets` and `internal` are read-only for the consumer.

`PyBuffer_FillInfo()` provides an easy way of exposing a simple bytes buffer while dealing correctly with all request types.

`PyObject_GetBuffer()` is the interface for the consumer that wraps this function.

[releasebufferproc](#) `PyBufferProcs.bf_releasebuffer`

The signature of this function is:

```
void (PyObject *exporter, Py_buffer *view);
```

Handle a request to release the resources of the buffer. If no resources need to be released,

`PyBufferProcs.bf_releasebuffer` may be `NULL`. Otherwise, a standard implementation of this function will take these optional steps:

1. Decrement an internal counter for the number of exports.
2. If the counter is 0, free all memory associated with `view`.

The exporter MUST use the `internal` field to keep track of buffer-specific resources. This field is guaranteed to remain

constant, while a consumer MAY pass a copy of the original buffer as the *view* argument.

This function MUST NOT decrement view->obj, since that is done automatically in `PyBuffer_Release()` (this scheme is useful for breaking reference cycles).

`PyBuffer_Release()` is the interface for the consumer that wraps this function.

## Async Object Structures

*New in version 3.5.*

type `PyAsyncMethods`

This structure holds pointers to the functions required to implement [awaitable](#) and [asynchronous iterator](#) objects.

Here is the structure definition:

```
typedef struct {
    unaryfunc am_await;
    unaryfunc am_aiter;
    unaryfunc am_anext;
    sendfunc am_send;
} PyAsyncMethods;
```

[unaryfunc](#) `PyAsyncMethods.am_await`

The signature of this function is:

```
PyObject *am_await(PyObject *self);
```

The returned object must be an [iterator](#), i.e.

[PyIter\\_Check\(\)](#) must return 1 for it.

This slot may be set to `NULL` if an object is not an [awaitable](#).

### [unaryfunc PyAsyncMethods.am\\_aiter](#)

The signature of this function is:

```
PyObject *am_aiter(PyObject *self);
```

Must return an [asynchronous iterator](#) object. See `__anext__()` for details.

This slot may be set to `NULL` if an object does not implement asynchronous iteration protocol.

### [unaryfunc PyAsyncMethods.am\\_anext](#)

The signature of this function is:

```
PyObject *am_anext(PyObject *self);
```

Must return an [awaitable](#) object. See `__anext__()` for details. This slot may be set to `NULL`.

### [sendfunc PyAsyncMethods.am\\_send](#)

The signature of this function is:

```
PySendResult am_send(PyObject *self, PyObject *arg,
```

See [PyIter\\_Send\(\)](#) for details. This slot may be set to `NULL`.

*New in version 3.10.*

## Slot Type typedefs

```
typedef PyObject *(*allocfunc)(PyTypeObject *cls, Py\_ssize\_t nitems)
```

*Part of the [Stable ABI](#).*

The purpose of this function is to separate memory allocation from memory initialization. It should return a pointer to a block of memory of adequate length for the instance, suitably

aligned, and initialized to zeros, but with `ob_refcnt` set to 1 and `ob_type` set to the type argument. If the type's `tp_itemsize` is non-zero, the object's `ob_size` field should be initialized to *nitems* and the length of the allocated memory block should be `tp_basicsize + nitems*tp_itemsize`, rounded up to a multiple of `sizeof(void*)`; otherwise, *nitems* is not used and the length of the block should be `tp_basicsize`.

This function should not do any other instance initialization, not even to allocate additional memory; that should be done by `tp_new`.

```
typedef void (*destructor)(PyObject*)
```

*Part of the [Stable ABI](#).*

```
typedef void (*freefunc)(void*)
```

See `tp_free`.

```
typedef PyObject *(*newfunc)(PyObject*, PyObject*, PyObject*)
```

*Part of the [Stable ABI](#).*

See `tp_new`.

```
typedef int (*initproc)(PyObject*, PyObject*, PyObject*)
```

*Part of the [Stable ABI](#).*

See `tp_init`.

```
typedef PyObject *(*reprfunc)(PyObject*)
```

*Part of the [Stable ABI](#).*

See `tp_repr`.

```
typedef PyObject *(*getattrfunc)(PyObject *self, char *attr)
```

*Part of the [Stable ABI](#).*

Return the value of the named attribute for the object.

```
typedef int (*setattrfunc)(PyObject *self, char *attr, PyObject  
*value)
```

*Part of the [Stable ABI](#).*

Set the value of the named attribute for the object. The value argument is set to `NULL` to delete the attribute.

```
typedef PyObject *(*getattrofunc)(PyObject *self, PyObject *attr)
```

*Part of the [Stable ABI](#).*

Return the value of the named attribute for the object.

See [tp\\_getattro](#).

```
typedef int (*setattrofunc)(PyObject *self, PyObject *attr, PyObject  
*value)
```

*Part of the [Stable ABI](#).*

Set the value of the named attribute for the object. The value argument is set to `NULL` to delete the attribute.

See [tp\\_setattro](#).

```
typedef PyObject *(*descrgetfunc)(PyObject*, PyObject*,  
PyObject*)
```

*Part of the [Stable ABI](#).*

See [tp\\_descr\\_get](#).

```
typedef int (*descrsetfunc)(PyObject*, PyObject*, PyObject*)
```

*Part of the [Stable ABI](#).*

See [tp\\_descr\\_set](#).

```
typedef Py_hash_t (*hashfunc)(PyObject*)
```

*Part of the [Stable ABI](#).*

See [tp\\_hash](#).

```
typedef PyObject *(*richcmpfunc)(PyObject*, PyObject*, int)
```

*Part of the [Stable ABI](#).*

See [tp\\_richcompare](#).

```
typedef PyObject *(*getiterfunc)(PyObject*)
```

*Part of the [Stable ABI](#).*

See [tp\\_iter](#).

typedef [PyObject](#) \*(\*iternextfunc)([PyObject](#)\*)

*Part of the [Stable ABI](#).*

See [tp\\_iternext](#).

typedef [Py\\_ssize\\_t](#) (\*lenfunc)([PyObject](#)\*)

*Part of the [Stable ABI](#).*

typedef int (\*getbufferproc)([PyObject](#)\*, [Py\\_buffer](#)\*, int)

typedef void (\*releasebufferproc)([PyObject](#)\*, [Py\\_buffer](#)\*)

typedef [PyObject](#) \*(\*unaryfunc)([PyObject](#)\*)

*Part of the [Stable ABI](#).*

typedef [PyObject](#) \*(\*binaryfunc)([PyObject](#)\*, [PyObject](#)\*)

*Part of the [Stable ABI](#).*

typedef [PySendResult](#) (\*sendfunc)([PyObject](#)\*, [PyObject](#)\*,  
[PyObject](#)\*\*)

See [am\\_send](#).

typedef [PyObject](#) \*(\*ternaryfunc)([PyObject](#)\*, [PyObject](#)\*, [PyObject](#)\*)

*Part of the [Stable ABI](#).*

typedef [PyObject](#) \*(\*ssizeargfunc)([PyObject](#)\*, [Py\\_ssize\\_t](#))

*Part of the [Stable ABI](#).*

typedef int (\*ssizeobjargproc)([PyObject](#)\*, [Py\\_ssize\\_t](#), [PyObject](#)\*)

*Part of the [Stable ABI](#).*

typedef int (\*objobjproc)([PyObject](#)\*, [PyObject](#)\*)

*Part of the [Stable ABI](#).*

typedef int (\*objobjargproc)([PyObject](#)\*, [PyObject](#)\*, [PyObject](#)\*)

*Part of the [Stable ABI](#).*

# Examples

The following are simple examples of Python type definitions. They include common usage you may encounter. Some demonstrate tricky corner cases. For more examples, practical info, and a tutorial, see [Defining Extension Types: Tutorial](#) and [Defining Extension Types: Assorted Topics](#).

A basic `static type`:

```
typedef struct {
    PyObject_HEAD
    const char *data;
} PyObject;

static PyTypeObject PyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyObject",
    .tp_basicsize = sizeof(MyObject),
    .tp_doc = PyDoc_STR("My objects"),
    .tp_new = myobj_new,
    .tp_dealloc = (destructor)myobj_dealloc,
    .tp_repr = (reprfunc)myobj_repr,
};
```

You may also find older code (especially in the CPython code base) with a more verbose initializer:

```
static PyTypeObject PyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    "mymod.MyObject",           /* tp_name */
    sizeof(MyObject),           /* tp_basicsize */
    0,                           /* tp_itemsize */
    (destructor)myobj_dealloc,   /* tp_dealloc */
    0,                           /* tp_vectorcall_offset */
    0,                           /* tp_getattr */
```

```

0, /* tp_setattr */
0, /* tp_as_async */
(reprfunc)myobj_repr, /* tp_repr */
0, /* tp_as_number */
0, /* tp_as_sequence */
0, /* tp_as_mapping */
0, /* tp_hash */
0, /* tp_call */
0, /* tp_str */
0, /* tp_getattro */
0, /* tp_setattro */
0, /* tp_as_buffer */
0, /* tp_flags */
PyDoc_STR("My objects"), /* tp_doc */
0, /* tp_traverse */
0, /* tp_clear */
0, /* tp_richcompare */
0, /* tp_weaklistoffset */
0, /* tp_iter */
0, /* tp_iternext */
0, /* tp_methods */
0, /* tp_members */
0, /* tp_getset */
0, /* tp_base */
0, /* tp_dict */
0, /* tp_descr_get */
0, /* tp_descr_set */
0, /* tp_dictoffset */
0, /* tp_init */
0, /* tp_alloc */
myobj_new, /* tp_new */
};

```

A type that supports weakrefs, instance dicts, and hashing:

```

typedef struct {
    PyObject_HEAD
    const char *data;
    PyObject *inst_dict;

```

```

    PyObject *weakreflist;
} MyObject;

static PyObject MyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyObject",
    .tp_basicsize = sizeof(MyObject),
    .tp_doc = PyDoc_STR("My objects"),
    .tp_weaklistoffset = offsetof(MyObject, weakreflist),
    .tp_dictoffset = offsetof(MyObject, inst_dict),
    .tp_flags = Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE,
    .tp_new = myobj_new,
    .tp_traverse = (traverseproc)myobj_traverse,
    .tp_clear = (inquiry)myobj_clear,
    .tp_alloc = PyType_GenericNew,
    .tp_dealloc = (destructor)myobj_dealloc,
    .tp_repr = (reprfunc)myobj_repr,
    .tp_hash = (hashfunc)myobj_hash,
    .tp_richcompare = PyBaseObject_Type.tp_richcompare,
};

```

A str subclass that cannot be subclassed and cannot be called to create instances (e.g. uses a separate factory func) using **Py\_TPFLAGS\_DISALLOW\_INSTANTIATION** flag:

```

typedef struct {
    PyUnicodeObject raw;
    char *extra;
} MyStr;

static PyObject MyStr_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyStr",
    .tp_basicsize = sizeof(MyStr),
    .tp_base = NULL, // set to &PyUnicode_Type in module
    .tp_doc = PyDoc_STR("my custom str"),
    .tp_flags = Py_TPFLAGS_DEFAULT | Py_TPFLAGS_DISALLOW_INSTANTIATION,
    .tp_repr = (reprfunc)myobj_repr,
};

```

The simplest [static type](#) with fixed-length instances:

```
typedef struct {
    PyObject_HEAD
} PyObject;

static PyTypeObject PyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyObject",
};
```

The simplest [static type](#) with variable-length instances:

```
typedef struct {
    PyObject_VAR_HEAD
    const char *data[1];
} PyObject;

static PyTypeObject PyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyObject",
    .tp_basicsize = sizeof(PyObject) - sizeof(char *),
    .tp_itemsize = sizeof(char *),
};
```

# Supporting Cyclic Garbage Collection

Python's support for detecting and collecting garbage which involves circular references requires support from object types which are "containers" for other objects which may also be containers. Types which do not store references to other objects, or which only store references to atomic types (such as numbers or strings), do not need to provide any explicit support for garbage collection.

To create a container type, the `tp_flags` field of the type object must include the `Py_TPFLAGS_HAVE_GC` and provide an implementation of the `tp_traverse` handler. If instances of the type are mutable, a `tp_clear` implementation must also be provided.

## `Py_TPFLAGS_HAVE_GC`

Objects with a type with this flag set must conform with the rules documented here. For convenience these objects will be referred to as container objects.

Constructors for container types must conform to two rules:

1. The memory for the object must be allocated using `PyObject_GC_New()` or `PyObject_GC_NewVar()`.
2. Once all the fields which may contain references to other containers are initialized, it must call `PyObject_GC_Track()`.

Similarly, the deallocator for the object must conform to a similar pair of rules:

1. Before fields which refer to other containers are invalidated, `PyObject_GC_UnTrack()` must be called.

2. The object's memory must be deallocated using `PyObject_GC_Del()`.

### Warning

If a type adds the `Py_TPFLAGS_HAVE_GC`, then it *must* implement at least a `tp_traverse` handler or explicitly use one from its subclass or subclasses.

When calling `PyType_Ready()` or some of the APIs that indirectly call it like `PyType_FromSpecWithBases()` or `PyType_FromSpec()` the interpreter will automatically populate the `tp_flags`, `tp_traverse` and `tp_clear` fields if the type inherits from a class that implements the garbage collector protocol and the child class does *not* include the `Py_TPFLAGS_HAVE_GC` flag.

`TYPE *PyObject_GC_New(TYPE, PyTypeObject *type)`

Analogous to `PyObject_New()` but for container objects with the `Py_TPFLAGS_HAVE_GC` flag set.

`TYPE *PyObject_GC_NewVar(TYPE, PyTypeObject *type, Py_ssize_t size)`

Analogous to `PyObject_NewVar()` but for container objects with the `Py_TPFLAGS_HAVE_GC` flag set.

`TYPE *PyObject_GC_Resize(TYPE, PyVarObject *op, Py_ssize_t newsize)`

Resize an object allocated by `PyObject_NewVar()`. Returns the resized object or `NULL` on failure. *op* must not be tracked by the collector yet.

`void PyObject_GC_Track(PyObject *op)`

*Part of the [Stable ABI](#).*

Adds the object *op* to the set of container objects tracked by the collector. The collector can run at unexpected times so

objects must be valid while being tracked. This should be called once all the fields followed by the `tp_traverse` handler become valid, usually near the end of the constructor.

`int PyObject_IS_GC(PyObject *obj)`

Returns non-zero if the object implements the garbage collector protocol, otherwise returns 0.

The object cannot be tracked by the garbage collector if this function returns 0.

`int PyObject_GC_IsTracked(PyObject *op)`

*Part of the [Stable ABI](#) since version 3.9.*

Returns 1 if the object type of *op* implements the GC protocol and *op* is being currently tracked by the garbage collector and 0 otherwise.

This is analogous to the Python function `gc.is_tracked()`.

*New in version 3.9.*

`int PyObject_GC_IsFinalized(PyObject *op)`

*Part of the [Stable ABI](#) since version 3.9.*

Returns 1 if the object type of *op* implements the GC protocol and *op* has been already finalized by the garbage collector and 0 otherwise.

This is analogous to the Python function `gc.is_finalized()`.

*New in version 3.9.*

`void PyObject_GC_Del(void *op)`

*Part of the [Stable ABI](#).*

Releases memory allocated to an object using `PyObject_GC_New()` or `PyObject_GC_NewVar()`.

```
void PyObject_GC_UnTrack(void *op)
```

*Part of the [Stable ABI](#).*

Remove the object *op* from the set of container objects tracked by the collector. Note that `PyObject_GC_Track()` can be called again on this object to add it back to the set of tracked objects. The deallocator (`tp_dealloc` handler) should call this for the object before any of the fields used by the `tp_traverse` handler become invalid.

*Changed in version 3.8:* The `_PyObject_GC_TRACK()` and `_PyObject_GC_UNTRACK()` macros have been removed from the public C API.

The `tp_traverse` handler accepts a function parameter of this type:

```
typedef int (*visitproc)(PyObject *object, void *arg)
```

*Part of the [Stable ABI](#).*

Type of the visitor function passed to the `tp_traverse` handler. The function should be called with an object to traverse as *object* and the third parameter to the `tp_traverse` handler as *arg*. The Python core uses several visitor functions to implement cyclic garbage detection; it's not expected that users will need to write their own visitor functions.

The `tp_traverse` handler must have the following type:

```
typedef int (*traverseproc)(PyObject *self, visitproc visit, void *arg)
```

*Part of the [Stable ABI](#).*

Traversal function for a container object. Implementations must call the *visit* function for each object directly contained by *self*, with the parameters to *visit* being the contained object and the *arg* value passed to the handler. The *visit* function must not be called with a `NULL` object argument. If *visit* returns a non-zero value that value should be returned immediately.

To simplify writing `tp_traverse` handlers, a `Py_VISIT()`

macro is provided. In order to use this macro, the `tp_traverse` implementation must name its arguments exactly *visit* and *arg*:

```
void Py_VISIT(PyObject *o)
```

If *o* is not `NULL`, call the *visit* callback, with arguments *o* and *arg*. If *visit* returns a non-zero value, then return it. Using this macro, `tp_traverse` handlers look like:

```
static int
my_traverse(Noddy *self, visitproc visit, void *arg)
{
    Py_VISIT(self->foo);
    Py_VISIT(self->bar);
    return 0;
}
```

The `tp_clear` handler must be of the `inquiry` type, or `NULL` if the object is immutable.

```
typedef int (*inquiry)(PyObject *self)
```

*Part of the [Stable ABI](#).*

Drop references that may have created reference cycles.

Immutable objects do not have to define this method since they can never directly create reference cycles. Note that the object must still be valid after calling this method (don't just call `Py_DECREF()` on a reference). The collector will call this method if it detects that this object is involved in a reference cycle.

## Controlling the Garbage Collector State

The C-API provides the following functions for controlling garbage collection runs.

```
Py_ssize_t PyGC_Collect(void)
```

*Part of the [Stable ABI](#).*

Perform a full garbage collection, if the garbage collector is enabled. (Note that `gc.collect()` runs it unconditionally.)

Returns the number of collected + unreachable objects which cannot be collected. If the garbage collector is disabled or already collecting, returns 0 immediately. Errors during garbage collection are passed to `sys.unraisablehook`. This function does not raise exceptions.

`int PyGC_Enable(void)`

*Part of the [Stable ABI](#) since version 3.10.*

Enable the garbage collector: similar to `gc.enable()`.

Returns the previous state, 0 for disabled and 1 for enabled.

*New in version 3.10.*

`int PyGC_Disable(void)`

*Part of the [Stable ABI](#) since version 3.10.*

Disable the garbage collector: similar to `gc.disable()`.

Returns the previous state, 0 for disabled and 1 for enabled.

*New in version 3.10.*

`int PyGC_IsEnabled(void)`

*Part of the [Stable ABI](#) since version 3.10.*

Query the state of the garbage collector: similar to

`gc.isenabled()`. Returns the current state, 0 for disabled and 1 for enabled.

*New in version 3.10.*

# API and ABI Versioning

CPython exposes its version number in the following macros. Note that these correspond to the version code is **built** with, not necessarily the version used at **run time**.

See [C API Stability](#) for a discussion of API and ABI stability across versions.

PY\_MAJOR\_VERSION

The 3 in 3.4.1a2.

PY\_MINOR\_VERSION

The 4 in 3.4.1a2.

PY\_MICRO\_VERSION

The 1 in 3.4.1a2.

PY\_RELEASE\_LEVEL

The a in 3.4.1a2. This can be 0xA for alpha, 0xB for beta, 0xC for release candidate or 0xF for final.

PY\_RELEASE\_SERIAL

The 2 in 3.4.1a2. Zero for final releases.

PY\_VERSION\_HEX

The Python version number encoded in a single integer.

The underlying version information can be found by treating it as a 32 bit number in the following manner:

**Python 3.4.1a2**  
(3 4 1 a 2)

---

0x00000003 PY\_MAJOR\_VERSION

---

0x00000004 PY\_MINOR\_VERSION

---

0x00000001 PY\_MICRO\_VERSION

---

~~25-28~~ `RELEASE_LEVEL`

~~29-32~~ `RELEASE_SERIAL`

---

Thus 3.4.1a2 is hexversion 0x030401a2 and 3.10.0 is hexversion 0x030a00f0.

Use this for numeric comparisons, e.g. `#if  
PY_VERSION_HEX >= ....`

This version is also available via the symbol **Py\_Version**.

`const unsigned long Py_Version`

*Part of the [Stable ABI](#) since version 3.11.*

The Python runtime version number encoded in a single constant integer, with the same format as the [PY\\_VERSION\\_HEX](#) macro. This contains the Python version used at run time.

*New in version 3.11.*

All the given macros are defined in [Include/patchlevel.h](#) [<https://github.com/python/cpython/tree/3.11/Include/patchlevel.h>].

# Distributing Python Modules

## Email

[distutils-sig@python.org](mailto:distutils-sig@python.org)

As a popular open source development project, Python has an active supporting community of contributors and users that also make their software available for other Python developers to use under open source license terms.

This allows Python users to share and collaborate effectively, benefiting from the solutions others have already created to common (and sometimes even rare!) problems, as well as potentially contributing their own solutions to the common pool.

This guide covers the distribution part of the process. For a guide to installing other Python projects, refer to the [installation guide](#).

## Note

For corporate and other institutional users, be aware that many organisations have their own policies around using and contributing to open source software. Please take such policies into account when making use of the distribution and installation tools provided with Python.

## Key terms

- the [Python Package Index](https://pypi.org/) [https://pypi.org/] is a public repository of open source licensed packages made available for use by other Python users
- the [Python Packaging Authority](https://www.pypa.io/) [https://www.pypa.io/] are the group of developers and documentation authors responsible for the maintenance and evolution of the standard packaging tools and the associated metadata and file format standards.

They maintain a variety of tools, documentation and issue trackers on both [GitHub](https://github.com/pypa) [https://github.com/pypa] and [Bitbucket](https://bitbucket.org/pypa/) [https://bitbucket.org/pypa/].

- **distutils** is the original build and distribution system first added to the Python standard library in 1998. While direct use of **distutils** is being phased out, it still laid the foundation for the current packaging and distribution infrastructure, and it not only remains part of the standard library, but its name lives on in other ways (such as the name of the mailing list used to coordinate Python packaging standards development).
- **setuptools** [https://setuptools.readthedocs.io/en/latest/] is a (largely) drop-in replacement for **distutils** first published in 2004. Its most notable addition over the unmodified **distutils** tools was the ability to declare dependencies on other packages. It is currently recommended as a more regularly updated alternative to **distutils** that offers consistent support for more recent packaging standards across a wide range of Python versions.
- **wheel** [https://wheel.readthedocs.io/] (in this context) is a project that adds the `bdist_wheel` command to **distutils**/**setuptools** [https://setuptools.readthedocs.io/en/latest/]. This produces a cross platform binary packaging format (called “wheels” or “wheel files” and defined in **PEP 427** [https://peps.python.org/pep-0427/]) that allows Python libraries, even those including binary extensions, to be installed on a system without needing to be built locally.

## Open source licensing and collaboration

In most parts of the world, software is automatically covered by copyright. This means that other developers require explicit permission to copy, use, modify and redistribute the software.

Open source licensing is a way of explicitly granting such permission in a relatively consistent way, allowing developers to share and collaborate efficiently by making common solutions to various problems freely available. This leaves many developers free to spend more time focusing on the problems that are relatively unique to their specific situation.

The distribution tools provided with Python are designed to make it reasonably straightforward for developers to make their own contributions back to that common pool of software if they choose to do so.

The same distribution tools can also be used to distribute software within an organisation, regardless of whether that software is published as open source software or not.

## Installing the tools

The standard library does not include build tools that support modern Python packaging standards, as the core development team has found that it is important to have standard tools that work consistently, even on older versions of Python.

The currently recommended build and distribution tools can be installed by invoking the `pip` module at the command line:

```
python -m pip install setuptools wheel twine
```

### Note

For POSIX users (including macOS and Linux users), these instructions assume the use of a [virtual environment](#).

For Windows users, these instructions assume that the option to adjust the system PATH environment variable was selected when installing Python.

The Python Packaging User Guide includes more details on the [currently recommended tools](https://packaging.python.org/guides/tool-recommendations/#packaging-tool-recommendations) [https://packaging.python.org/guides/tool-recommendations/#packaging-tool-recommendations].

## Reading the Python Packaging User Guide

The Python Packaging User Guide covers the various key steps and elements involved in creating and publishing a project:

- [Project structure](https://packaging.python.org/tutorials/packaging-projects/#packaging-python-projects) [https://packaging.python.org/tutorials/packaging-projects/#packaging-python-projects]
- [Building and packaging the project](https://packaging.python.org/tutorials/packaging-projects/#creating-the-package-files) [https://packaging.python.org/tutorials/packaging-projects/#creating-the-package-files]
- [Uploading the project to the Python Package Index](https://packaging.python.org/tutorials/packaging-projects/#uploading-the-distribution-archives) [https://packaging.python.org/tutorials/packaging-projects/#uploading-the-distribution-archives]
- [The .pyprc file](https://packaging.python.org/specifications/pypirc/) [https://packaging.python.org/specifications/pypirc/]

## How do I...?

These are quick answers or links for some common tasks.

### ... choose a name for my project?

This isn't an easy topic, but here are a few tips:

- check the Python Package Index to see if the name is already in use
- check popular hosting sites like GitHub, Bitbucket, etc to see if there is already a project with that name
- check what comes up in a web search for the name you're considering
- avoid particularly common words, especially ones with multiple meanings, as they can make it difficult for users to find your software when searching for it

### ... create and distribute binary extensions?

This is actually quite a complex topic, with a variety of alternatives available depending on exactly what you're aiming to achieve. See the Python Packaging User Guide for more information and recommendations.

[Python Packaging User Guide: Binary Extensions](https://packaging.python.org/guides/packaging-binary-extensions/) [https://packaging.python.org/guides/packaging-binary-extensions/]

# Installing Python Modules

## Email

[distutils-sig@python.org](mailto:distutils-sig@python.org)

As a popular open source development project, Python has an active supporting community of contributors and users that also make their software available for other Python developers to use under open source license terms.

This allows Python users to share and collaborate effectively, benefiting from the solutions others have already created to common (and sometimes even rare!) problems, as well as potentially contributing their own solutions to the common pool.

This guide covers the installation part of the process. For a guide to creating and sharing your own Python projects, refer to the [distribution guide](#).

## Note

For corporate and other institutional users, be aware that many organisations have their own policies around using and contributing to open source software. Please take such policies into account when making use of the distribution and installation tools provided with Python.

## Key terms

- `pip` is the preferred installer program. Starting with Python 3.4, it is included by default with the Python binary installers.
- A *virtual environment* is a semi-isolated Python environment that allows packages to be installed for use by a particular application, rather than being installed system wide.
- `venv` is the standard tool for creating virtual environments,

and has been part of Python since Python 3.3. Starting with Python 3.4, it defaults to installing `pip` into all created virtual environments.

- `virtualenv` is a third party alternative (and predecessor) to `venv`. It allows virtual environments to be used on versions of Python prior to 3.4, which either don't provide `venv` at all, or aren't able to automatically install `pip` into created environments.
- The [Python Package Index](https://pypi.org/) [https://pypi.org/] is a public repository of open source licensed packages made available for use by other Python users.
- the [Python Packaging Authority](https://www.pypa.io/) [https://www.pypa.io/] is the group of developers and documentation authors responsible for the maintenance and evolution of the standard packaging tools and the associated metadata and file format standards. They maintain a variety of tools, documentation, and issue trackers on both [GitHub](https://github.com/pypa) [https://github.com/pypa] and [Bitbucket](https://bitbucket.org/pypa/) [https://bitbucket.org/pypa/].
- `distutils` is the original build and distribution system first added to the Python standard library in 1998. While direct use of `distutils` is being phased out, it still laid the foundation for the current packaging and distribution infrastructure, and it not only remains part of the standard library, but its name lives on in other ways (such as the name of the mailing list used to coordinate Python packaging standards development).

*Changed in version 3.5:* The use of `venv` is now recommended for creating virtual environments.

## See also

[Python Packaging User Guide: Creating and using virtual environments](https://packaging.python.org/installing/#creating-virtual-environments) [https://packaging.python.org/installing/#creating-virtual-environments]

## Basic usage

The standard packaging tools are all designed to be used from the

command line.

The following command will install the latest version of a module and its dependencies from the Python Package Index:

```
python -m pip install SomePackage
```

### Note

For POSIX users (including macOS and Linux users), the examples in this guide assume the use of a [virtual environment](#).

For Windows users, the examples in this guide assume that the option to adjust the system PATH environment variable was selected when installing Python.

It's also possible to specify an exact or minimum version directly on the command line. When using comparator operators such as `>`, `<` or some other special character which get interpreted by shell, the package name and the version should be enclosed within double quotes:

```
python -m pip install SomePackage==1.0.4      # specific version
python -m pip install "SomePackage>=1.0.4"    # minimum version
```

Normally, if a suitable module is already installed, attempting to install it again will have no effect. Upgrading existing modules must be requested explicitly:

```
python -m pip install --upgrade SomePackage
```

More information and resources regarding `pip` and its capabilities can be found in the [Python Packaging User Guide](https://packaging.python.org/) [https://packaging.python.org/].

Creation of virtual environments is done through the [venv](#) module. Installing packages into an active virtual environment uses the commands shown above.

### See also

## How do I ...?

These are quick answers or links for some common tasks.

### **... install `pip` in versions of Python prior to Python 3.4?**

Python only started bundling `pip` with Python 3.4. For earlier versions, `pip` needs to be “bootstrapped” as described in the Python Packaging User Guide.

#### **See also**

[Python Packaging User Guide: Requirements for Installing Packages](https://packaging.python.org/installing/#requirements-for-installing-packages) [https://packaging.python.org/installing/#requirements-for-installing-packages]

### **... install packages just for the current user?**

Passing the `--user` option to `python -m pip install` will install a package just for the current user, rather than for all users of the system.

### **... install scientific Python packages?**

A number of scientific Python packages have complex binary dependencies, and aren’t currently easy to install using `pip` directly. At this point in time, it will often be easier for users to install these packages by [other means](https://packaging.python.org/science/) [https://packaging.python.org/science/] rather than attempting to install them with `pip`.

#### **See also**

[Python Packaging User Guide: Installing Scientific Packages](https://packaging.python.org/science/) [https://packaging.python.org/science/]

## ... work with multiple versions of Python installed in parallel?

On Linux, macOS, and other POSIX systems, use the versioned Python commands in combination with the `-m` switch to run the appropriate copy of `pip`:

```
python2      -m pip install SomePackage # default Python 2
python2.7    -m pip install SomePackage # specifically Python 2.7
python3      -m pip install SomePackage # default Python 3
python3.4    -m pip install SomePackage # specifically Python 3.4
```

Appropriately versioned `pip` commands may also be available.

On Windows, use the `py` Python launcher in combination with the `-m` switch:

```
py -2      -m pip install SomePackage # default Python 2
py -2.7    -m pip install SomePackage # specifically Python 2.7
py -3      -m pip install SomePackage # default Python 3
py -3.4    -m pip install SomePackage # specifically Python 3.4
```

## Common installation issues

### Installing into the system Python on Linux

On Linux systems, a Python installation will typically be included as part of the distribution. Installing into this Python installation requires root access to the system, and may interfere with the operation of the system package manager and other components of the system if a component is unexpectedly upgraded using `pip`.

On such systems, it is often better to use a virtual environment or a per-user installation when installing packages with `pip`.

### Pip not installed

It is possible that `pip` does not get installed by default. One potential fix is:

```
python -m ensurepip --default-pip
```

There are also additional resources for [installing pip](https://packaging.python.org/en/latest/tutorials/installing-packages/#ensure-pip-setuptools-and-wheel-are-up-to-date). [https://packaging.python.org/en/latest/tutorials/installing-packages/#ensure-pip-setuptools-and-wheel-are-up-to-date]

## Installing binary extensions

Python has typically relied heavily on source based distribution, with end users being expected to compile extension modules from source as part of the installation process.

With the introduction of support for the binary `wheel` format, and the ability to publish wheels for at least Windows and macOS through the Python Package Index, this problem is expected to diminish over time, as users are more regularly able to install pre-built extensions rather than needing to build them themselves.

Some of the solutions for installing [scientific software](https://packaging.python.org/science/) [https://packaging.python.org/science/] that are not yet available as pre-built `wheel` files may also help with obtaining other binary extensions without needing to build them locally.

# Python HOWTOs

Python HOWTOs are documents that cover a single, specific topic, and attempt to cover it fairly completely. Modelled on the Linux Documentation Project's HOWTO collection, this collection is an effort to foster documentation that's more detailed than the Python Library Reference.

Currently, the HOWTOs are:

- [Porting Python 2 Code to Python 3](#)
- [Porting Extension Modules to Python 3](#)
- [Curses Programming with Python](#)
- [Descriptor HowTo Guide](#)
- [Enum HOWTO](#)
- [Functional Programming HOWTO](#)
- [Logging HOWTO](#)
- [Logging Cookbook](#)
- [Regular Expression HOWTO](#)
- [Socket Programming HOWTO](#)
- [Sorting HOW TO](#)
- [Unicode HOWTO](#)
- [HOWTO Fetch Internet Resources Using The urllib Package](#)
- [Argparse Tutorial](#)
- [An introduction to the ipaddress module](#)
- [Argument Clinic How-To](#)
- [Instrumenting CPython with DTrace and SystemTap](#)
- [Annotations Best Practices](#)
- [Isolating Extension Modules](#)

# Porting Python 2 Code to Python 3

author

Brett Cannon

## Abstract

With Python 3 being the future of Python while Python 2 is still in active use, it is good to have your project available for both major releases of Python. This guide is meant to help you figure out how best to support both Python 2 & 3 simultaneously.

If you are looking to port an extension module instead of pure Python code, please see [Porting Extension Modules to Python 3](#).

If you would like to read one core Python developer's take on why Python 3 came into existence, you can read Nick Coghlan's [Python 3 Q & A](https://ncoghlan-devs-python-notes.readthedocs.io/en/latest/python3/questions_and_answers.html) [https://ncoghlan-devs-python-notes.readthedocs.io/en/latest/python3/questions\_and\_answers.html] or Brett Cannon's [Why Python 3 exists](https://snarky.ca/why-python-3-exists) [https://snarky.ca/why-python-3-exists].

For help with porting, you can view the archived [python-porting](https://mail.python.org/pipermail/python-porting/) [https://mail.python.org/pipermail/python-porting/] mailing list.

## The Short Explanation

To make your project be single-source Python 2/3 compatible, the basic steps are:

1. Only worry about supporting Python 2.7
2. Make sure you have good test coverage ([coverage.py](https://pypi.org/project/coverage) [https://pypi.org/project/coverage] can help; `python -m pip install coverage`)

3. Learn the differences between Python 2 & 3
4. Use [Futurize](https://python-future.org/automatic_conversion.html) [https://python-future.org/automatic\_conversion.html] (or [Modernize](https://python-modernize.readthedocs.io/) [https://python-modernize.readthedocs.io/]) to update your code (e.g. `python -m pip install future`)
5. Use [Pylint](https://pypi.org/project/pylint) [https://pypi.org/project/pylint] to help make sure you don't regress on your Python 3 support (`python -m pip install pylint`)
6. Use [caniusepython3](https://pypi.org/project/caniusepython3) [https://pypi.org/project/caniusepython3] to find out which of your dependencies are blocking your use of Python 3 (`python -m pip install caniusepython3`)
7. Once your dependencies are no longer blocking you, use continuous integration to make sure you stay compatible with Python 2 & 3 ([tox](https://pypi.org/project/tox) [https://pypi.org/project/tox] can help test against multiple versions of Python; `python -m pip install tox`)
8. Consider using optional static type checking to make sure your type usage works in both Python 2 & 3 (e.g. use [mypy](https://mypy-lang.org/) [https://mypy-lang.org/] to check your typing under both Python 2 & Python 3; `python -m pip install mypy`).

## Note

Note: Using `python -m pip install` guarantees that the `pip` you invoke is the one installed for the Python currently in use, whether it be a system-wide `pip` or one installed within a [virtual environment](#).

## Details

A key point about supporting Python 2 & 3 simultaneously is that you can start **today**! Even if your dependencies are not supporting Python 3 yet that does not mean you can't modernize your code **now** to support Python 3. Most changes required to support Python 3 lead to cleaner code using newer practices even in Python 2 code.

Another key point is that modernizing your Python 2 code to also support Python 3 is largely automated for you. While you might have to make some API decisions thanks to Python 3 clarifying text data versus binary data, the lower-level work is now mostly done

for you and thus can at least benefit from the automated changes immediately.

Keep those key points in mind while you read on about the details of porting your code to support Python 2 & 3 simultaneously.

## Drop support for Python 2.6 and older

While you can make Python 2.5 work with Python 3, it is **much** easier if you only have to work with Python 2.7. If dropping Python 2.5 is not an option then the [six](https://pypi.org/project/six) [https://pypi.org/project/six] project can help you support Python 2.5 & 3 simultaneously (`python -m pip install six`). Do realize, though, that nearly all the projects listed in this HOWTO will not be available to you.

If you are able to skip Python 2.5 and older, then the required changes to your code should continue to look and feel like idiomatic Python code. At worst you will have to use a function instead of a method in some instances or have to import a function instead of using a built-in one, but otherwise the overall transformation should not feel foreign to you.

But you should aim for only supporting Python 2.7. Python 2.6 is no longer freely supported and thus is not receiving bugfixes. This means **you** will have to work around any issues you come across with Python 2.6. There are also some tools mentioned in this HOWTO which do not support Python 2.6 (e.g., [Pylint](https://pypi.org/project/pylint) [https://pypi.org/project/pylint]), and this will become more commonplace as time goes on. It will simply be easier for you if you only support the versions of Python that you have to support.

## Make sure you specify the proper version support in your `setup.py` file

In your `setup.py` file you should have the proper [trove classifier](https://pypi.org/classifiers) [https://pypi.org/classifiers] specifying what versions of Python you support. As your project does not support Python 3 yet you should at least have `Programming Language :: Python :: 2 :: Only` specified. Ideally you should also specify each major/minor version of Python that you do support, e.g. `Programming`

Language :: Python :: 2.7.

## Have good test coverage

Once you have your code supporting the oldest version of Python 2 you want it to, you will want to make sure your test suite has good coverage. A good rule of thumb is that if you want to be confident enough in your test suite that any failures that appear after having tools rewrite your code are actual bugs in the tools and not in your code. If you want a number to aim for, try to get over 80% coverage (and don't feel bad if you find it hard to get better than 90% coverage). If you don't already have a tool to measure test coverage then [coverage.py](https://pypi.org/project/coverage) [https://pypi.org/project/coverage] is recommended.

## Learn the differences between Python 2 & 3

Once you have your code well-tested you are ready to begin porting your code to Python 3! But to fully understand how your code is going to change and what you want to look out for while you code, you will want to learn what changes Python 3 makes in terms of Python 2. Typically the two best ways of doing that is reading the “What's New” doc for each release of Python 3 and the [Porting to Python 3](http://python3porting.com/) [http://python3porting.com/] book (which is free online). There is also a handy [cheat sheet](https://python-future.org/compatible_idioms.html) [https://python-future.org/compatible\_idioms.html] from the Python-Future project.

## Update your code

Once you feel like you know what is different in Python 3 compared to Python 2, it's time to update your code! You have a choice between two tools in porting your code automatically: [Futurize](https://python-future.org/automatic_conversion.html) [https://python-future.org/automatic\_conversion.html] and [Modernize](https://python-modernize.readthedocs.io/) [https://python-modernize.readthedocs.io/]. Which tool you choose will depend on how much like Python 3 you want your code to be. [Futurize](https://python-future.org/automatic_conversion.html) [https://python-future.org/automatic\_conversion.html] does its best to make Python 3 idioms and practices exist in Python 2, e.g. backporting the bytes type from Python 3 so that you have semantic parity between the major versions of Python. [Modernize](https://python-modernize.readthedocs.io/) [https://python-modernize.readthedocs.io/], on the other hand, is more conservative and targets a Python 2/3 subset of Python, directly relying on [six](#)

[<https://pypi.org/project/six>] to help provide compatibility. As Python 3 is the future, it might be best to consider Futurize to begin adjusting to any new practices that Python 3 introduces which you are not accustomed to yet.

Regardless of which tool you choose, they will update your code to run under Python 3 while staying compatible with the version of Python 2 you started with. Depending on how conservative you want to be, you may want to run the tool over your test suite first and visually inspect the diff to make sure the transformation is accurate. After you have transformed your test suite and verified that all the tests still pass as expected, then you can transform your application code knowing that any tests which fail is a translation failure.

Unfortunately the tools can't automate everything to make your code work under Python 3 and so there are a handful of things you will need to update manually to get full Python 3 support (which of these steps are necessary vary between the tools). Read the documentation for the tool you choose to use to see what it fixes by default and what it can do optionally to know what will (not) be fixed for you and what you may have to fix on your own (e.g. using `io.open()` over the built-in `open()` function is off by default in Modernize). Luckily, though, there are only a couple of things to watch out for which can be considered large issues that may be hard to debug if not watched for.

## Division

In Python 3, `5 / 2 == 2.5` and not `2`; all division between `int` values result in a `float`. This change has actually been planned since Python 2.2 which was released in 2002. Since then users have been encouraged to add `from __future__ import division` to any and all files which use the `/` and `//` operators or to be running the interpreter with the `-Q` flag. If you have not been doing this then you will need to go through your code and do two things:

1. Add `from __future__ import division` to your files
2. Update any division operator as necessary to either use `//` to

use floor division or continue using `/` and expect a float

The reason that `/` isn't simply translated to `//` automatically is that if an object defines a `__truediv__` method but not `__floordiv__` then your code would begin to fail (e.g. a user-defined class that uses `/` to signify some operation but not `//` for the same thing or at all).

## Text versus binary data

In Python 2 you could use the `str` type for both text and binary data. Unfortunately this confluence of two different concepts could lead to brittle code which sometimes worked for either kind of data, sometimes not. It also could lead to confusing APIs if people didn't explicitly state that something that accepted `str` accepted either text or binary data instead of one specific type. This complicated the situation especially for anyone supporting multiple languages as APIs wouldn't bother explicitly supporting `unicode` when they claimed text data support.

To make the distinction between text and binary data clearer and more pronounced, Python 3 did what most languages created in the age of the internet have done and made text and binary data distinct types that cannot blindly be mixed together (Python predates widespread access to the internet). For any code that deals only with text or only binary data, this separation doesn't pose an issue. But for code that has to deal with both, it does mean you might have to now care about when you are using text compared to binary data, which is why this cannot be entirely automated.

To start, you will need to decide which APIs take text and which take binary (it is **highly** recommended you don't design APIs that can take both due to the difficulty of keeping the code working; as stated earlier it is difficult to do well). In Python 2 this means making sure the APIs that take text can work with `unicode` and those that work with binary data work with the `bytes` type from Python 3 (which is a subset of `str` in Python 2 and acts as an alias for `bytes` type in Python 2). Usually the biggest issue is realizing which methods exist on which types in Python 2 & 3 simultaneously (for text that's `unicode` in Python 2 and `str` in Python 3, for

binary that's `str/bytes` in Python 2 and `bytes` in Python 3). The following table lists the **unique** methods of each data type across Python 2 & 3 (e.g., the `decode()` method is usable on the equivalent binary data type in either Python 2 or 3, but it can't be used by the textual data type consistently between Python 2 and 3 because `str` in Python 3 doesn't have the method). Do note that as of Python 3.5 the `__mod__` method was added to the `bytes` type.

### **Binary data**

<code>decode</code>	
<code>encode</code>	
<code>format</code>	
<code>isdecimal</code>	
<code>isnumeric</code>	

Making the distinction easier to handle can be accomplished by encoding and decoding between binary data and text at the edge of your code. This means that when you receive text in binary data, you should immediately decode it. And if your code needs to send text as binary data then encode it as late as possible. This allows your code to work with only text internally and thus eliminates having to keep track of what type of data you are working with.

The next issue is making sure you know whether the string literals in your code represent text or binary data. You should add a `b` prefix to any literal that presents binary data. For text you should add a `u` prefix to the text literal. (there is a `__future__` import to force all unspecified literals to be Unicode, but usage has shown it isn't as effective as adding a `b` or `u` prefix to all literals explicitly)

As part of this dichotomy you also need to be careful about opening files. Unless you have been working on Windows, there is a chance you have not always bothered to add the `b` mode when opening a binary file (e.g., `rb` for binary reading). Under Python 3, binary files and text files are clearly distinct and mutually incompatible; see the `io` module for details. Therefore, you **must** make a decision of whether a file will be used for binary access (allowing binary data to be read and/or written) or textual access (allowing text data to be read and/or written). You should also use `io.open()` for opening files instead of the built-in `open()` function as the `io`

module is consistent from Python 2 to 3 while the built-in `open()` function is not (in Python 3 it's actually `io.open()`). Do not bother with the outdated practice of using `codecs.open()` as that's only necessary for keeping compatibility with Python 2.5.

The constructors of both `str` and `bytes` have different semantics for the same arguments between Python 2 & 3. Passing an integer to `bytes` in Python 2 will give you the string representation of the integer: `bytes(3) == '3'`. But in Python 3, an integer argument to `bytes` will give you a bytes object as long as the integer specified, filled with null bytes: `bytes(3) == b'\x00\x00\x00'`. A similar worry is necessary when passing a bytes object to `str`. In Python 2 you just get the bytes object back: `str(b'3') == b'3'`. But in Python 3 you get the string representation of the bytes object: `str(b'3') == "b'3'"`.

Finally, the indexing of binary data requires careful handling (slicing does **not** require any special handling). In Python 2, `b'123'[1] == b'2'` while in Python 3 `b'123'[1] == 50`. Because binary data is simply a collection of binary numbers, Python 3 returns the integer value for the byte you index on. But in Python 2 because `bytes == str`, indexing returns a one-item slice of bytes. The [six](https://pypi.org/project/six) [https://pypi.org/project/six] project has a function named `six.indexbytes()` which will return an integer like in Python 3: `six.indexbytes(b'123', 1)`.

To summarize:

1. Decide which of your APIs take text and which take binary data
2. Make sure that your code that works with text also works with `unicode` and code for binary data works with `bytes` in Python 2 (see the table above for what methods you cannot use for each type)
3. Mark all binary literals with a `b` prefix, textual literals with a `u` prefix
4. Decode binary data to text as soon as possible, encode text as binary data as late as possible
5. Open files using `io.open()` and make sure to specify the `b` mode when appropriate
6. Be careful when indexing into binary data

## Use feature detection instead of version detection

Inevitably you will have code that has to choose what to do based on what version of Python is running. The best way to do this is with feature detection of whether the version of Python you're running under supports what you need. If for some reason that doesn't work then you should make the version check be against Python 2 and not Python 3. To help explain this, let's look at an example.

Let's pretend that you need access to a feature of `importlib` that is available in Python's standard library since Python 3.3 and available for Python 2 through `importlib2` [<https://pypi.org/project/importlib2>] on PyPI. You might be tempted to write code to access e.g. the `importlib.abc` module by doing the following:

```
import sys

if sys.version_info[0] == 3:
    from importlib import abc
else:
    from importlib2 import abc
```

The problem with this code is what happens when Python 4 comes out? It would be better to treat Python 2 as the exceptional case instead of Python 3 and assume that future Python versions will be more compatible with Python 3 than Python 2:

```
import sys

if sys.version_info[0] > 2:
    from importlib import abc
else:
    from importlib2 import abc
```

The best solution, though, is to do no version detection at all and instead rely on feature detection. That avoids any potential issues of getting the version detection wrong and helps keep you future-compatible:

```
try:
    from importlib import abc
except ImportError:
    from importlib2 import abc
```

## Prevent compatibility regressions

Once you have fully translated your code to be compatible with Python 3, you will want to make sure your code doesn't regress and stop working under Python 3. This is especially true if you have a dependency which is blocking you from actually running under Python 3 at the moment.

To help with staying compatible, any new modules you create should have at least the following block of code at the top of it:

```
from __future__ import absolute_import
from __future__ import division
from __future__ import print_function
```

You can also run Python 2 with the `-3` flag to be warned about various compatibility issues your code triggers during execution. If you turn warnings into errors with `-Werror` then you can make sure that you don't accidentally miss a warning.

You can also use the [Pylint](https://pypi.org/project/pylint) [https://pypi.org/project/pylint] project and its `--py3k` flag to lint your code to receive warnings when your code begins to deviate from Python 3 compatibility. This also prevents you from having to run [Modernize](https://python-modernize.readthedocs.io/) [https://python-modernize.readthedocs.io/] Or [Futurize](https://python-future.org/automatic_conversion.html) [https://python-future.org/automatic\_conversion.html] over your code regularly to catch compatibility regressions. This does require you only support Python 2.7 and Python 3.4 or newer as that is Pylint's minimum Python version support.

## Check which dependencies block your transition

**After** you have made your code compatible with Python 3 you should begin to care about whether your dependencies have also been ported. The [caniusepython3](https://pypi.org/project/caniusepython3) [https://pypi.org/project/caniusepython3]

project was created to help you determine which projects – directly or indirectly – are blocking you from supporting Python 3. There is both a command-line tool as well as a web interface at <https://caniusepython3.com>.

The project also provides code which you can integrate into your test suite so that you will have a failing test when you no longer have dependencies blocking you from using Python 3. This allows you to avoid having to manually check your dependencies and to be notified quickly when you can start running on Python 3.

## Update your `setup.py` file to denote Python 3 compatibility

Once your code works under Python 3, you should update the classifiers in your `setup.py` to contain `Programming Language :: Python :: 3` and to not specify sole Python 2 support. This will tell anyone using your code that you support Python 2 and 3. Ideally you will also want to add classifiers for each major/minor version of Python you now support.

## Use continuous integration to stay compatible

Once you are able to fully run under Python 3 you will want to make sure your code always works under both Python 2 & 3. Probably the best tool for running your tests under multiple Python interpreters is [tox](https://pypi.org/project/tox) [https://pypi.org/project/tox]. You can then integrate tox with your continuous integration system so that you never accidentally break Python 2 or 3 support.

You may also want to use the `-bb` flag with the Python 3 interpreter to trigger an exception when you are comparing bytes to strings or bytes to an int (the latter is available starting in Python 3.5). By default type-differing comparisons simply return `False`, but if you made a mistake in your separation of text/binary data handling or indexing on bytes you wouldn't easily find the mistake. This flag will raise an exception when these kinds of comparisons occur, making the mistake much easier to track down.

And that's mostly it! At this point your code base is compatible with

both Python 2 and 3 simultaneously. Your testing will also be set up so that you don't accidentally break Python 2 or 3 compatibility regardless of which version you typically run your tests under while developing.

## **Consider using optional static type checking**

Another way to help port your code is to use a static type checker like [mypy](https://mypy-lang.org/) [https://mypy-lang.org/] or [pytype](https://github.com/google/pytype) [https://github.com/google/pytype] on your code. These tools can be used to analyze your code as if it's being run under Python 2, then you can run the tool a second time as if your code is running under Python 3. By running a static type checker twice like this you can discover if you're e.g. misusing binary data type in one version of Python compared to another. If you add optional type hints to your code you can also explicitly state whether your APIs use textual or binary data, helping to make sure everything functions as expected in both versions of Python.

# Porting Extension Modules to Python 3

We recommend the following resources for porting extension modules to Python 3:

- The [Migrating C extensions](http://python3porting.com/cextensions.html) [http://python3porting.com/cextensions.html] chapter from *Supporting Python 3: An in-depth guide*, a book on moving from Python 2 to Python 3 in general, guides the reader through porting an extension module.
- The [Porting guide](https://py3c.readthedocs.io/en/latest/guide.html) [https://py3c.readthedocs.io/en/latest/guide.html] from the *py3c* project provides opinionated suggestions with supporting code.
- The [Cython](https://cython.org/) [https://cython.org/] and [CFFI](https://cffi.readthedocs.io/en/latest/) [https://cffi.readthedocs.io/en/latest/] libraries offer abstractions over Python's C API. Extensions generally need to be re-written to use one of them, but the library then handles differences between various Python versions and implementations.

# Curses Programming with Python

**Author**

A.M. Kuchling, Eric S. Raymond

**Release**

2.04

## Abstract

This document describes how to use the `curses` extension module to control text-mode displays.

## What is curses?

The curses library supplies a terminal-independent screen-painting and keyboard-handling facility for text-based terminals; such terminals include VT100s, the Linux console, and the simulated terminal provided by various programs. Display terminals support various control codes to perform common operations such as moving the cursor, scrolling the screen, and erasing areas. Different terminals use widely differing codes, and often have their own minor quirks.

In a world of graphical displays, one might ask “why bother”? It’s true that character-cell display terminals are an obsolete technology, but there are niches in which being able to do fancy things with them are still valuable. One niche is on small-footprint or embedded Unixes that don’t run an X server. Another is tools such as OS installers and kernel configurators that may have to run before any graphical support is available.

The curses library provides fairly basic functionality, providing the programmer with an abstraction of a display containing multiple

non-overlapping windows of text. The contents of a window can be changed in various ways—adding text, erasing it, changing its appearance—and the curses library will figure out what control codes need to be sent to the terminal to produce the right output. curses doesn't provide many user-interface concepts such as buttons, checkboxes, or dialogs; if you need such features, consider a user interface library such as [Urwid](https://pypi.org/project/urwid/) [https://pypi.org/project/urwid/].

The curses library was originally written for BSD Unix; the later System V versions of Unix from AT&T added many enhancements and new functions. BSD curses is no longer maintained, having been replaced by ncurses, which is an open-source implementation of the AT&T interface. If you're using an open-source Unix such as Linux or FreeBSD, your system almost certainly uses ncurses. Since most current commercial Unix versions are based on System V code, all the functions described here will probably be available. The older versions of curses carried by some proprietary Unixes may not support everything, though.

The Windows version of Python doesn't include the `curses` module. A ported version called [UniCurses](https://pypi.org/project/UniCurses) [https://pypi.org/project/UniCurses] is available.

## The Python curses module

The Python module is a fairly simple wrapper over the C functions provided by curses; if you're already familiar with curses programming in C, it's really easy to transfer that knowledge to Python. The biggest difference is that the Python interface makes things simpler by merging different C functions such as `addstr()`, `mvaddstr()`, and `mvwaddstr()` into a single `addstr()` method. You'll see this covered in more detail later.

This HOWTO is an introduction to writing text-mode programs with curses and Python. It doesn't attempt to be a complete guide to the curses API; for that, see the Python library guide's section on ncurses, and the C manual pages for ncurses. It will, however, give you the basic ideas.

## Starting and ending a curses application

Before doing anything, curses must be initialized. This is done by calling the `initscr()` function, which will determine the terminal type, send any required setup codes to the terminal, and create various internal data structures. If successful, `initscr()` returns a window object representing the entire screen; this is usually called `stdscr` after the name of the corresponding C variable.

```
import curses
stdscr = curses.initscr()
```

Usually curses applications turn off automatic echoing of keys to the screen, in order to be able to read keys and only display them under certain circumstances. This requires calling the `noecho()` function.

```
curses.noecho()
```

Applications will also commonly need to react to keys instantly, without requiring the Enter key to be pressed; this is called cbreak mode, as opposed to the usual buffered input mode.

```
curses.cbreak()
```

Terminals usually return special keys, such as the cursor keys or navigation keys such as Page Up and Home, as a multibyte escape sequence. While you could write your application to expect such sequences and process them accordingly, curses can do it for you, returning a special value such as `curses.KEY_LEFT`. To get curses to do the job, you'll have to enable keypad mode.

```
stdscr.keypad(True)
```

Terminating a curses application is much easier than starting one. You'll need to call:

```
curses.nocbreak()
stdscr.keypad(False)
curses.echo()
```

to reverse the curses-friendly terminal settings. Then call the

`endwin()` function to restore the terminal to its original operating mode.

```
curses.endwin()
```

A common problem when debugging a curses application is to get your terminal messed up when the application dies without restoring the terminal to its previous state. In Python this commonly happens when your code is buggy and raises an uncaught exception. Keys are no longer echoed to the screen when you type them, for example, which makes using the shell difficult.

In Python you can avoid these complications and make debugging much easier by importing the `curses.wrapper()` function and using it like this:

```
from curses import wrapper

def main(stdscr):
    # Clear screen
    stdscr.clear()

    # This raises ZeroDivisionError when i == 10.
    for i in range(0, 11):
        v = i-10
        stdscr.addstr(i, 0, '10 divided by {} is {}'.format(i, v))

    stdscr.refresh()
    stdscr.getkey()

wrapper(main)
```

The `wrapper()` function takes a callable object and does the initializations described above, also initializing colors if color support is present. `wrapper()` then runs your provided callable. Once the callable returns, `wrapper()` will restore the original state of the terminal. The callable is called inside a `try...except` that catches exceptions, restores the state of the terminal, and then re-raises the exception. Therefore your terminal won't be left in a funny state on exception and you'll be able to read the exception's

message and traceback.

## Windows and Pads

Windows are the basic abstraction in curses. A window object represents a rectangular area of the screen, and supports methods to display text, erase it, allow the user to input strings, and so forth.

The `stdscr` object returned by the `initscr()` function is a window object that covers the entire screen. Many programs may need only this single window, but you might wish to divide the screen into smaller windows, in order to redraw or clear them separately. The `newwin()` function creates a new window of a given size, returning the new window object.

```
begin_x = 20; begin_y = 7
height = 5; width = 40
win = curses.newwin(height, width, begin_y, begin_x)
```

Note that the coordinate system used in curses is unusual. Coordinates are always passed in the order *y,x*, and the top-left corner of a window is coordinate (0,0). This breaks the normal convention for handling coordinates where the *x* coordinate comes first. This is an unfortunate difference from most other computer applications, but it's been part of curses since it was first written, and it's too late to change things now.

Your application can determine the size of the screen by using the **`curses.LINES`** and **`curses.COLS`** variables to obtain the *y* and *x* sizes. Legal coordinates will then extend from (0,0) to (`curses.LINES - 1`, `curses.COLS - 1`).

When you call a method to display or erase text, the effect doesn't immediately show up on the display. Instead you must call the **`refresh()`** method of window objects to update the screen.

This is because curses was originally written with slow 300-baud terminal connections in mind; with these terminals, minimizing the time required to redraw the screen was very important. Instead curses accumulates changes to the screen and displays them in the

most efficient manner when you call **refresh()**. For example, if your program displays some text in a window and then clears the window, there's no need to send the original text because they're never visible.

In practice, explicitly telling curses to redraw a window doesn't really complicate programming with curses much. Most programs go into a flurry of activity, and then pause waiting for a keypress or some other action on the part of the user. All you have to do is to be sure that the screen has been redrawn before pausing to wait for user input, by first calling **stdscr.refresh()** or the **refresh()** method of some other relevant window.

A pad is a special case of a window; it can be larger than the actual display screen, and only a portion of the pad displayed at a time. Creating a pad requires the pad's height and width, while refreshing a pad requires giving the coordinates of the on-screen area where a subsection of the pad will be displayed.

```
pad = curses.newpad(100, 100)
# These loops fill the pad with letters; addch() is
# explained in the next section
for y in range(0, 99):
    for x in range(0, 99):
        pad.addch(y,x, ord('a') + (x*x+y*y) % 26)

# Displays a section of the pad in the middle of the screen
# (0,0) : coordinate of upper-left corner of pad area to be
# (5,5) : coordinate of upper-left corner of window area to
#         with pad content.
# (20, 75) : coordinate of lower-right corner of window area
#           : filled with pad content.
pad.refresh( 0,0, 5,5, 20,75)
```

The **refresh()** call displays a section of the pad in the rectangle extending from coordinate (5,5) to coordinate (20,75) on the screen; the upper left corner of the displayed section is coordinate (0,0) on the pad. Beyond that difference, pads are exactly like ordinary windows and support the same methods.

If you have multiple windows and pads on screen there is a more efficient way to update the screen and prevent annoying screen flicker as each part of the screen gets updated. **refresh()** actually does two things:

1. Calls the **noutrefresh()** method of each window to update an underlying data structure representing the desired state of the screen.
2. Calls the function **doupdate()** function to change the physical screen to match the desired state recorded in the data structure.

Instead you can call **noutrefresh()** on a number of windows to update the data structure, and then call **doupdate()** to update the screen.

## Displaying Text

From a C programmer's point of view, curses may sometimes look like a twisty maze of functions, all subtly different. For example, **addstr()** displays a string at the current cursor location in the `stdscr` window, while **mvaddstr()** moves to a given y,x coordinate first before displaying the string. **waddstr()** is just like **addstr()**, but allows specifying a window to use instead of using `stdscr` by default. **mvwaddstr()** allows specifying both a window and a coordinate.

Fortunately the Python interface hides all these details. `stdscr` is a window object like any other, and methods such as **addstr()** accept multiple argument forms. Usually there are four different forms.

### Description

---

**Display** the string *str* or character *ch* at the current position

---

**Display** the string *str* or character *ch*, using attribute *attr* at the current position

---

**Move to position** y,x within the window, and display *str* or *ch*

---

**Move to position** y,x within the window, and display *str* or *ch*, using attribute *attr*

---

Attributes allow displaying text in highlighted forms such as boldface, underline, reverse code, or in color. They'll be explained in more detail in the next subsection.

The `addstr()` method takes a Python string or bytestring as the value to be displayed. The contents of bytestrings are sent to the terminal as-is. Strings are encoded to bytes using the value of the window's `encoding` attribute; this defaults to the default system encoding as returned by `locale.getencoding()`.

The `addch()` methods take a character, which can be either a string of length 1, a bytestring of length 1, or an integer.

Constants are provided for extension characters; these constants are integers greater than 255. For example, `ACS_PLMINUS` is a `+/-` symbol, and `ACS_ULCORNER` is the upper left corner of a box (handy for drawing borders). You can also use the appropriate Unicode character.

Windows remember where the cursor was left after the last operation, so if you leave out the `y,x` coordinates, the string or character will be displayed wherever the last operation left off. You can also move the cursor with the `move(y, x)` method. Because some terminals always display a flashing cursor, you may want to ensure that the cursor is positioned in some location where it won't be distracting; it can be confusing to have the cursor blinking at some apparently random location.

If your application doesn't need a blinking cursor at all, you can call `curs_set(False)` to make it invisible. For compatibility with older curses versions, there's a `leaveok(bool)` function that's a synonym for `curs_set()`. When `bool` is true, the curses library will attempt to suppress the flashing cursor, and you won't need to worry about leaving it in odd locations.

## Attributes and Color

Characters can be displayed in different ways. Status lines in a text-based application are commonly shown in reverse video, or a text viewer may need to highlight certain words. curses supports this by allowing you to specify an attribute for each cell on the screen.

An attribute is an integer, each bit representing a different attribute. You can try to display text with multiple attribute bits set, but curses doesn't guarantee that all the possible combinations are available, or that they're all visually distinct. That depends on the ability of the terminal being used, so it's safest to stick to the most commonly available attributes, listed here.

Description
<u>Blinking</u> text
<u>Extra bright</u> or bold text
<u>Half bright</u> text
<u>Reverse video</u> text
<u>The best</u> highlighting mode available
<u>Underlined</u> text

So, to display a reverse-video status line on the top line of the screen, you could code:

```
stdscr.addstr(0, 0, "Current mode: Typing mode",
               curses.A_REVERSE)
stdscr.refresh()
```

The curses library also supports color on those terminals that provide it. The most common such terminal is probably the Linux console, followed by color xterms.

To use color, you must call the `start_color()` function soon after calling `initscr()`, to initialize the default color set (the `curses.wrapper()` function does this automatically). Once that's done, the `has_colors()` function returns TRUE if the terminal in use can actually display color. (Note: curses uses the American spelling 'color', instead of the Canadian/British spelling 'colour'. If you're used to the British spelling, you'll have to resign yourself to misspelling it for the sake of these functions.)

The curses library maintains a finite number of color pairs, containing a foreground (or text) color and a background color. You can get the attribute value corresponding to a color pair with the `color_pair()` function; this can be bitwise-OR'ed with other attributes such as `A_REVERSE`, but again, such combinations are not guaranteed to work on all terminals.

An example, which displays a line of text using color pair 1:

```
stdscr.addstr("Pretty text", curses.color_pair(1))
stdscr.refresh()
```

As I said before, a color pair consists of a foreground and background color. The `init_pair(n, f, b)` function changes the definition of color pair *n*, to foreground color *f* and background color *b*. Color pair 0 is hard-wired to white on black, and cannot be changed.

Colors are numbered, and `start_color()` initializes 8 basic colors when it activates color mode. They are: 0:black, 1:red, 2:green, 3:yellow, 4:blue, 5:magenta, 6:cyan, and 7:white. The `curses` module defines named constants for each of these colors: `curses.COLOR_BLACK`, `curses.COLOR_RED`, and so forth.

Let's put all this together. To change color 1 to red text on a white background, you would call:

```
curses.init_pair(1, curses.COLOR_RED, curses.COLOR_WHITE)
```

When you change a color pair, any text already displayed using that color pair will change to the new colors. You can also display new text in this color with:

```
stdscr.addstr(0,0, "RED ALERT!", curses.color_pair(1))
```

Very fancy terminals can change the definitions of the actual colors to a given RGB value. This lets you change color 1, which is usually red, to purple or blue or any other color you like. Unfortunately, the Linux console doesn't support this, so I'm unable to try it out, and can't provide any examples. You can check if your terminal can do this by calling `can_change_color()`, which returns `True` if the capability is there. If you're lucky enough to have such a talented terminal, consult your system's man pages for more information.

## User Input

The C `curses` library offers only very simple input mechanisms.

Python's **curses** module adds a basic text-input widget. (Other libraries such as **Urwid** [<https://pypi.org/project/urwid/>] have more extensive collections of widgets.)

There are two methods for getting input from a window:

- **getch()** refreshes the screen and then waits for the user to hit a key, displaying the key if **echo()** has been called earlier. You can optionally specify a coordinate to which the cursor should be moved before pausing.
- **getkey()** does the same thing but converts the integer to a string. Individual characters are returned as 1-character strings, and special keys such as function keys return longer strings containing a key name such as `KEY_UP` or `^G`.

It's possible to not wait for the user using the **nodelay()** window method. After `nodelay(True)`, **getch()** and **getkey()** for the window become non-blocking. To signal that no input is ready, **getch()** returns `curses.ERR` (a value of -1) and **getkey()** raises an exception. There's also a **halfdelay()** function, which can be used to (in effect) set a timer on each **getch()**; if no input becomes available within a specified delay (measured in tenths of a second), `curses` raises an exception.

The **getch()** method returns an integer; if it's between 0 and 255, it represents the ASCII code of the key pressed. Values greater than 255 are special keys such as Page Up, Home, or the cursor keys. You can compare the value returned to constants such as **curses.KEY\_PPAGE**, **curses.KEY\_HOME**, or **curses.KEY\_LEFT**. The main loop of your program may look something like this:

```
while True:
    c = stdscr.getch()
    if c == ord('p'):
        PrintDocument()
    elif c == ord('q'):
        break # Exit the while loop
    elif c == curses.KEY_HOME:
        x = y = 0
```

The `curses.ascii` module supplies ASCII class membership functions that take either integer or 1-character string arguments; these may be useful in writing more readable tests for such loops. It also supplies conversion functions that take either integer or 1-character-string arguments and return the same type. For example, `curses.ascii.ctrl()` returns the control character corresponding to its argument.

There's also a method to retrieve an entire string, `getstr()`. It isn't used very often, because its functionality is quite limited; the only editing keys available are the backspace key and the Enter key, which terminates the string. It can optionally be limited to a fixed number of characters.

```
curses.echo()                # Enable echoing of characters

# Get a 15-character string, with the cursor on the top
s = stdscr.getstr(0,0, 15)
```

The `curses.textpad` module supplies a text box that supports an Emacs-like set of keybindings. Various methods of the `Textbox` class support editing with input validation and gathering the edit results either with or without trailing spaces. Here's an example:

```
import curses
from curses.textpad import Textbox, rectangle

def main(stdscr):
    stdscr.addstr(0, 0, "Enter IM message: (hit Ctrl-G t

    editwin = curses.newwin(5,30, 2,1)
    rectangle(stdscr, 1,0, 1+5+1, 1+30+1)
    stdscr.refresh()

    box = Textbox(editwin)

    # Let the user edit until Ctrl-G is struck.
    box.edit()

    # Get resulting contents
```

```
message = box.gather()
```

See the library documentation on [curses.textpad](#) for more details.

## For More Information

This HOWTO doesn't cover some advanced topics, such as reading the contents of the screen or capturing mouse events from an xterm instance, but the Python library page for the [curses](#) module is now reasonably complete. You should browse it next.

If you're in doubt about the detailed behavior of the curses functions, consult the manual pages for your curses implementation, whether it's ncurses or a proprietary Unix vendor's. The manual pages will document any quirks, and provide complete lists of all the functions, attributes, and **ACS\_\*** characters available to you.

Because the curses API is so large, some functions aren't supported in the Python interface. Often this isn't because they're difficult to implement, but because no one has needed them yet. Also, Python doesn't yet support the menu library associated with ncurses. Patches adding support for these would be welcome; see [the Python Developer's Guide](#) [<https://devguide.python.org/>] to learn more about submitting patches to Python.

**Descriptors** let objects customize attribute lookup, storage, and deletion.

This guide has four major sections:

1. The “primer” gives a basic overview, moving gently from simple examples, adding one feature at a time. Start here if you’re new to descriptors.
2. The second section shows a complete, practical descriptor example. If you already know the basics, start there.
3. The third section provides a more technical tutorial that goes into the detailed mechanics of how descriptors work. Most people don’t need this level of detail.
4. The last section has pure Python equivalents for built-in descriptors that are written in C. Read this if you’re curious about how functions turn into bound methods or about the implementation of common tools like `classmethod()`, `staticmethod()`, `property()`, and `__slots__`.

## Primer

In this primer, we start with the most basic possible example and then we’ll add new capabilities one by one.

### Simple example: A descriptor that returns a constant

The `Ten` class is a descriptor whose `__get__()` method always returns the constant `10`:

```
class Ten:
    def __get__(self, obj, objtype=None):
        return 10
```

To use the descriptor, it must be stored as a class variable in another class:

```
class A:
    x = 5                                # Regular class attribute
    y = Ten()                           # Descriptor instance
```

An interactive session shows the difference between normal attribute lookup and descriptor lookup:

```
>>> a = A()                            # Make an instance of class A
>>> a.x                                # Normal attribute lookup
5
>>> a.y                                # Descriptor lookup
10
```

In the `a.x` attribute lookup, the dot operator finds `'x': 5` in the class dictionary. In the `a.y` lookup, the dot operator finds a descriptor instance, recognized by its `__get__` method. Calling that method returns `10`.

Note that the value `10` is not stored in either the class dictionary or the instance dictionary. Instead, the value `10` is computed on demand.

This example shows how a simple descriptor works, but it isn't very useful. For retrieving constants, normal attribute lookup would be better.

In the next section, we'll create something more useful, a dynamic lookup.

## Dynamic lookups

Interesting descriptors typically run computations instead of returning constants:

```
import os

class DirectorySize:

    def __get__(self, obj, objtype=None):
        return len(os.listdir(obj.dirname))
```

```

class Directory:

    size = DirectorySize()                # Descriptor instance

    def __init__(self, dirname):
        self.dirname = dirname            # Regular instance attribute

```

An interactive session shows that the lookup is dynamic — it computes different, updated answers each time:

```

>>> s = Directory('songs')
>>> g = Directory('games')
>>> s.size                                # The songs directory
20
>>> g.size                                # The games directory
3
>>> os.remove('games/chess')              # Delete a game
>>> g.size                                # File count is
2

```

Besides showing how descriptors can run computations, this example also reveals the purpose of the parameters to `__get__()`. The *self* parameter is *size*, an instance of *DirectorySize*. The *obj* parameter is either *g* or *s*, an instance of *Directory*. It is the *obj* parameter that lets the `__get__()` method learn the target directory. The *objtype* parameter is the class *Directory*.

## Managed attributes

A popular use for descriptors is managing access to instance data. The descriptor is assigned to a public attribute in the class dictionary while the actual data is stored as a private attribute in the instance dictionary. The descriptor's `__get__()` and `__set__()` methods are triggered when the public attribute is accessed.

In the following example, *age* is the public attribute and *\_age* is the private attribute. When the public attribute is accessed, the descriptor logs the lookup or update:

```

import logging

logging.basicConfig(level=logging.INFO)

class LoggedAgeAccess:

    def __get__(self, obj, objtype=None):
        value = obj._age
        logging.info('Accessing %r giving %r', 'age', value)
        return value

    def __set__(self, obj, value):
        logging.info('Updating %r to %r', 'age', value)
        obj._age = value

class Person:

    age = LoggedAgeAccess()  # Descriptor instance

    def __init__(self, name, age):
        self.name = name    # Regular instance attribute
        self.age = age      # Calls __set__()

    def birthday(self):
        self.age += 1       # Calls both __get__() and __set__()

```

An interactive session shows that all access to the managed attribute *age* is logged, but that the regular attribute *name* is not logged:

```

>>> mary = Person('Mary M', 30)  # The initial age is 30
INFO:root:Updating 'age' to 30
>>> dave = Person('David D', 40)
INFO:root:Updating 'age' to 40

>>> vars(mary)  # The actual data dictionary
{'name': 'Mary M', '_age': 30}
>>> vars(dave)
{'name': 'David D', '_age': 40}

```

```

>>> mary.age                                     # Access the data
INFO:root:Accessing 'age' giving 30
30
>>> mary.birthday()                             # Updates are local
INFO:root:Accessing 'age' giving 30
INFO:root:Updating 'age' to 31

>>> dave.name                                    # Regular attribute
'David D'
>>> dave.age                                     # Only the managed
INFO:root:Accessing 'age' giving 40
40

```

One major issue with this example is that the private name `_age` is hardwired in the `LoggedAgeAccess` class. That means that each instance can only have one logged attribute and that its name is unchangeable. In the next example, we'll fix that problem.

## Customized names

When a class uses descriptors, it can inform each descriptor about which variable name was used.

In this example, the **Person** class has two descriptor instances, *name* and *age*. When the **Person** class is defined, it makes a callback to `__set_name__()` in `LoggedAccess` so that the field names can be recorded, giving each descriptor its own *public\_name* and *private\_name*:

```

import logging

logging.basicConfig(level=logging.INFO)

class LoggedAccess:

    def __set_name__(self, owner, name):
        self.public_name = name
        self.private_name = '_' + name

```

```

def __get__(self, obj, objtype=None):
    value = getattr(obj, self.private_name)
    logging.info('Accessing %r giving %r', self.public_name, value)
    return value

def __set__(self, obj, value):
    logging.info('Updating %r to %r', self.public_name, value)
    setattr(obj, self.private_name, value)

```

```
class Person:
```

```

    name = LoggedAccess()           # First descriptor
    age = LoggedAccess()            # Second descriptor

    def __init__(self, name, age):
        self.name = name            # Calls the first descriptor
        self.age = age              # Calls the second descriptor

    def birthday(self):
        self.age += 1

```

An interactive session shows that the **Person** class has called **\_\_set\_name\_\_()** so that the field names would be recorded. Here we call **vars()** to look up the descriptor without triggering it:

```

>>> vars(vars(Person)['name'])
{'public_name': 'name', 'private_name': '_name'}
>>> vars(vars(Person)['age'])
{'public_name': 'age', 'private_name': '_age'}

```

The new class now logs access to both *name* and *age*:

```

>>> pete = Person('Peter P', 10)
INFO:root:Updating 'name' to 'Peter P'
INFO:root:Updating 'age' to 10
>>> kate = Person('Catherine C', 20)
INFO:root:Updating 'name' to 'Catherine C'
INFO:root:Updating 'age' to 20

```

The two *Person* instances contain only the private names:

```
>>> vars(pete)
{'_name': 'Peter P', '_age': 10}
>>> vars(kate)
{'_name': 'Catherine C', '_age': 20}
```

## Closing thoughts

A [descriptor](#) is what we call any object that defines `__get__()`, `__set__()`, or `__delete__()`.

Optionally, descriptors can have a `__set_name__()` method. This is only used in cases where a descriptor needs to know either the class where it was created or the name of class variable it was assigned to. (This method, if present, is called even if the class is not a descriptor.)

Descriptors get invoked by the dot operator during attribute lookup. If a descriptor is accessed indirectly with `vars(some_class)[descriptor_name]`, the descriptor instance is returned without invoking it.

Descriptors only work when used as class variables. When put in instances, they have no effect.

The main motivation for descriptors is to provide a hook allowing objects stored in class variables to control what happens during attribute lookup.

Traditionally, the calling class controls what happens during lookup. Descriptors invert that relationship and allow the data being looked-up to have a say in the matter.

Descriptors are used throughout the language. It is how functions turn into bound methods. Common tools like [classmethod\(\)](#), [staticmethod\(\)](#), [property\(\)](#), and [functools.cached\\_property\(\)](#) are all implemented as descriptors.

# Complete Practical Example

In this example, we create a practical and powerful tool for locating notoriously hard to find data corruption bugs.

## Validator class

A validator is a descriptor for managed attribute access. Prior to storing any data, it verifies that the new value meets various type and range restrictions. If those restrictions aren't met, it raises an exception to prevent data corruption at its source.

This **Validator** class is both an [abstract base class](#) and a managed attribute descriptor:

```
from abc import ABC, abstractmethod

class Validator(ABC):

    def __set_name__(self, owner, name):
        self.private_name = '_' + name

    def __get__(self, obj, objtype=None):
        return getattr(obj, self.private_name)

    def __set__(self, obj, value):
        self.validate(value)
        setattr(obj, self.private_name, value)

    @abstractmethod
    def validate(self, value):
        pass
```

Custom validators need to inherit from **Validator** and must supply a **validate()** method to test various restrictions as needed.

## Custom validators

Here are three practical data validation utilities:

1. **OneOf** verifies that a value is one of a restricted set of options.
2. **Number** verifies that a value is either an **int** or **float**. Optionally, it verifies that a value is between a given minimum or maximum.
3. **String** verifies that a value is a **str**. Optionally, it validates a given minimum or maximum length. It can validate a user-defined **predicate** [[https://en.wikipedia.org/wiki/Predicate\\_\(mathematical\\_logic\)](https://en.wikipedia.org/wiki/Predicate_(mathematical_logic))] as well.

```
class OneOf(Validator):

    def __init__(self, *options):
        self.options = set(options)

    def validate(self, value):
        if value not in self.options:
            raise ValueError(f'Expected {value!r} to be one of {self.options!r}')

class Number(Validator):

    def __init__(self, minvalue=None, maxvalue=None):
        self.minvalue = minvalue
        self.maxvalue = maxvalue

    def validate(self, value):
        if not isinstance(value, (int, float)):
            raise TypeError(f'Expected {value!r} to be a number')
        if self.minvalue is not None and value < self.minvalue:
            raise ValueError(
                f'Expected {value!r} to be at least {self.minvalue!r}'
            )
        if self.maxvalue is not None and value > self.maxvalue:
            raise ValueError(
                f'Expected {value!r} to be no more than {self.maxvalue!r}'
            )
```

```

class String(Validator):

    def __init__(self, minsize=None, maxsize=None, predicate=None):
        self.minsize = minsize
        self.maxsize = maxsize
        self.predicate = predicate

    def validate(self, value):
        if not isinstance(value, str):
            raise TypeError(f'Expected {value!r} to be a string')
        if self.minsize is not None and len(value) < self.minsize:
            raise ValueError(
                f'Expected {value!r} to be no smaller than {self.minsize}'
            )
        if self.maxsize is not None and len(value) > self.maxsize:
            raise ValueError(
                f'Expected {value!r} to be no bigger than {self.maxsize}'
            )
        if self.predicate is not None and not self.predicate(value):
            raise ValueError(
                f'Expected {self.predicate} to be true for {value!r}'
            )

```

## Practical application

Here's how the data validators can be used in a real class:

```

class Component:

    name = String(minsize=3, maxsize=10, predicate=str.isalpha)
    kind = OneOf('wood', 'metal', 'plastic')
    quantity = Number(minvalue=0)

    def __init__(self, name, kind, quantity):
        self.name = name
        self.kind = kind
        self.quantity = quantity

```

The descriptors prevent invalid instances from being created:

```
>>> Component('Widget', 'metal', 5)          # Blocked: 'Wid
Traceback (most recent call last):
...
ValueError: Expected <method 'isupper' of 'str' objects>

>>> Component('WIDGET', 'metle', 5)          # Blocked: 'met
Traceback (most recent call last):
...
ValueError: Expected 'metle' to be one of {'metal', 'pla

>>> Component('WIDGET', 'metal', -5)         # Blocked: -5 i
Traceback (most recent call last):
...
ValueError: Expected -5 to be at least 0
>>> Component('WIDGET', 'metal', 'V')       # Blocked: 'V'
Traceback (most recent call last):
...
TypeError: Expected 'V' to be an int or float

>>> c = Component('WIDGET', 'metal', 5)     # Allowed: The
```

## Technical Tutorial

What follows is a more technical tutorial for the mechanics and details of how descriptors work.

### Abstract

Defines descriptors, summarizes the protocol, and shows how descriptors are called. Provides an example showing how object relational mappings work.

Learning about descriptors not only provides access to a larger toolset, it creates a deeper understanding of how Python works.

### Definition and introduction

In general, a descriptor is an attribute value that has one of the

methods in the descriptor protocol. Those methods are `__get__()`, `__set__()`, and `__delete__()`. If any of those methods are defined for an attribute, it is said to be a [descriptor](#).

The default behavior for attribute access is to get, set, or delete the attribute from an object's dictionary. For instance, `a.x` has a lookup chain starting with `a.__dict__['x']`, then `type(a).__dict__['x']`, and continuing through the method resolution order of `type(a)`. If the looked-up value is an object defining one of the descriptor methods, then Python may override the default behavior and invoke the descriptor method instead. Where this occurs in the precedence chain depends on which descriptor methods were defined.

Descriptors are a powerful, general purpose protocol. They are the mechanism behind properties, methods, static methods, class methods, and [super\(\)](#). They are used throughout Python itself. Descriptors simplify the underlying C code and offer a flexible set of new tools for everyday Python programs.

## Descriptor protocol

```
descr.__get__(self, obj, type=None) -> value
```

```
descr.__set__(self, obj, value) -> None
```

```
descr.__delete__(self, obj) -> None
```

That is all there is to it. Define any of these methods and an object is considered a descriptor and can override default behavior upon being looked up as an attribute.

If an object defines `__set__()` or `__delete__()`, it is considered a data descriptor. Descriptors that only define `__get__()` are called non-data descriptors (they are often used for methods but other uses are possible).

Data and non-data descriptors differ in how overrides are calculated with respect to entries in an instance's dictionary. If an instance's dictionary has an entry with the same name as a data descriptor, the data descriptor takes precedence. If an instance's dictionary has

an entry with the same name as a non-data descriptor, the dictionary entry takes precedence.

To make a read-only data descriptor, define both `__get__()` and `__set__()` with the `__set__()` raising an `AttributeError` when called. Defining the `__set__()` method with an exception raising placeholder is enough to make it a data descriptor.

## Overview of descriptor invocation

A descriptor can be called directly with `desc.__get__(obj)` or `desc.__get__(None, cls)`.

But it is more common for a descriptor to be invoked automatically from attribute access.

The expression `obj.x` looks up the attribute `x` in the chain of namespaces for `obj`. If the search finds a descriptor outside of the instance `__dict__`, its `__get__()` method is invoked according to the precedence rules listed below.

The details of invocation depend on whether `obj` is an object, class, or instance of super.

## Invocation from an instance

Instance lookup scans through a chain of namespaces giving data descriptors the highest priority, followed by instance variables, then non-data descriptors, then class variables, and lastly `__getattr__()` if it is provided.

If a descriptor is found for `a.x`, then it is invoked with:  
`desc.__get__(a, type(a))`.

The logic for a dotted lookup is in `object.__getattribute__()`. Here is a pure Python equivalent:

```
def find_name_in_mro(cls, name, default):
    "Emulate _PyType_Lookup() in Objects/typeobject.c"
    for base in cls.__mro__:
```

```

        if name in vars(base):
            return vars(base)[name]
    return default

def object_getattribute(obj, name):
    "Emulate PyObject_GenericGetAttr() in Objects/object.c"
    null = object()
    objtype = type(obj)
    cls_var = find_name_in_mro(objtype, name, null)
    descr_get = getattr(type(cls_var), '__get__', null)
    if descr_get is not null:
        if (hasattr(type(cls_var), '__set__')
            or hasattr(type(cls_var), '__delete__')):
            return descr_get(cls_var, obj, objtype)
    if hasattr(obj, '__dict__') and name in vars(obj):
        return vars(obj)[name]
    if descr_get is not null:
        return descr_get(cls_var, obj, objtype)
    if cls_var is not null:
        return cls_var
    raise AttributeError(name)

```

Note, there is no `__getattr__()` hook in the `__getattribute__()` code. That is why calling `__getattribute__()` directly or with `super().__getattribute__` will bypass `__getattr__()` entirely.

Instead, it is the dot operator and the `getattr()` function that are responsible for invoking `__getattr__()` whenever `__getattribute__()` raises an `AttributeError`. Their logic is encapsulated in a helper function:

```

def getattr_hook(obj, name):
    "Emulate slot_tp_getattr_hook() in Objects/typeobject.c"
    try:
        return obj.__getattribute__(name)
    except AttributeError:
        if not hasattr(type(obj), '__getattr__'):

```

```
        raise
    return type(obj).__getattr__(obj, name)
```

## Invocation from a class

The logic for a dotted lookup such as `A.x` is in `type.__getattribute__()`. The steps are similar to those for `object.__getattribute__()` but the instance dictionary lookup is replaced by a search through the class's [method resolution order](#).

If a descriptor is found, it is invoked with `desc.__get__(None, A)`.

The full C implementation can be found in `type_getattro()` and `_PyType_Lookup()` in [Objects/typeobject.c](#) [<https://github.com/python/cpython/tree/3.11/Objects/typeobject.c>].

## Invocation from super

The logic for super's dotted lookup is in the `__getattribute__()` method for object returned by `super()`.

A dotted lookup such as `super(A, obj).m` searches `obj.__class__.__mro__` for the base class `B` immediately following `A` and then returns `B.__dict__['m'].__get__(obj, A)`. If not a descriptor, `m` is returned unchanged.

The full C implementation can be found in `super_getattro()` in [Objects/typeobject.c](#) [<https://github.com/python/cpython/tree/3.11/Objects/typeobject.c>]. A pure Python equivalent can be found in [Guido's Tutorial](#) [<https://www.python.org/download/releases/2.2.3/descrintro/#cooperation>].

## Summary of invocation logic

The mechanism for descriptors is embedded in the `__getattribute__()` methods for [object](#), [type](#), and [super\(\)](#).

The important points to remember are:

- Descriptors are invoked by the `__getattribute__()` method.
- Classes inherit this machinery from `object`, `type`, or `super()`.
- Overriding `__getattribute__()` prevents automatic descriptor calls because all the descriptor logic is in that method.
- `object.__getattribute__()` and `type.__getattribute__()` make different calls to `__get__()`. The first includes the instance and may include the class. The second puts in `None` for the instance and always includes the class.
- Data descriptors always override instance dictionaries.
- Non-data descriptors may be overridden by instance dictionaries.

## Automatic name notification

Sometimes it is desirable for a descriptor to know what class variable name it was assigned to. When a new class is created, the `type` metaclass scans the dictionary of the new class. If any of the entries are descriptors and if they define `__set_name__()`, that method is called with two arguments. The *owner* is the class where the descriptor is used, and the *name* is the class variable the descriptor was assigned to.

The implementation details are in `type_new()` and `set_names()` in [Objects/typeobject.c](https://github.com/python/cpython/tree/3.11/Objects/typeobject.c) [https://github.com/python/cpython/tree/3.11/Objects/typeobject.c].

Since the update logic is in `type.__new__()`, notifications only take place at the time of class creation. If descriptors are added to the class afterwards, `__set_name__()` will need to be called manually.

## ORM example

The following code is a simplified skeleton showing how data

descriptors could be used to implement an [object relational mapping](https://en.wikipedia.org/wiki/Object%E2%80%93relational_mapping) [https://en.wikipedia.org/wiki/Object%E2%80%93relational\_mapping].

The essential idea is that the data is stored in an external database. The Python instances only hold keys to the database's tables. Descriptors take care of lookups or updates:

```
class Field:

    def __set_name__(self, owner, name):
        self.fetch = f'SELECT {name} FROM {owner.table}'
        self.store = f'UPDATE {owner.table} SET {name}=?'

    def __get__(self, obj, objtype=None):
        return conn.execute(self.fetch, [obj.key]).fetchone()

    def __set__(self, obj, value):
        conn.execute(self.store, [value, obj.key])
        conn.commit()
```

We can use the **Field** class to define [models](https://en.wikipedia.org/wiki/Database_model) [https://en.wikipedia.org/wiki/Database\_model] that describe the schema for each table in a database:

```
class Movie:
    table = 'Movies'                # Table name
    key = 'title'                   # Primary key
    director = Field()
    year = Field()

    def __init__(self, key):
        self.key = key

class Song:
    table = 'Music'
    key = 'title'
    artist = Field()
    year = Field()
    genre = Field()
```

```
def __init__(self, key):
    self.key = key
```

To use the models, first connect to the database:

```
>>> import sqlite3
>>> conn = sqlite3.connect('entertainment.db')
```

An interactive session shows how data is retrieved from the database and how it can be updated:

```
>>> Movie('Star Wars').director
'George Lucas'
>>> jaws = Movie('Jaws')
>>> f'Released in {jaws.year} by {jaws.director}'
'Released in 1975 by Steven Spielberg'

>>> Song('Country Roads').artist
'John Denver'

>>> Movie('Star Wars').director = 'J.J. Abrams'
>>> Movie('Star Wars').director
'J.J. Abrams'
```

## Pure Python Equivalents

The descriptor protocol is simple and offers exciting possibilities. Several use cases are so common that they have been prepackaged into built-in tools. Properties, bound methods, static methods, class methods, and `__slots__` are all based on the descriptor protocol.

### Properties

Calling `property()` is a succinct way of building a data descriptor that triggers a function call upon access to an attribute. Its signature is:

```
property(fget=None, fset=None, fdel=None, doc=None) -> p
```

The documentation shows a typical use to define a managed attribute `x`:

```
class C:
    def getx(self): return self.__x
    def setx(self, value): self.__x = value
    def delx(self): del self.__x
    x = property(getx, setx, delx, "I'm the 'x' property")
```

To see how `property()` is implemented in terms of the descriptor protocol, here is a pure Python equivalent:

```
class Property:
    "Emulate PyProperty_Type() in Objects/descrobject.c"

    def __init__(self, fget=None, fset=None, fdel=None,
                 self.fget = fget
                 self.fset = fset
                 self.fdel = fdel
                 if doc is None and fget is not None:
                     doc = fget.__doc__
                 self.__doc__ = doc
                 self._name = ''

    def __set_name__(self, owner, name):
        self._name = name

    def __get__(self, obj, objtype=None):
        if obj is None:
            return self
        if self.fget is None:
            raise AttributeError(f"property '{self._name}' of '{objtype}' object has no attribute '{self._name}'")
        return self.fget(obj)

    def __set__(self, obj, value):
        if self.fset is None:
            raise AttributeError(f"property '{self._name}' of '{objtype}' object is read-only")
        self.fset(obj, value)
```

```

def __delete__(self, obj):
    if self.fdel is None:
        raise AttributeError(f"property '{self._name}' of {self.fdel(obj)} object has no attribute '{self._name}'")

def getter(self, fget):
    prop = type(self)(fget, self.fset, self.fdel, self._name)
    return prop

def setter(self, fset):
    prop = type(self)(self.fget, fset, self.fdel, self._name)
    return prop

def deleter(self, fdel):
    prop = type(self)(self.fget, self.fset, fdel, self._name)
    return prop

```

The `property()` builtin helps whenever a user interface has granted attribute access and then subsequent changes require the intervention of a method.

For instance, a spreadsheet class may grant access to a cell value through `Cell('b10').value`. Subsequent improvements to the program require the cell to be recalculated on every access; however, the programmer does not want to affect existing client code accessing the attribute directly. The solution is to wrap access to the value attribute in a property data descriptor:

```

class Cell:
    ...

    @property
    def value(self):
        "Recalculate the cell before returning value"
        self.recalc()
        return self._value

```

Either the built-in `property()` or our `Property()` equivalent would work in this example.

## Functions and methods

Python's object oriented features are built upon a function based environment. Using non-data descriptors, the two are merged seamlessly.

Functions stored in class dictionaries get turned into methods when invoked. Methods only differ from regular functions in that the object instance is prepended to the other arguments. By convention, the instance is called *self* but could be called *this* or any other variable name.

Methods can be created manually with `types.MethodType` which is roughly equivalent to:

```
class MethodType:
    "Emulate PyMethod_Type in Objects/classobject.c"

    def __init__(self, func, obj):
        self.__func__ = func
        self.__self__ = obj

    def __call__(self, *args, **kwargs):
        func = self.__func__
        obj = self.__self__
        return func(obj, *args, **kwargs)
```

To support automatic creation of methods, functions include the `__get__()` method for binding methods during attribute access. This means that functions are non-data descriptors that return bound methods during dotted lookup from an instance. Here's how it works:

```
class Function:
    ...

    def __get__(self, obj, objtype=None):
```

```
"Simulate func_descr_get() in Objects/funcobject.c"
if obj is None:
    return self
return MethodType(self, obj)
```

Running the following class in the interpreter shows how the function descriptor works in practice:

```
class D:
    def f(self, x):
        return x
```

The function has a [qualified name](#) attribute to support introspection:

```
>>> D.f.__qualname__
'D.f'
```

Accessing the function through the class dictionary does not invoke `__get__()`. Instead, it just returns the underlying function object:

```
>>> D.__dict__['f']
<function D.f at 0x00C45070>
```

Dotted access from a class calls `__get__()` which just returns the underlying function unchanged:

```
>>> D.f
<function D.f at 0x00C45070>
```

The interesting behavior occurs during dotted access from an instance. The dotted lookup calls `__get__()` which returns a bound method object:

```
>>> d = D()
>>> d.f
<bound method D.f of <__main__.D object at 0x00B18C90>>
```

Internally, the bound method stores the underlying function and the bound instance:

```
>>> d.f.__func__
<function D.f at 0x00C45070>

>>> d.f.__self__
<__main__.D object at 0x1012e1f98>
```

If you have ever wondered where *self* comes from in regular methods or where *cls* comes from in class methods, this is it!

## Kinds of methods

Non-data descriptors provide a simple mechanism for variations on the usual patterns of binding functions into methods.

To recap, functions have a `__get__()` method so that they can be converted to a method when accessed as attributes. The non-data descriptor transforms an `obj.f(*args)` call into `f(obj, *args)`. Calling `cls.f(*args)` becomes `f(*args)`.

This chart summarizes the binding and its two most useful variants:

Called from an object	
<code>f(obj)</code>	<code>f(obj, *args)</code>
<code>f(*args)</code>	<code>f(*args)</code>
<code>f(cls, obj)</code>	<code>f(cls, obj, *args)</code>

## Static methods

Static methods return the underlying function without changes. Calling either `c.f` or `C.f` is the equivalent of a direct lookup into `object.__getattribute__(c, "f")` or `object.__getattribute__(C, "f")`. As a result, the function becomes identically accessible from either an object or a class.

Good candidates for static methods are methods that do not reference the `self` variable.

For instance, a statistics package may include a container class for experimental data. The class provides normal methods for computing the average, mean, median, and other descriptive statistics that depend on the data. However, there may be useful

functions which are conceptually related but do not depend on the data. For instance, `erf(x)` is handy conversion routine that comes up in statistical work but does not directly depend on a particular dataset. It can be called either from an object or the class:

```
s.erf(1.5) --> .9332 or Sample.erf(1.5) --> .9332.
```

Since static methods return the underlying function with no changes, the example calls are unexciting:

```
class E:
    @staticmethod
    def f(x):
        return x * 10
```

```
>>> E.f(3)
30
>>> E().f(3)
30
```

Using the non-data descriptor protocol, a pure Python version of `staticmethod()` would look like this:

```
import functools
```

```
class StaticMethod:
    "Emulate PyStaticMethod_Type() in Objects/funcobject.c"

    def __init__(self, f):
        self.f = f
        functools.update_wrapper(self, f)

    def __get__(self, obj, objtype=None):
        return self.f

    def __call__(self, *args, **kwargs):
        return self.f(*args, **kwargs)
```

The `functools.update_wrapper()` call adds a `__wrapped__` attribute that refers to the underlying function. Also it carries forward the attributes necessary to make the wrapper look like the

wrapped function: `__name__`, `__qualname__`, `__doc__`, and `__annotations__`.

## Class methods

Unlike static methods, class methods prepend the class reference to the argument list before calling the function. This format is the same for whether the caller is an object or a class:

```
class F:
    @classmethod
    def f(cls, x):
        return cls.__name__, x
```

```
>>> F.f(3)
('F', 3)
>>> F().f(3)
('F', 3)
```

This behavior is useful whenever the method only needs to have a class reference and does not rely on data stored in a specific instance. One use for class methods is to create alternate class constructors. For example, the classmethod `dict.fromkeys()` creates a new dictionary from a list of keys. The pure Python equivalent is:

```
class Dict(dict):
    @classmethod
    def fromkeys(cls, iterable, value=None):
        "Emulate dict_fromkeys() in Objects/dictobject.c"
        d = cls()
        for key in iterable:
            d[key] = value
        return d
```

Now a new dictionary of unique keys can be constructed like this:

```
>>> d = Dict.fromkeys('abracadabra')
>>> type(d) is Dict
True
```

```
>>> d
{'a': None, 'b': None, 'r': None, 'c': None, 'd': None}
```

Using the non-data descriptor protocol, a pure Python version of `classmethod()` would look like this:

```
import functools

class ClassMethod:
    "Emulate PyClassMethod_Type() in Objects/funcobject.c"

    def __init__(self, f):
        self.f = f
        functools.update_wrapper(self, f)

    def __get__(self, obj, cls=None):
        if cls is None:
            cls = type(obj)
        if hasattr(type(self.f), '__get__'):
            # This code path was added in Python 3.9
            # and was deprecated in Python 3.11.
            return self.f.__get__(cls, cls)
        return MethodType(self.f, cls)
```

The code path for `hasattr(type(self.f), '__get__')` was added in Python 3.9 and makes it possible for `classmethod()` to support chained decorators. For example, a classmethod and property could be chained together. In Python 3.11, this functionality was deprecated.

```
class G:
    @classmethod
    @property
    def __doc__(cls):
        return f'A doc for {cls.__name__!r}'

>>> G.__doc__
"A doc for 'G'"
```

The `functools.update_wrapper()` call in `ClassMethod`

adds a `__wrapped__` attribute that refers to the underlying function. Also it carries forward the attributes necessary to make the wrapper look like the wrapped function: `__name__`, `__qualname__`, `__doc__`, and `__annotations__`.

## Member objects and `__slots__`

When a class defines `__slots__`, it replaces instance dictionaries with a fixed-length array of slot values. From a user point of view that has several effects:

1. Provides immediate detection of bugs due to misspelled attribute assignments. Only attribute names specified in `__slots__` are allowed:

```
class Vehicle:
    __slots__ = ('id_number', 'make', 'model')

>>> auto = Vehicle()
>>> auto.id_nubmer = 'VYE483814LQEX'
Traceback (most recent call last):
...
AttributeError: 'Vehicle' object has no attribute 'id_nu
```

2. Helps create immutable objects where descriptors manage access to private attributes stored in `__slots__`:

```
class Immutable:

    __slots__ = ('_dept', '_name')                # Replace the dict with slots

    def __init__(self, dept, name):
        self._dept = dept                        # Store to private attribute
        self._name = name                        # Store to private attribute

    @property                                    # Read-only
    def dept(self):
        return self._dept

    @property
```

```

def name(self):
    return self._name                                # Read-only

>>> mark = Immutable('Botany', 'Mark Watney')
>>> mark.dept
'Botany'
>>> mark.dept = 'Space Pirate'
Traceback (most recent call last):
...
AttributeError: property 'dept' of 'Immutable' object has no attribute 'dept'
>>> mark.location = 'Mars'
Traceback (most recent call last):
...
AttributeError: 'Immutable' object has no attribute 'location'

```

3. Saves memory. On a 64-bit Linux build, an instance with two attributes takes 48 bytes with `__slots__` and 152 bytes without.

This [flyweight design pattern](https://en.wikipedia.org/wiki/Flyweight_pattern) [https://en.wikipedia.org/wiki/Flyweight\_pattern] likely only matters when a large number of instances are going to be created.

4. Improves speed. Reading instance variables is 35% faster with `__slots__` (as measured with Python 3.10 on an Apple M1 processor).

5. Blocks tools like `functools.cached_property()` which require an instance dictionary to function correctly:

```

from functools import cached_property

class CP:
    __slots__ = ()                                # Eliminates instance dictionary

    @cached_property                              # Requires instance dictionary
    def pi(self):
        return 4 * sum((-1.0)**n / (2.0*n + 1.0)
                        for n in reversed(range(100_000)))

>>> CP().pi
Traceback (most recent call last):

```

...

TypeError: No '\_\_dict\_\_' attribute on 'CP' instance to c

It is not possible to create an exact drop-in pure Python version of `__slots__` because it requires direct access to C structures and control over object memory allocation. However, we can build a mostly faithful simulation where the actual C structure for slots is emulated by a private `_slotvalues` list. Reads and writes to that private structure are managed by member descriptors:

```
null = object()
```

```
class Member:
```

```
    def __init__(self, name, clsname, offset):
        'Emulate PyMemberDef in Include/structmember.h'
        # Also see descr_new() in Objects/descrobject.c
        self.name = name
        self.clsname = clsname
        self.offset = offset

    def __get__(self, obj, objtype=None):
        'Emulate member_get() in Objects/descrobject.c'
        # Also see PyMember_GetOne() in Python/structmem
        if obj is None:
            return self
        value = obj._slotvalues[self.offset]
        if value is null:
            raise AttributeError(self.name)
        return value

    def __set__(self, obj, value):
        'Emulate member_set() in Objects/descrobject.c'
        obj._slotvalues[self.offset] = value

    def __delete__(self, obj):
        'Emulate member_delete() in Objects/descrobject.c'
        value = obj._slotvalues[self.offset]
        if value is null:
```

```

        raise AttributeError(self.name)
    obj._slotvalues[self.offset] = null

```

```

def __repr__(self):
    'Emulate member_repr() in Objects/descrobject.c'
    return f'<Member {self.name!r} of {self.clsname!r}'

```

The **type.\_\_new\_\_()** method takes care of adding member objects to class variables:

```

class Type(type):
    'Simulate how the type metaclass adds member objects'

    def __new__(mcls, clsname, bases, mapping, **kwargs):
        'Emulate type_new() in Objects/typeobject.c'
        # type_new() calls PyTypeReady() which calls add_slot
        slot_names = mapping.get('slot_names', [])
        for offset, name in enumerate(slot_names):
            mapping[name] = Member(name, clsname, offset)
        return type.__new__(mcls, clsname, bases, mapping)

```

The **object.\_\_new\_\_()** method takes care of creating instances that have slots instead of an instance dictionary. Here is a rough simulation in pure Python:

```

class Object:
    'Simulate how object.__new__() allocates memory for'

    def __new__(cls, *args, **kwargs):
        'Emulate object_new() in Objects/typeobject.c'
        inst = super().__new__(cls)
        if hasattr(cls, 'slot_names'):
            empty_slots = [null] * len(cls.slot_names)
            object.__setattr__(inst, '_slotvalues', empty_slots)
        return inst

    def __setattr__(self, name, value):
        'Emulate _PyObject_GenericSetAttrWithDict() in Objects/object.c'
        cls = type(self)

```

```

        if hasattr(cls, 'slot_names') and name not in cls.slot_names:
            raise AttributeError(
                f'{cls.__name__!r} object has no attribute {name!r}'
            )
        super().__setattr__(name, value)

    def __delattr__(self, name):
        'Emulate _PyObject_GenericSetAttrWithDict() Object'
        cls = type(self)
        if hasattr(cls, 'slot_names') and name not in cls.slot_names:
            raise AttributeError(
                f'{cls.__name__!r} object has no attribute {name!r}'
            )
        super().__delattr__(name)

```

To use the simulation in a real class, just inherit from **Object** and set the **metaclass** to **Type**:

```

class H(Object, metaclass=Type):
    'Instance variables stored in slots'

    slot_names = ['x', 'y']

    def __init__(self, x, y):
        self.x = x
        self.y = y

```

At this point, the metaclass has loaded member objects for *x* and *y*:

```

>>> from pprint import pp
>>> pp(dict(vars(H)))
{'__module__': '__main__',
 '__doc__': 'Instance variables stored in slots',
 'slot_names': ['x', 'y'],
 '__init__': <function H.__init__ at 0x7fb5d302f9d0>,
 'x': <Member 'x' of 'H'>,
 'y': <Member 'y' of 'H'>}

```

When instances are created, they have a `slot_values` list where the attributes are stored:

```
>>> h = H(10, 20)
>>> vars(h)
{'_slotvalues': [10, 20]}
>>> h.x = 55
>>> vars(h)
{'_slotvalues': [55, 20]}
```

**Misspelled or unassigned attributes will raise an exception:**

```
>>> h.xz
Traceback (most recent call last):
...
AttributeError: 'H' object has no attribute 'xz'
```

# Enum HOWTO

An **Enum** is a set of symbolic names bound to unique values. They are similar to global variables, but they offer a more useful **repr()**, grouping, type-safety, and a few other features.

They are most useful when you have a variable that can take one of a limited selection of values. For example, the days of the week:

```
>>> from enum import Enum
>>> class Weekday(Enum):
...     MONDAY = 1
...     TUESDAY = 2
...     WEDNESDAY = 3
...     THURSDAY = 4
...     FRIDAY = 5
...     SATURDAY = 6
...     SUNDAY = 7
```

Or perhaps the RGB primary colors:

```
>>> from enum import Enum
>>> class Color(Enum):
...     RED = 1
...     GREEN = 2
...     BLUE = 3
```

As you can see, creating an **Enum** is as simple as writing a class that inherits from **Enum** itself.

## Note

### Case of Enum Members

Because Enums are used to represent constants we recommend using UPPER\_CASE names for members, and will be using that

style in our examples.

Depending on the nature of the enum a member's value may or may not be important, but either way that value can be used to get the corresponding member:

```
>>> Weekday(3)
<Weekday.WEDNESDAY: 3>
```

As you can see, the `repr()` of a member shows the enum name, the member name, and the value. The `str()` of a member shows only the enum name and member name:

```
>>> print(Weekday.THURSDAY)
Weekday.THURSDAY
```

The *type* of an enumeration member is the enum it belongs to:

```
>>> type(Weekday.MONDAY)
<enum 'Weekday'>
>>> isinstance(Weekday.FRIDAY, Weekday)
True
```

Enum members have an attribute that contains just their **name**:

```
>>> print(Weekday.TUESDAY.name)
TUESDAY
```

Likewise, they have an attribute for their **value**:

```
>>> Weekday.WEDNESDAY.value
3
```

Unlike many languages that treat enumerations solely as name/value pairs, Python Enums can have behavior added. For example, `datetime.date` has two methods for returning the weekday: `weekday()` and `isoweekday()`. The difference is that one of them counts from 0-6 and the other from 1-7. Rather than keep track of that ourselves we can add a method to the **Weekday** enum to extract the day from the **date** instance and return the matching enum member:

```
@classmethod
def from_date(cls, date):
    return cls(date.isoweekday())
```

The complete **Weekday** enum now looks like this:

```
>>> class Weekday(Enum):
...     MONDAY = 1
...     TUESDAY = 2
...     WEDNESDAY = 3
...     THURSDAY = 4
...     FRIDAY = 5
...     SATURDAY = 6
...     SUNDAY = 7
...     #
...     @classmethod
...     def from_date(cls, date):
...         return cls(date.isoweekday())
```

Now we can find out what today is! Observe:

```
>>> from datetime import date
>>> Weekday.from_date(date.today())
<Weekday.TUESDAY: 2>
```

Of course, if you're reading this on some other day, you'll see that day instead.

This **Weekday** enum is great if our variable only needs one day, but what if we need several? Maybe we're writing a function to plot chores during a week, and don't want to use a **list** – we could use a different type of **Enum**:

```
>>> from enum import Flag
>>> class Weekday(Flag):
...     MONDAY = 1
...     TUESDAY = 2
...     WEDNESDAY = 4
...     THURSDAY = 8
...     FRIDAY = 16
```

```
...     SATURDAY = 32
...     SUNDAY = 64
```

We've changed two things: we're inherited from **Flag**, and the values are all powers of 2.

Just like the original **Weekday** enum above, we can have a single selection:

```
>>> first_week_day = Weekday.MONDAY
>>> first_week_day
<Weekday.MONDAY: 1>
```

But **Flag** also allows us to combine several members into a single variable:

```
>>> weekend = Weekday.SATURDAY | Weekday.SUNDAY
>>> weekend
<Weekday.SATURDAY | SUNDAY: 96>
```

You can even iterate over a **Flag** variable:

```
>>> for day in weekend:
...     print(day)
Weekday.SATURDAY
Weekday.SUNDAY
```

Okay, let's get some chores set up:

```
>>> chores_for_ethan = {
...     'feed the cat': Weekday.MONDAY | Weekday.WEDNESDAY,
...     'do the dishes': Weekday.TUESDAY | Weekday.THURSDAY,
...     'answer SO questions': Weekday.SATURDAY,
... }
```

And a function to display the chores for a given day:

```
>>> def show_chores(chores, day):
...     for chore, days in chores.items():
...         if day in days:
...             print(chore)
```

```
>>> show_chores(chores_for_ethan, Weekday.SATURDAY)
answer SO questions
```

In cases where the actual values of the members do not matter, you can save yourself some work and use `auto()` for the values:

```
>>> from enum import auto
>>> class Weekday(Flag):
...     MONDAY = auto()
...     TUESDAY = auto()
...     WEDNESDAY = auto()
...     THURSDAY = auto()
...     FRIDAY = auto()
...     SATURDAY = auto()
...     SUNDAY = auto()
...     WEEKEND = SATURDAY | SUNDAY
```

## Programmatic access to enumeration members and their attributes

Sometimes it's useful to access members in enumerations programmatically (i.e. situations where `Color.RED` won't do because the exact color is not known at program-writing time). Enum allows such access:

```
>>> Color(1)
<Color.RED: 1>
>>> Color(3)
<Color.BLUE: 3>
```

If you want to access enum members by *name*, use item access:

```
>>> Color['RED']
<Color.RED: 1>
>>> Color['GREEN']
<Color.GREEN: 2>
```

If you have an enum member and need its **name** or **value**:

```
>>> member = Color.RED
>>> member.name
'RED'
>>> member.value
1
```

## Duplicating enum members and values

Having two enum members with the same name is invalid:

```
>>> class Shape(Enum):
...     SQUARE = 2
...     SQUARE = 3
...
Traceback (most recent call last):
...
TypeError: 'SQUARE' already defined as 2
```

However, an enum member can have other names associated with it. Given two entries `A` and `B` with the same value (and `A` defined first), `B` is an alias for the member `A`. By-value lookup of the value of `A` will return the member `A`. By-name lookup of `A` will return the member `A`. By-name lookup of `B` will also return the member `A`:

```
>>> class Shape(Enum):
...     SQUARE = 2
...     DIAMOND = 1
...     CIRCLE = 3
...     ALIAS_FOR_SQUARE = 2
...
>>> Shape.SQUARE
<Shape.SQUARE: 2>
>>> Shape.ALIAS_FOR_SQUARE
<Shape.SQUARE: 2>
>>> Shape(2)
<Shape.SQUARE: 2>
```

### Note

Attempting to create a member with the same name as an already defined attribute (another member, a method, etc.) or attempting to create an attribute with the same name as a member is not allowed.

## Ensuring unique enumeration values

By default, enumerations allow multiple names as aliases for the same value. When this behavior isn't desired, you can use the `unique()` decorator:

```
>>> from enum import Enum, unique
>>> @unique
... class Mistake(Enum):
...     ONE = 1
...     TWO = 2
...     THREE = 3
...     FOUR = 3
...
Traceback (most recent call last):
...
ValueError: duplicate values found in <enum 'Mistake'>:
```

## Using automatic values

If the exact value is unimportant you can use `auto`:

```
>>> from enum import Enum, auto
>>> class Color(Enum):
...     RED = auto()
...     BLUE = auto()
...     GREEN = auto()
...
>>> [member.value for member in Color]
[1, 2, 3]
```

The values are chosen by `_generate_next_value_()`, which can be overridden:

```
>>> class AutoName(Enum):
...     def _generate_next_value_(name, start, count, last_value):
...         return name
...
>>> class Ordinal(AutoName):
...     NORTH = auto()
...     SOUTH = auto()
...     EAST = auto()
...     WEST = auto()
...
>>> [member.value for member in Ordinal]
['NORTH', 'SOUTH', 'EAST', 'WEST']
```

### Note

The `_generate_next_value_()` method must be defined before any members.

## Iteration

Iterating over the members of an enum does not provide the aliases:

```
>>> list(Shape)
[<Shape.SQUARE: 2>, <Shape.DIAMOND: 1>, <Shape.CIRCLE: 3>]
>>> list(Weekday)
[<Weekday.MONDAY: 1>, <Weekday.TUESDAY: 2>, <Weekday.WEDNESDAY: 3>]
```

Note that the aliases `Shape.ALIAS_FOR_SQUARE` and `Weekday.WEEKEND` aren't shown.

The special attribute `__members__` is a read-only ordered mapping of names to members. It includes all names defined in the enumeration, including the aliases:

```
>>> for name, member in Shape.__members__.items():
...     name, member
...
('SQUARE', <Shape.SQUARE: 2>)
```

```
('DIAMOND', <Shape.DIAMOND: 1>)  
( 'CIRCLE', <Shape.CIRCLE: 3>)  
( 'ALIAS_FOR_SQUARE', <Shape.SQUARE: 2>)
```

The `__members__` attribute can be used for detailed programmatic access to the enumeration members. For example, finding all the aliases:

```
>>> [name for name, member in Shape.__members__.items()  
      ['ALIAS_FOR_SQUARE']]
```

### Note

Aliases for flags include values with multiple flags set, such as 3, and no flags set, i.e. 0.

## Comparisons

Enumeration members are compared by identity:

```
>>> Color.RED is Color.RED  
True  
>>> Color.RED is Color.BLUE  
False  
>>> Color.RED is not Color.BLUE  
True
```

Ordered comparisons between enumeration values are *not* supported. Enum members are not integers (but see [IntEnum](#) below):

```
>>> Color.RED < Color.BLUE  
Traceback (most recent call last):  
  File "<stdin>", line 1, in <module>  
TypeError: '<' not supported between instances of 'Color'
```

Equality comparisons are defined though:

```
>>> Color.BLUE == Color.RED
```

```
False
>>> Color.BLUE != Color.RED
True
>>> Color.BLUE == Color.BLUE
True
```

Comparisons against non-enumeration values will always compare not equal (again, [IntEnum](#) was explicitly designed to behave differently, see below):

```
>>> Color.BLUE == 2
False
```

### Warning

It is possible to reload modules – if a reloaded module contains enums, they will be recreated, and the new members may not compare identical/equal to the original members.

## Allowed members and attributes of enumerations

Most of the examples above use integers for enumeration values. Using integers is short and handy (and provided by default by the [Functional API](#)), but not strictly enforced. In the vast majority of use-cases, one doesn't care what the actual value of an enumeration is. But if the value is important, enumerations can have arbitrary values.

Enumerations are Python classes, and can have methods and special methods as usual. If we have this enumeration:

```
>>> class Mood(Enum):
...     FUNKY = 1
...     HAPPY = 3
...
...     def describe(self):
...         # self is the member here
```

```

...         return self.name, self.value
...
...     def __str__(self):
...         return 'my custom str! {0}'.format(self.value)
...
...     @classmethod
...     def favorite_mood(cls):
...         # cls here is the enumeration
...         return cls.HAPPY
...

```

Then:

```

>>> Mood.favorite_mood()
<Mood.HAPPY: 3>
>>> Mood.HAPPY.describe()
('HAPPY', 3)
>>> str(Mood.FUNKY)
'my custom str! 1'

```

The rules for what is allowed are as follows: names that start and end with a single underscore are reserved by enum and cannot be used; all other attributes defined within an enumeration will become members of this enumeration, with the exception of special methods (`__str__()`, `__add__()`, etc.), descriptors (methods are also descriptors), and variable names listed in `__ignore__`.

Note: if your enumeration defines `__new__()` and/or `__init__()` then any value(s) given to the enum member will be passed into those methods. See [Planet](#) for an example.

## Restricted Enum subclassing

A new [Enum](#) class must have one base enum class, up to one concrete data type, and as many [object](#)-based mixin classes as needed. The order of these base classes is:

```

class EnumName([mix-in, ...,] [data-type,] base-enum):
    pass

```

Also, subclassing an enumeration is allowed only if the enumeration does not define any members. So this is forbidden:

```
>>> class MoreColor(Color):
...     PINK = 17
...
Traceback (most recent call last):
...
TypeError: <enum 'MoreColor'> cannot extend <enum 'Color'
```

But this is allowed:

```
>>> class Foo(Enum):
...     def some_behavior(self):
...         pass
...
>>> class Bar(Foo):
...     HAPPY = 1
...     SAD = 2
...
```

Allowing subclassing of enums that define members would lead to a violation of some important invariants of types and instances. On the other hand, it makes sense to allow sharing some common behavior between a group of enumerations. (See [OrderedEnum](#) for an example.)

## Pickling

Enumerations can be pickled and unpickled:

```
>>> from test.test_enum import Fruit
>>> from pickle import dumps, loads
>>> Fruit.TOMATO is loads(dumps(Fruit.TOMATO))
True
```

The usual restrictions for pickling apply: picklable enums must be defined in the top level of a module, since unpickling requires them to be importable from that module.

## Note

With pickle protocol version 4 it is possible to easily pickle enums nested in other classes.

It is possible to modify how enum members are pickled/unpickled by defining `__reduce_ex__()` in the enumeration class. The default method is by-value, but enums with complicated values may want to use by-name:

```
>>> class MyEnum(Enum):  
...     __reduce_ex__ = enum.pickle_by_enum_name
```

## Note

Using by-name for flags is not recommended, as unnamed aliases will not unpickle.

# Functional API

The `Enum` class is callable, providing the following functional API:

```
>>> Animal = Enum('Animal', 'ANT BEE CAT DOG')  
>>> Animal  
<enum 'Animal'>  
>>> Animal.ANT  
<Animal.ANT: 1>  
>>> list(Animal)  
[<Animal.ANT: 1>, <Animal.BEE: 2>, <Animal.CAT: 3>, <Animal.DOG: 4>]
```

The semantics of this API resemble `namedtuple`. The first argument of the call to `Enum` is the name of the enumeration.

The second argument is the *source* of enumeration member names. It can be a whitespace-separated string of names, a sequence of names, a sequence of 2-tuples with key/value pairs, or a mapping (e.g. dictionary) of names to values. The last two options enable assigning arbitrary values to enumerations; the others auto-assign increasing integers starting with 1 (use the `start` parameter to

specify a different starting value). A new class derived from `Enum` is returned. In other words, the above assignment to `Animal` is equivalent to:

```
>>> class Animal(Enum):  
...     ANT = 1  
...     BEE = 2  
...     CAT = 3  
...     DOG = 4  
...
```

The reason for defaulting to 1 as the starting number and not 0 is that 0 is `False` in a boolean sense, but by default enum members all evaluate to `True`.

Pickling enums created with the functional API can be tricky as frame stack implementation details are used to try and figure out which module the enumeration is being created in (e.g. it will fail if you use a utility function in a separate module, and also may not work on IronPython or Jython). The solution is to specify the module name explicitly as follows:

```
>>> Animal = Enum('Animal', 'ANT BEE CAT DOG', module=___
```

## Warning

If `module` is not supplied, and `Enum` cannot determine what it is, the new `Enum` members will not be unpicklable; to keep errors closer to the source, pickling will be disabled.

The new pickle protocol 4 also, in some circumstances, relies on `__qualname__` being set to the location where pickle will be able to find the class. For example, if the class was made available in class `SomeData` in the global scope:

```
>>> Animal = Enum('Animal', 'ANT BEE CAT DOG', qualname=___
```

The complete signature is:

```
Enum (
```

```
value='NewEnumName',
names=<...>,
*,
module='...',
qualname='...',
type=<mixed-in class>,
start=1,
)
```

## **value**

What the new enum class will record as its name.

## **names**

The enum members. This can be a whitespace- or comma-separated string (values will start at 1 unless otherwise specified):

'RED GREEN BLUE' | 'RED, GREEN, BLUE' | 'RED GREEN BLUE'

or an iterator of names:

['RED', 'GREEN', 'BLUE']

or an iterator of (name, value) pairs:

[('CYAN', 4), ('MAGENTA', 5), ('YELLOW', 6)]

or a mapping:

{ 'CHARTREUSE': 7, 'SEA\_GREEN': 11, 'ROSEMARY': 12 }

## **module**

name of module where new enum class can be found.

## **qualname**

where in module new enum class can be found.

## **type**

type to mix in to new enum class.

**start**

number to start counting at if only names are passed in.

*Changed in version 3.5:* The *start* parameter was added.

## Derived Enumerations

### IntEnum

The first variation of `Enum` that is provided is also a subclass of `int`. Members of an `IntEnum` can be compared to integers; by extension, integer enumerations of different types can also be compared to each other:

```
>>> from enum import IntEnum
>>> class Shape(IntEnum):
...     CIRCLE = 1
...     SQUARE = 2
...
>>> class Request(IntEnum):
...     POST = 1
...     GET = 2
...
>>> Shape == 1
False
>>> Shape.CIRCLE == 1
True
>>> Shape.CIRCLE == Request.POST
True
```

However, they still can't be compared to standard `Enum` enumerations:

```
>>> class Shape(IntEnum):
...     CIRCLE = 1
...     SQUARE = 2
...
>>> class Color(Enum):
```

```
...     RED = 1
...     GREEN = 2
...
>>> Shape.CIRCLE == Color.RED
False
```

**IntEnum** values behave like integers in other ways you'd expect:

```
>>> int(Shape.CIRCLE)
1
>>> ['a', 'b', 'c'][Shape.CIRCLE]
'b'
>>> [i for i in range(Shape.SQUARE)]
[0, 1]
```

## StrEnum

The second variation of **Enum** that is provided is also a subclass of **str**. Members of a **StrEnum** can be compared to strings; by extension, string enumerations of different types can also be compared to each other.

*New in version 3.11.*

## IntFlag

The next variation of **Enum** provided, **IntFlag**, is also based on **int**. The difference being **IntFlag** members can be combined using the bitwise operators (&, |, ^, ~) and the result is still an **IntFlag** member, if possible. Like **IntEnum**, **IntFlag** members are also integers and can be used wherever an **int** is used.

### Note

Any operation on an **IntFlag** member besides the bit-wise operations will lose the **IntFlag** membership.

Bit-wise operations that result in invalid **IntFlag** values will lose the **IntFlag** membership. See **FlagBoundary** for details.

*New in version 3.6.*

*Changed in version 3.11.*

Sample **IntFlag** class:

```
>>> from enum import IntFlag
>>> class Perm(IntFlag):
...     R = 4
...     W = 2
...     X = 1
...
>>> Perm.R | Perm.W
<Perm.R|W: 6>
>>> Perm.R + Perm.W
6
>>> RW = Perm.R | Perm.W
>>> Perm.R in RW
True
```

It is also possible to name the combinations:

```
>>> class Perm(IntFlag):
...     R = 4
...     W = 2
...     X = 1
...     RWX = 7
>>> Perm.RWX
<Perm.RWX: 7>
>>> ~Perm.RWX
<Perm: 0>
>>> Perm(7)
<Perm.RWX: 7>
```

## Note

Named combinations are considered aliases. Aliases do not show up during iteration, but can be returned from by-value lookups.

*Changed in version 3.11.*

Another important difference between **IntFlag** and **Enum** is that if no flags are set (the value is 0), its boolean evaluation is **False**:

```
>>> Perm.R & Perm.X
<Perm: 0>
>>> bool(Perm.R & Perm.X)
False
```

Because **IntFlag** members are also subclasses of **int** they can be combined with them (but may lose **IntFlag** membership:

```
>>> Perm.X | 4
<Perm.R|X: 5>

>>> Perm.X | 8
9
```

## Note

The negation operator, `~`, always returns an **IntFlag** member with a positive value:

```
>>> (~Perm.X).value == (Perm.R|Perm.W).value == 6
True
```

**IntFlag** members can also be iterated over:

```
>>> list(RW)
[<Perm.R: 4>, <Perm.W: 2>]
```

*New in version 3.11.*

## Flag

The last variation is **Flag**. Like **IntFlag**, **Flag** members can be combined using the bitwise operators (`&`, `|`, `^`, `~`). Unlike **IntFlag**, they cannot be combined with, nor compared against, any other **Flag** enumeration, nor **int**. While it is possible to specify the

values directly it is recommended to use `auto` as the value and let `Flag` select an appropriate value.

*New in version 3.6.*

Like `IntFlag`, if a combination of `Flag` members results in no flags being set, the boolean evaluation is `False`:

```
>>> from enum import Flag, auto
>>> class Color(Flag):
...     RED = auto()
...     BLUE = auto()
...     GREEN = auto()
...
>>> Color.RED & Color.GREEN
<Color: 0>
>>> bool(Color.RED & Color.GREEN)
False
```

Individual flags should have values that are powers of two (1, 2, 4, 8, ...), while combinations of flags will not:

```
>>> class Color(Flag):
...     RED = auto()
...     BLUE = auto()
...     GREEN = auto()
...     WHITE = RED | BLUE | GREEN
...
>>> Color.WHITE
<Color.WHITE: 7>
```

Giving a name to the “no flags set” condition does not change its boolean value:

```
>>> class Color(Flag):
...     BLACK = 0
...     RED = auto()
...     BLUE = auto()
...     GREEN = auto()
...
```

```
>>> Color.BLACK
<Color.BLACK: 0>
>>> bool(Color.BLACK)
False
```

**Flag** members can also be iterated over:

```
>>> purple = Color.RED | Color.BLUE
>>> list(purple)
[<Color.RED: 1>, <Color.BLUE: 2>]
```

*New in version 3.11.*

## Note

For the majority of new code, **Enum** and **Flag** are strongly recommended, since **IntEnum** and **IntFlag** break some semantic promises of an enumeration (by being comparable to integers, and thus by transitivity to other unrelated enumerations). **IntEnum** and **IntFlag** should be used only in cases where **Enum** and **Flag** will not do; for example, when integer constants are replaced with enumerations, or for interoperability with other systems.

## Others

While **IntEnum** is part of the **enum** module, it would be very simple to implement independently:

```
class IntEnum(int, Enum):
    pass
```

This demonstrates how similar derived enumerations can be defined; for example a **FloatEnum** that mixes in **float** instead of **int**.

Some rules:

1. When subclassing **Enum**, mix-in types must appear before **Enum** itself in the sequence of bases, as in the **IntEnum**

example above.

2. Mix-in types must be subclassable. For example, `bool` and `range` are not subclassable and will throw an error during Enum creation if used as the mix-in type.
3. While `Enum` can have members of any type, once you mix in an additional type, all the members must have values of that type, e.g. `int` above. This restriction does not apply to mixins which only add methods and don't specify another type.
4. When another data type is mixed in, the `value` attribute is *not the same* as the enum member itself, although it is equivalent and will compare equal.
5. A data type is a mixin that defines `__new__()`.
6. %-style formatting: `%s` and `%r` call the `Enum` class's `__str__()` and `__repr__()` respectively; other codes (such as `%i` or `%h` for `IntEnum`) treat the enum member as its mixed-in type.
7. Formatted string literals, `str.format()`, and `format()` will use the enum's `__str__()` method.

## Note

Because `IntEnum`, `IntFlag`, and `StrEnum` are designed to be drop-in replacements for existing constants, their `__str__()` method has been reset to their data types' `__str__()` method.

## When to use `__new__()` vs. `__init__()`

`__new__()` must be used whenever you want to customize the actual value of the `Enum` member. Any other modifications may go in either `__new__()` or `__init__()`, with `__init__()` being preferred.

For example, if you want to pass several items to the constructor, but only want one of them to be the value:

```
>>> class Coordinate(bytes, Enum):
...     """
...     Coordinate with binary codes that can be indexed
...     """
```

```

...     def __new__(cls, value, label, unit):
...         obj = bytes.__new__(cls, [value])
...         obj._value_ = value
...         obj.label = label
...         obj.unit = unit
...         return obj
...     PX = (0, 'P.X', 'km')
...     PY = (1, 'P.Y', 'km')
...     VX = (2, 'V.X', 'km/s')
...     VY = (3, 'V.Y', 'km/s')
...

```

```

>>> print(Coordinate['PY'])
Coordinate.PY

```

```

>>> print(Coordinate(3))
Coordinate.VY

```

## Finer Points

### Supported `__dunder__` names

`__members__` is a read-only ordered mapping of `member_name:member` items. It is only available on the class.

`__new__()`, if specified, must create and return the enum members; it is also a very good idea to set the member's `__value__` appropriately. Once all the members are created it is no longer used.

### Supported `__sunder__` names

- `__name__` – name of the member
- `__value__` – value of the member; can be set / modified in `__new__`
- `__missing__` – a lookup function used when a value is not found; may be overridden
- `__ignore__` – a list of names, either as a [list](#) or a [str](#), that will not be transformed into members, and will be removed

from the final class

- `_order_` – used in Python 2/3 code to ensure member order is consistent (class attribute, removed during class creation)
- `_generate_next_value_` – used by the [Functional API](#) and by [auto](#) to get an appropriate value for an enum member; may be overridden

## Note

For standard [Enum](#) classes the next value chosen is the last value seen incremented by one.

For [Flag](#) classes the next value chosen will be the next highest power-of-two, regardless of the last value seen.

*New in version 3.6:* `_missing_`, `_order_`,  
`_generate_next_value_`

*New in version 3.7:* `_ignore_`

To help keep Python 2 / Python 3 code in sync an `_order_` attribute can be provided. It will be checked against the actual order of the enumeration and raise an error if the two do not match:

```
>>> class Color(Enum):
...     _order_ = 'RED GREEN BLUE'
...     RED = 1
...     BLUE = 3
...     GREEN = 2
...
Traceback (most recent call last):
...
TypeError: member order does not match _order_:
    ['RED', 'BLUE', 'GREEN']
    ['RED', 'GREEN', 'BLUE']
```

## Note

In Python 2 code the `_order_` attribute is necessary as definition order is lost before it can be recorded.

## **`_Private_names`**

**Private names** are not converted to enum members, but remain normal attributes.

*Changed in version 3.11.*

## **Enum member type**

Enum members are instances of their enum class, and are normally accessed as `EnumClass.member`. In certain situations, such as writing custom enum behavior, being able to access one member directly from another is useful, and is supported.

*Changed in version 3.5.*

## **Creating members that are mixed with other data types**

When subclassing other data types, such as `int` or `str`, with an **Enum**, all values after the `=` are passed to that data type's constructor. For example:

```
>>> class MyEnum(IntEnum):           # help(int) -> int(x, base)
...     example = '11', 16           # so x='11' and base=16
...
>>> MyEnum.example.value             # and hex(11) is...
17
```

## **Boolean value of Enum classes and members**

Enum classes that are mixed with non-**Enum** types (such as `int`, `str`, etc.) are evaluated according to the mixed-in type's rules; otherwise, all members evaluate as **True**. To make your own enum's boolean evaluation depend on the member's value add the following to your class:

```
def __bool__(self):
    return bool(self.value)
```

Plain **Enum** classes always evaluate as **True**.

## Enum classes with methods

If you give your enum subclass extra methods, like the **Planet** class below, those methods will show up in a **dir()** of the member, but not of the class:

```
>>> dir(Planet)
['EARTH', 'JUPITER', 'MARS', 'MERCURY', 'NEPTUNE', 'SATURN']
>>> dir(Planet.EARTH)
['__class__', '__doc__', '__module__', 'mass', 'name', 'radius']
```

## Combining members of Flag

Iterating over a combination of **Flag** members will only return the members that are comprised of a single bit:

```
>>> class Color(Flag):
...     RED = auto()
...     GREEN = auto()
...     BLUE = auto()
...     MAGENTA = RED | BLUE
...     YELLOW = RED | GREEN
...     CYAN = GREEN | BLUE
...
>>> Color(3) # named combination
<Color.YELLOW: 3>
>>> Color(7) # not named combination
<Color.RED|GREEN|BLUE: 7>
```

## Flag and IntFlag minutia

Using the following snippet for our examples:

```
>>> class Color(IntFlag):
```

```
...     BLACK = 0
...     RED = 1
...     GREEN = 2
...     BLUE = 4
...     PURPLE = RED | BLUE
...     WHITE = RED | GREEN | BLUE
...
```

the following are true:

- single-bit flags are canonical
- multi-bit and zero-bit flags are aliases
- only canonical flags are returned during iteration:

```
>>> list(Color.WHITE)
[<Color.RED: 1>, <Color.GREEN: 2>, <Color.BLUE: 4>]
```

- negating a flag or flag set returns a new flag/flag set with the corresponding positive integer value:

```
>>> Color.BLUE
<Color.BLUE: 4>
```

```
>>> ~Color.BLUE
<Color.RED|GREEN: 3>
```

- names of pseudo-flags are constructed from their members' names:

```
>>> (Color.RED | Color.GREEN).name
'RED|GREEN'
```

- multi-bit flags, aka aliases, can be returned from operations:

```
>>> Color.RED | Color.BLUE
<Color.PURPLE: 5>
```

```
>>> Color(7) # or Color(-1)
<Color.WHITE: 7>
```

```
>>> Color(0)
<Color.BLACK: 0>
```

- membership / containment checking: zero-valued flags are always considered to be contained:

```
>>> Color.BLACK in Color.WHITE
True
```

otherwise, only if all bits of one flag are in the other flag will True be returned:

```
>>> Color.PURPLE in Color.WHITE
True
```

```
>>> Color.GREEN in Color.PURPLE
False
```

There is a new boundary mechanism that controls how out-of-range / invalid bits are handled: `STRICT`, `CONFORM`, `EJECT`, and `KEEP`:

- `STRICT` -> raises an exception when presented with invalid values
- `CONFORM` -> discards any invalid bits
- `EJECT` -> lose Flag status and become a normal int with the given value
- `KEEP` -> keep the extra bits
  - keeps Flag status and extra bits
  - extra bits do not show up in iteration
  - extra bits do show up in `repr()` and `str()`

The default for Flag is `STRICT`, the default for `IntFlag` is `EJECT`, and the default for `_convert_` is `KEEP` (see `ssl.Options` for an example of when `KEEP` is needed).

## How are Enums and Flags different?

Enums have a custom metaclass that affects many aspects of both derived `Enum` classes and their instances (members).

## Enum Classes

The `EnumType` metaclass is responsible for providing the `__contains__()`, `__dir__()`, `__iter__()` and other methods that allow one to do things with an `Enum` class that fail on a typical class, such as `list(Color)` or `some_enum_var in Color`. `EnumType` is responsible for ensuring that various other methods on the final `Enum` class are correct (such as `__new__()`, `__getnewargs__()`, `__str__()` and `__repr__()`).

## Flag Classes

Flags have an expanded view of aliasing: to be canonical, the value of a flag needs to be a power-of-two value, and not a duplicate name. So, in addition to the `Enum` definition of alias, a flag with no value (a.k.a. 0) or with more than one power-of-two value (e.g. 3) is considered an alias.

## Enum Members (aka instances)

The most interesting thing about enum members is that they are singletons. `EnumType` creates them all while it is creating the enum class itself, and then puts a custom `__new__()` in place to ensure that no new ones are ever instantiated by returning only the existing member instances.

## Flag Members

Flag members can be iterated over just like the `Flag` class, and only the canonical members will be returned. For example:

```
>>> list(Color)
[<Color.RED: 1>, <Color.GREEN: 2>, <Color.BLUE: 4>]
```

(Note that `BLACK`, `PURPLE`, and `WHITE` do not show up.)

Inverting a flag member returns the corresponding positive value,

rather than a negative value — for example:

```
>>> ~Color.RED  
<Color.GREEN|BLUE: 6>
```

Flag members have a length corresponding to the number of power-of-two values they contain. For example:

```
>>> len(Color.PURPLE)  
2
```

## Enum Cookbook

While `Enum`, `IntEnum`, `StrEnum`, `Flag`, and `IntFlag` are expected to cover the majority of use-cases, they cannot cover them all. Here are recipes for some different types of enumerations that can be used directly, or as examples for creating one's own.

### Omitting values

In many use-cases, one doesn't care what the actual value of an enumeration is. There are several ways to define this type of simple enumeration:

- use instances of `auto` for the value
- use instances of `object` as the value
- use a descriptive string as the value
- use a tuple as the value and a custom `__new__()` to replace the tuple with an `int` value

Using any of these methods signifies to the user that these values are not important, and also enables one to add, remove, or reorder members without having to renumber the remaining members.

### Using `auto`

Using `auto` would look like:

```
>>> class Color(Enum):  
...     RED = auto()
```

```
...     BLUE = auto()
...     GREEN = auto()
...
>>> Color.GREEN
<Color.GREEN: 3>
```

## Using `object`

Using `object` would look like:

```
>>> class Color(Enum):
...     RED = object()
...     GREEN = object()
...     BLUE = object()
...
>>> Color.GREEN
<Color.GREEN: <object object at 0x...>>
```

This is also a good example of why you might want to write your own `__repr__()`:

```
>>> class Color(Enum):
...     RED = object()
...     GREEN = object()
...     BLUE = object()
...     def __repr__(self):
...         return "<%s.%s>" % (self.__class__.__name__,
...
...
>>> Color.GREEN
<Color.GREEN>
```

## Using a descriptive string

Using a string as the value would look like:

```
>>> class Color(Enum):
...     RED = 'stop'
...     GREEN = 'go'
...     BLUE = 'too fast!'
```

```

...         self.pantone = pantone
...     AUBURN = '3497'
...     SEA_GREEN = '1246'
...     BLEACHED_CORAL = () # New color, no Pantone code
...
>>> Swatch.SEA_GREEN
<Swatch.SEA_GREEN: 2>
>>> Swatch.SEA_GREEN.pantone
'1246'
>>> Swatch.BLEACHED_CORAL.pantone
'unknown'

```

## Note

The `__new__()` method, if defined, is used during creation of the Enum members; it is then replaced by Enum's `__new__()` which is used after class creation for lookup of existing members.

## OrderedEnum

An ordered enumeration that is not based on `IntEnum` and so maintains the normal `Enum` invariants (such as not being comparable to other enumerations):

```

>>> class OrderedEnum(Enum):
...     def __ge__(self, other):
...         if self.__class__ is other.__class__:
...             return self.value >= other.value
...         return NotImplemented
...     def __gt__(self, other):
...         if self.__class__ is other.__class__:
...             return self.value > other.value
...         return NotImplemented
...     def __le__(self, other):
...         if self.__class__ is other.__class__:
...             return self.value <= other.value
...         return NotImplemented
...     def __lt__(self, other):

```

```

...         if self.__class__ is other.__class__:
...             return self.value < other.value
...         return NotImplemented
...
>>> class Grade(OrderedEnum):
...     A = 5
...     B = 4
...     C = 3
...     D = 2
...     F = 1
...
>>> Grade.C < Grade.A
True

```

## DuplicateFreeEnum

Raises an error if a duplicate member value is found instead of creating an alias:

```

>>> class DuplicateFreeEnum(Enum):
...     def __init__(self, *args):
...         cls = self.__class__
...         if any(self.value == e.value for e in cls):
...             a = self.name
...             e = cls(self.value).name
...             raise ValueError(
...                 "aliases not allowed in DuplicateFreeEnum:
...                 % (a, e))
...
>>> class Color(DuplicateFreeEnum):
...     RED = 1
...     GREEN = 2
...     BLUE = 3
...     GRENE = 2
...
Traceback (most recent call last):
...
ValueError: aliases not allowed in DuplicateFreeEnum:

```

## Note

This is a useful example for subclassing Enum to add or change other behaviors as well as disallowing aliases. If the only desired change is disallowing aliases, the `unique()` decorator can be used instead.

## Planet

If `__new__()` or `__init__()` is defined, the value of the enum member will be passed to those methods:

```
>>> class Planet(Enum):
...     MERCURY = (3.303e+23, 2.4397e6)
...     VENUS   = (4.869e+24, 6.0518e6)
...     EARTH   = (5.976e+24, 6.37814e6)
...     MARS    = (6.421e+23, 3.3972e6)
...     JUPITER = (1.9e+27, 7.1492e7)
...     SATURN  = (5.688e+26, 6.0268e7)
...     URANUS  = (8.686e+25, 2.5559e7)
...     NEPTUNE = (1.024e+26, 2.4746e7)
...     def __init__(self, mass, radius):
...         self.mass = mass          # in kilograms
...         self.radius = radius      # in meters
...     @property
...     def surface_gravity(self):
...         # universal gravitational constant (m3 kg-1
...         G = 6.67300E-11
...         return G * self.mass / (self.radius * self.r
...
>>> Planet.EARTH.value
(5.976e+24, 6378140.0)
>>> Planet.EARTH.surface_gravity
9.802652743337129
```

## TimePeriod

An example to show the `__ignore__` attribute in use:

```

>>> from datetime import timedelta
>>> class Period(timedelta, Enum):
...     "different lengths of time"
...     _ignore_ = 'Period i'
...     Period = vars()
...     for i in range(367):
...         Period['day_%d' % i] = i
...
>>> list(Period)[:2]
[<Period.day_0: datetime.timedelta(0)>, <Period.day_1: datetime.timedelta(days=1)>]
>>> list(Period)[-2:]
[<Period.day_365: datetime.timedelta(days=365)>, <Period.day_366: datetime.timedelta(days=366)>]

```

## Subclassing EnumType

While most enum needs can be met by customizing [Enum](#) subclasses, either with class decorators or custom functions, [EnumType](#) can be subclassed to provide a different Enum experience.

# Functional Programming HOWTO

Author

A. M. Kuchling

Release

0.32

In this document, we'll take a tour of Python's features suitable for implementing programs in a functional style. After an introduction to the concepts of functional programming, we'll look at language features such as [iterators](#) and [generators](#) and relevant library modules such as [itertools](#) and [functools](#).

## Introduction

This section explains the basic concept of functional programming; if you're just interested in learning about Python language features, skip to the next section on [Iterators](#).

Programming languages support decomposing problems in several different ways:

- Most programming languages are **procedural**: programs are lists of instructions that tell the computer what to do with the program's input. C, Pascal, and even Unix shells are procedural languages.
- In **declarative** languages, you write a specification that describes the problem to be solved, and the language implementation figures out how to perform the computation efficiently. SQL is the declarative language you're most likely to be familiar with; a SQL query describes the data set you want to retrieve, and the SQL engine decides whether to scan tables or use indexes, which subclauses should be performed first, etc.

- **Object-oriented** programs manipulate collections of objects. Objects have internal state and support methods that query or modify this internal state in some way. Smalltalk and Java are object-oriented languages. C++ and Python are languages that support object-oriented programming, but don't force the use of object-oriented features.
- **Functional** programming decomposes a problem into a set of functions. Ideally, functions only take inputs and produce outputs, and don't have any internal state that affects the output produced for a given input. Well-known functional languages include the ML family (Standard ML, OCaml, and other variants) and Haskell.

The designers of some computer languages choose to emphasize one particular approach to programming. This often makes it difficult to write programs that use a different approach. Other languages are multi-paradigm languages that support several different approaches. Lisp, C++, and Python are multi-paradigm; you can write programs or libraries that are largely procedural, object-oriented, or functional in all of these languages. In a large program, different sections might be written using different approaches; the GUI might be object-oriented while the processing logic is procedural or functional, for example.

In a functional program, input flows through a set of functions. Each function operates on its input and produces some output. Functional style discourages functions with side effects that modify internal state or make other changes that aren't visible in the function's return value. Functions that have no side effects at all are called **purely functional**. Avoiding side effects means not using data structures that get updated as a program runs; every function's output must only depend on its input.

Some languages are very strict about purity and don't even have assignment statements such as `a=3` or `c = a + b`, but it's difficult to avoid all side effects, such as printing to the screen or writing to a disk file. Another example is a call to the `print()` or `time.sleep()` function, neither of which returns a useful value. Both are called only for their side effects of sending some text to the screen or pausing execution for a second.

Python programs written in functional style usually won't go to the extreme of avoiding all I/O or all assignments; instead, they'll provide a functional-appearing interface but will use non-functional features internally. For example, the implementation of a function will still use assignments to local variables, but won't modify global variables or have other side effects.

Functional programming can be considered the opposite of object-oriented programming. Objects are little capsules containing some internal state along with a collection of method calls that let you modify this state, and programs consist of making the right set of state changes. Functional programming wants to avoid state changes as much as possible and works with data flowing between functions. In Python you might combine the two approaches by writing functions that take and return instances representing objects in your application (e-mail messages, transactions, etc.).

Functional design may seem like an odd constraint to work under. Why should you avoid objects and side effects? There are theoretical and practical advantages to the functional style:

- Formal provability.
- Modularity.
- Composability.
- Ease of debugging and testing.

## Formal provability

A theoretical benefit is that it's easier to construct a mathematical proof that a functional program is correct.

For a long time researchers have been interested in finding ways to mathematically prove programs correct. This is different from testing a program on numerous inputs and concluding that its output is usually correct, or reading a program's source code and concluding that the code looks right; the goal is instead a rigorous proof that a program produces the right result for all possible inputs.

The technique used to prove programs correct is to write down **invariants**, properties of the input data and of the program's

variables that are always true. For each line of code, you then show that if invariants X and Y are true **before** the line is executed, the slightly different invariants X' and Y' are true **after** the line is executed. This continues until you reach the end of the program, at which point the invariants should match the desired conditions on the program's output.

Functional programming's avoidance of assignments arose because assignments are difficult to handle with this technique; assignments can break invariants that were true before the assignment without producing any new invariants that can be propagated onward.

Unfortunately, proving programs correct is largely impractical and not relevant to Python software. Even trivial programs require proofs that are several pages long; the proof of correctness for a moderately complicated program would be enormous, and few or none of the programs you use daily (the Python interpreter, your XML parser, your web browser) could be proven correct. Even if you wrote down or generated a proof, there would then be the question of verifying the proof; maybe there's an error in it, and you wrongly believe you've proved the program correct.

## Modularity

A more practical benefit of functional programming is that it forces you to break apart your problem into small pieces. Programs are more modular as a result. It's easier to specify and write a small function that does one thing than a large function that performs a complicated transformation. Small functions are also easier to read and to check for errors.

## Ease of debugging and testing

Testing and debugging a functional-style program is easier.

Debugging is simplified because functions are generally small and clearly specified. When a program doesn't work, each function is an interface point where you can check that the data are correct. You can look at the intermediate inputs and outputs to quickly isolate the function that's responsible for a bug.

Testing is easier because each function is a potential subject for a unit test. Functions don't depend on system state that needs to be replicated before running a test; instead you only have to synthesize the right input and then check that the output matches expectations.

## Composability

As you work on a functional-style program, you'll write a number of functions with varying inputs and outputs. Some of these functions will be unavoidably specialized to a particular application, but others will be useful in a wide variety of programs. For example, a function that takes a directory path and returns all the XML files in the directory, or a function that takes a filename and returns its contents, can be applied to many different situations.

Over time you'll form a personal library of utilities. Often you'll assemble new programs by arranging existing functions in a new configuration and writing a few functions specialized for the current task.

## Iterators

I'll start by looking at a Python language feature that's an important foundation for writing functional-style programs: iterators.

An iterator is an object representing a stream of data; this object returns the data one element at a time. A Python iterator must support a method called `__next__()` that takes no arguments and always returns the next element of the stream. If there are no more elements in the stream, `__next__()` must raise the `StopIteration` exception. Iterators don't have to be finite, though; it's perfectly reasonable to write an iterator that produces an infinite stream of data.

The built-in `iter()` function takes an arbitrary object and tries to return an iterator that will return the object's contents or elements, raising `TypeError` if the object doesn't support iteration. Several of Python's built-in data types support iteration, the most common being lists and dictionaries. An object is called `iterable` if you can

get an iterator for it.

You can experiment with the iteration interface manually:

```
>>> L = [1, 2, 3]
>>> it = iter(L)
>>> it
<...iterator object at ...>
>>> it.__next__() # same as next(it)
1
>>> next(it)
2
>>> next(it)
3
>>> next(it)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
StopIteration
>>>
```

Python expects iterable objects in several different contexts, the most important being the **for** statement. In the statement **for X in Y**, Y must be an iterator or some object for which **iter()** can create an iterator. These two statements are equivalent:

```
for i in iter(obj):
    print(i)
```

```
for i in obj:
    print(i)
```

Iterators can be materialized as lists or tuples by using the **list()** or **tuple()** constructor functions:

```
>>> L = [1, 2, 3]
>>> iterator = iter(L)
>>> t = tuple(iterator)
>>> t
(1, 2, 3)
```

Sequence unpacking also supports iterators: if you know an iterator will return N elements, you can unpack them into an N-tuple:

```
>>> L = [1, 2, 3]
>>> iterator = iter(L)
>>> a, b, c = iterator
>>> a, b, c
(1, 2, 3)
```

Built-in functions such as `max()` and `min()` can take a single iterator argument and will return the largest or smallest element. The `"in"` and `"not in"` operators also support iterators: `X in iterator` is true if X is found in the stream returned by the iterator. You'll run into obvious problems if the iterator is infinite; `max()`, `min()` will never return, and if the element X never appears in the stream, the `"in"` and `"not in"` operators won't return either.

Note that you can only go forward in an iterator; there's no way to get the previous element, reset the iterator, or make a copy of it. Iterator objects can optionally provide these additional capabilities, but the iterator protocol only specifies the `__next__()` method. Functions may therefore consume all of the iterator's output, and if you need to do something different with the same stream, you'll have to create a new iterator.

## Data Types That Support Iterators

We've already seen how lists and tuples support iterators. In fact, any Python sequence type, such as strings, will automatically support creation of an iterator.

Calling `iter()` on a dictionary returns an iterator that will loop over the dictionary's keys:

```
>>> m = {'Jan': 1, 'Feb': 2, 'Mar': 3, 'Apr': 4, 'May':
...      'Jul': 7, 'Aug': 8, 'Sep': 9, 'Oct': 10, 'Nov':
>>> for key in m:
...     print(key, m[key])
Jan 1
```

Feb 2

Apr 4  
May 5  
Jun 6  
Jul 7  
Aug 8  
Sep 9  
Oct 10  
Nov 11  
Dec 12

Note that starting with Python 3.7, dictionary iteration order is guaranteed to be the same as the insertion order. In earlier versions, the behaviour was unspecified and could vary between implementations.

Applying `iter()` to a dictionary always loops over the keys, but dictionaries have methods that return other iterators. If you want to iterate over values or key/value pairs, you can explicitly call the `values()` or `items()` methods to get an appropriate iterator.

The `dict()` constructor can accept an iterator that returns a finite stream of (key, value) tuples:

```
>>> L = [('Italy', 'Rome'), ('France', 'Paris'), ('US',  
>>> dict(iter(L))  
{'Italy': 'Rome', 'France': 'Paris', 'US': 'Washington D
```

Files also support iteration by calling the `readline()` method until there are no more lines in the file. This means you can read each line of a file like this:

```
for line in file:  
    # do something for each line  
    ...
```

Sets can take their contents from an iterable and let you iterate over the set's elements:

```
>>> S = {2, 3, 5, 7, 11, 13}
```

```
>>> for i in S:
...     print(i)
2
3
5
7
11
13
```

## Generator expressions and list comprehensions

Two common operations on an iterator's output are 1) performing some operation for every element, 2) selecting a subset of elements that meet some condition. For example, given a list of strings, you might want to strip off trailing whitespace from each line or extract all the strings containing a given substring.

List comprehensions and generator expressions (short form: “listcomps” and “genexps”) are a concise notation for such operations, borrowed from the functional programming language Haskell (<https://www.haskell.org/>). You can strip all the whitespace from a stream of strings with the following code:

```
>>> line_list = [' line 1\n', 'line 2  \n', ' \n', '']

>>> # Generator expression -- returns iterator
>>> stripped_iter = (line.strip() for line in line_list)

>>> # List comprehension -- returns list
>>> stripped_list = [line.strip() for line in line_list]
```

You can select only certain elements by adding an “if” condition:

```
>>> stripped_list = [line.strip() for line in line_list
...                  if line != ""]
```

With a list comprehension, you get back a Python list; `stripped_list` is a list containing the resulting lines, not an

iterator. Generator expressions return an iterator that computes the values as necessary, not needing to materialize all the values at once. This means that list comprehensions aren't useful if you're working with iterators that return an infinite stream or a very large amount of data. Generator expressions are preferable in these situations.

Generator expressions are surrounded by parentheses (“()”) and list comprehensions are surrounded by square brackets (“[]”). Generator expressions have the form:

```
( expression for expr in sequence1
    if condition1
    for expr2 in sequence2
    if condition2
    for expr3 in sequence3
    ...
    if condition3
    for exprN in sequenceN
    if conditionN )
```

Again, for a list comprehension only the outside brackets are different (square brackets instead of parentheses).

The elements of the generated output will be the successive values of `expression`. The `if` clauses are all optional; if present, `expression` is only evaluated and added to the result when `condition` is true.

Generator expressions always have to be written inside parentheses, but the parentheses signalling a function call also count. If you want to create an iterator that will be immediately passed to a function you can write:

```
obj_total = sum(obj.count for obj in list_all_objects())
```

The `for...in` clauses contain the sequences to be iterated over. The sequences do not have to be the same length, because they are iterated over from left to right, **not** in parallel. For each element in `sequence1`, `sequence2` is looped over from the beginning. `sequence3` is then looped over for each resulting pair of elements

from sequence1 and sequence2.

To put it another way, a list comprehension or generator expression is equivalent to the following Python code:

```
for expr1 in sequence1:
    if not (condition1):
        continue    # Skip this element
for expr2 in sequence2:
    if not (condition2):
        continue    # Skip this element
...
for exprN in sequenceN:
    if not (conditionN):
        continue    # Skip this element

    # Output the value of
    # the expression.
```

This means that when there are multiple `for...in` clauses but no `if` clauses, the length of the resulting output will be equal to the product of the lengths of all the sequences. If you have two lists of length 3, the output list is 9 elements long:

```
>>> seq1 = 'abc'
>>> seq2 = (1, 2, 3)
>>> [(x, y) for x in seq1 for y in seq2]
[('a', 1), ('a', 2), ('a', 3),
 ('b', 1), ('b', 2), ('b', 3),
 ('c', 1), ('c', 2), ('c', 3)]
```

To avoid introducing an ambiguity into Python's grammar, if expression is creating a tuple, it must be surrounded with parentheses. The first list comprehension below is a syntax error, while the second one is correct:

```
# Syntax error
[x, y for x in seq1 for y in seq2]
# Correct
[(x, y) for x in seq1 for y in seq2]
```

# Generators

Generators are a special class of functions that simplify the task of writing iterators. Regular functions compute a value and return it, but generators return an iterator that returns a stream of values.

You're doubtless familiar with how regular function calls work in Python or C. When you call a function, it gets a private namespace where its local variables are created. When the function reaches a `return` statement, the local variables are destroyed and the value is returned to the caller. A later call to the same function creates a new private namespace and a fresh set of local variables. But, what if the local variables weren't thrown away on exiting a function? What if you could later resume the function where it left off? This is what generators provide; they can be thought of as resumable functions.

Here's the simplest example of a generator function:

```
>>> def generate_ints(N):  
...     for i in range(N):  
...         yield i
```

Any function containing a `yield` keyword is a generator function; this is detected by Python's `bytecode` compiler which compiles the function specially as a result.

When you call a generator function, it doesn't return a single value; instead it returns a generator object that supports the iterator protocol. On executing the `yield` expression, the generator outputs the value of `i`, similar to a `return` statement. The big difference between `yield` and a `return` statement is that on reaching a `yield` the generator's state of execution is suspended and local variables are preserved. On the next call to the generator's `__next__()` method, the function will resume executing.

Here's a sample usage of the `generate_ints()` generator:

```
>>> gen = generate_ints(3)  
>>> gen
```

```

<generator object generate_ints at ...>
>>> next(gen)
0
>>> next(gen)
1
>>> next(gen)
2
>>> next(gen)
Traceback (most recent call last):
  File "stdin", line 1, in <module>
  File "stdin", line 2, in generate_ints
StopIteration

```

You could equally write `for i in generate_ints(5), or a, b, c = generate_ints(3).`

Inside a generator function, `return value` causes `StopIteration(value)` to be raised from the `__next__()` method. Once this happens, or the bottom of the function is reached, the procession of values ends and the generator cannot yield any further values.

You could achieve the effect of generators manually by writing your own class and storing all the local variables of the generator as instance variables. For example, returning a list of integers could be done by setting `self.count` to 0, and having the `__next__()` method increment `self.count` and return it. However, for a moderately complicated generator, writing a corresponding class can be much messier.

The test suite included with Python's library, [Lib/test/test\\_generators.py](https://github.com/python/cpython/tree/3.11/Lib/test/test_generators.py) [https://github.com/python/cpython/tree/3.11/Lib/test/test\_generators.py], contains a number of more interesting examples. Here's one generator that implements an in-order traversal of a tree using generators recursively.

```

# A recursive generator that generates Tree leaves in in
def inorder(t):
    if t:
        for x in inorder(t.left):

```

```
        yield x

    yield t.label

    for x in inorder(t.right):
        yield x
```

Two other examples in `test_generators.py` produce solutions for the N-Queens problem (placing N queens on an NxN chess board so that no queen threatens another) and the Knight's Tour (finding a route that takes a knight to every square of an NxN chessboard without visiting any square twice).

## Passing values into a generator

In Python 2.4 and earlier, generators only produced output. Once a generator's code was invoked to create an iterator, there was no way to pass any new information into the function when its execution is resumed. You could hack together this ability by making the generator look at a global variable or by passing in some mutable object that callers then modify, but these approaches are messy.

In Python 2.5 there's a simple way to pass values into a generator. `yield` became an expression, returning a value that can be assigned to a variable or otherwise operated on:

```
val = (yield i)
```

I recommend that you **always** put parentheses around a `yield` expression when you're doing something with the returned value, as in the above example. The parentheses aren't always necessary, but it's easier to always add them instead of having to remember when they're needed.

([PEP 342](https://peps.python.org/pep-0342/) [https://peps.python.org/pep-0342/] explains the exact rules, which are that a `yield`-expression must always be parenthesized except when it occurs at the top-level expression on the right-hand side of an assignment. This means you can write `val = yield i` but have to use parentheses when there's an operation, as in `val`

```
= (yield i) + 12.)
```

Values are sent into a generator by calling its `send(value)` method. This method resumes the generator's code and the `yield` expression returns the specified value. If the regular `__next__()` method is called, the `yield` returns `None`.

Here's a simple counter that increments by 1 and allows changing the value of the internal counter.

```
def counter(maximum):
    i = 0
    while i < maximum:
        val = (yield i)
        # If value provided, change counter
        if val is not None:
            i = val
        else:
            i += 1
```

And here's an example of changing the counter:

```
>>> it = counter(10)
>>> next(it)
0
>>> next(it)
1
>>> it.send(8)
8
>>> next(it)
9
>>> next(it)
Traceback (most recent call last):
  File "t.py", line 15, in <module>
    it.next()
StopIteration
```

Because `yield` will often be returning `None`, you should always check for this case. Don't just use its value in expressions unless you're sure that the `send()` method will be the only method used

to resume your generator function.

In addition to `send()`, there are two other methods on generators:

- `throw(value)` is used to raise an exception inside the generator; the exception is raised by the `yield` expression where the generator's execution is paused.
- `close()` raises a `GeneratorExit` exception inside the generator to terminate the iteration. On receiving this exception, the generator's code must either raise `GeneratorExit` or `StopIteration`; catching the exception and doing anything else is illegal and will trigger a `RuntimeError`. `close()` will also be called by Python's garbage collector when the generator is garbage-collected.

If you need to run cleanup code when a `GeneratorExit` occurs, I suggest using a `try: ... finally: suite` instead of catching `GeneratorExit`.

The cumulative effect of these changes is to turn generators from one-way producers of information into both producers and consumers.

Generators also become **coroutines**, a more generalized form of subroutines. Subroutines are entered at one point and exited at another point (the top of the function, and a `return` statement), but coroutines can be entered, exited, and resumed at many different points (the `yield` statements).

## Built-in functions

Let's look in more detail at built-in functions often used with iterators.

Two of Python's built-in functions, `map()` and `filter()` duplicate the features of generator expressions:

`map(f, iterA, iterB, ...)` returns an iterator over the sequence

```

f(iterA[0], iterB[0]), f(iterA[1], iterB[1]),
f(iterA[2], iterB[2]), ....

>>> def upper(s):
...     return s.upper()

>>> list(map(upper, ['sentence', 'fragment']))
['SENTENCE', 'FRAGMENT']
>>> [upper(s) for s in ['sentence', 'fragment']]
['SENTENCE', 'FRAGMENT']

```

You can of course achieve the same effect with a list comprehension.

**filter(predicate, iter)** returns an iterator over all the sequence elements that meet a certain condition, and is similarly duplicated by list comprehensions. A **predicate** is a function that returns the truth value of some condition; for use with **filter()**, the predicate must take a single value.

```

>>> def is_even(x):
...     return (x % 2) == 0

>>> list(filter(is_even, range(10)))
[0, 2, 4, 6, 8]

```

This can also be written as a list comprehension:

```

>>> list(x for x in range(10) if is_even(x))
[0, 2, 4, 6, 8]

```

**enumerate(iter, start=0)** counts off the elements in the iterable returning 2-tuples containing the count (from *start*) and each element.

```

>>> for item in enumerate(['subject', 'verb', 'object']):
...     print(item)
(0, 'subject')
(1, 'verb')
(2, 'object')

```

**enumerate()** is often used when looping through a list and recording the indexes at which certain conditions are met:

```
f = open('data.txt', 'r')
for i, line in enumerate(f):
    if line.strip() == '':
        print('Blank line at line #%i' % i)
```

**sorted(iterable, key=None, reverse=False)** collects all the elements of the iterable into a list, sorts the list, and returns the sorted result. The *key* and *reverse* arguments are passed through to the constructed list's **sort()** method.

```
>>> import random
>>> # Generate 8 random numbers between [0, 10000)
>>> rand_list = random.sample(range(10000), 8)
>>> rand_list
[769, 7953, 9828, 6431, 8442, 9878, 6213, 2207]
>>> sorted(rand_list)
[769, 2207, 6213, 6431, 7953, 8442, 9828, 9878]
>>> sorted(rand_list, reverse=True)
[9878, 9828, 8442, 7953, 6431, 6213, 2207, 769]
```

(For a more detailed discussion of sorting, see the [Sorting HOW TO](#).)

The **any(iter)** and **all(iter)** built-ins look at the truth values of an iterable's contents. **any()** returns `True` if any element in the iterable is a true value, and **all()** returns `True` if all of the elements are true values:

```
>>> any([0, 1, 0])
True
>>> any([0, 0, 0])
False
>>> any([1, 1, 1])
True
>>> all([0, 1, 0])
False
>>> all([0, 0, 0])
```

```
False
>>> all([1, 1, 1])
True
```

`zip(iterA, iterB, ...)` takes one element from each iterable and returns them in a tuple:

```
zip(['a', 'b', 'c'], (1, 2, 3)) =>
    ('a', 1), ('b', 2), ('c', 3)
```

It doesn't construct an in-memory list and exhaust all the input iterators before returning; instead tuples are constructed and returned only if they're requested. (The technical term for this behaviour is [lazy evaluation](https://en.wikipedia.org/wiki/Lazy_evaluation) [https://en.wikipedia.org/wiki/Lazy\_evaluation].)

This iterator is intended to be used with iterables that are all of the same length. If the iterables are of different lengths, the resulting stream will be the same length as the shortest iterable.

```
zip(['a', 'b'], (1, 2, 3)) =>
    ('a', 1), ('b', 2)
```

You should avoid doing this, though, because an element may be taken from the longer iterators and discarded. This means you can't go on to use the iterators further because you risk skipping a discarded element.

## The `itertools` module

The `itertools` module contains a number of commonly used iterators as well as functions for combining several iterators. This section will introduce the module's contents by showing small examples.

The module's functions fall into a few broad classes:

- Functions that create a new iterator based on an existing iterator.
- Functions for treating an iterator's elements as function

arguments.

- Functions for selecting portions of an iterator's output.
- A function for grouping an iterator's output.

## Creating new iterators

**`itertools.count(start, step)`** returns an infinite stream of evenly spaced values. You can optionally supply the starting number, which defaults to 0, and the interval between numbers, which defaults to 1:

```
itertools.count() =>
    0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
itertools.count(10) =>
    10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...
itertools.count(10, 5) =>
    10, 15, 20, 25, 30, 35, 40, 45, 50, 55, ...
```

**`itertools.cycle(iter)`** saves a copy of the contents of a provided iterable and returns a new iterator that returns its elements from first to last. The new iterator will repeat these elements infinitely.

```
itertools.cycle([1, 2, 3, 4, 5]) =>
    1, 2, 3, 4, 5, 1, 2, 3, 4, 5, ...
```

**`itertools.repeat(elem, [n])`** returns the provided element *n* times, or returns the element endlessly if *n* is not provided.

```
itertools.repeat('abc') =>
    abc, abc, abc, abc, abc, abc, abc, abc, abc, abc, ...
itertools.repeat('abc', 5) =>
    abc, abc, abc, abc, abc
```

**`itertools.chain(iterA, iterB, ...)`** takes an arbitrary number of iterables as input, and returns all the elements of the first iterator, then all the elements of the second, and so on, until all of the iterables have been exhausted.

```
itertools.chain(['a', 'b', 'c'], (1, 2, 3)) =>
```

```
a, b, c, 1, 2, 3
```

**`itertools.islice(iter, [start], stop, [step])`**

returns a stream that's a slice of the iterator. With a single *stop* argument, it will return the first *stop* elements. If you supply a starting index, you'll get *stop-start* elements, and if you supply a value for *step*, elements will be skipped accordingly. Unlike Python's string and list slicing, you can't use negative values for *start*, *stop*, or *step*.

```
itertools.islice(range(10), 8) =>
    0, 1, 2, 3, 4, 5, 6, 7
itertools.islice(range(10), 2, 8) =>
    2, 3, 4, 5, 6, 7
itertools.islice(range(10), 2, 8, 2) =>
    2, 4, 6
```

**`itertools.tee(iter, [n])`** replicates an iterator; it returns *n* independent iterators that will all return the contents of the source iterator. If you don't supply a value for *n*, the default is 2. Replicating iterators requires saving some of the contents of the source iterator, so this can consume significant memory if the iterator is large and one of the new iterators is consumed more than the others.

```
itertools.tee( itertools.count() ) =>
    iterA, iterB
```

```
where iterA ->
    0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
```

```
and iterB ->
    0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
```

## Calling functions on elements

The **`operator`** module contains a set of functions corresponding to Python's operators. Some examples are **`operator.add(a, b)`** (adds two values), **`operator.ne(a, b)`** (same as `a != b`), and **`operator.attrgetter('id')`** (returns a callable that fetches

the `.id` attribute).

**`itertools.starmap(func, iter)`** assumes that the iterable will return a stream of tuples, and calls *func* using these tuples as the arguments:

```
itertools.starmap(os.path.join,
                  [('/bin', 'python'), ('/usr', 'bin', 'python'),
                   ('/usr', 'bin', 'perl'), ('/usr', 'bin', 'ruby')])
=>
    /bin/python, /usr/bin/java, /usr/bin/perl, /usr/bin/ruby
```

## Selecting elements

Another group of functions chooses a subset of an iterator's elements based on a predicate.

**`itertools.filterfalse(predicate, iter)`** is the opposite of **`filter()`**, returning all elements for which the predicate returns false:

```
itertools.filterfalse(is_even, itertools.count()) =>
    1, 3, 5, 7, 9, 11, 13, 15, ...
```

**`itertools.takewhile(predicate, iter)`** returns elements for as long as the predicate returns true. Once the predicate returns false, the iterator will signal the end of its results.

```
def less_than_10(x):
    return x < 10
```

```
itertools.takewhile(less_than_10, itertools.count()) =>
    0, 1, 2, 3, 4, 5, 6, 7, 8, 9
```

```
itertools.takewhile(is_even, itertools.count()) =>
    0
```

**`itertools.dropwhile(predicate, iter)`** discards elements while the predicate returns true, and then returns the rest of the iterable's results.

```
itertools.dropwhile(less_than_10, itertools.count()) =>
    10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...

itertools.dropwhile(is_even, itertools.count()) =>
    1, 2, 3, 4, 5, 6, 7, 8, 9, 10, ...
```

**`itertools.compress(data, selectors)`** takes two iterators and returns only those elements of *data* for which the corresponding element of *selectors* is true, stopping whenever either one is exhausted:

```
itertools.compress([1, 2, 3, 4, 5], [True, True, False,
    1, 2, 5
```

## Combinatoric functions

The **`itertools.combinations(iterable, r)`** returns an iterator giving all possible *r*-tuple combinations of the elements contained in *iterable*.

```
itertools.combinations([1, 2, 3, 4, 5], 2) =>
    (1, 2), (1, 3), (1, 4), (1, 5),
    (2, 3), (2, 4), (2, 5),
    (3, 4), (3, 5),
    (4, 5)
```

```
itertools.combinations([1, 2, 3, 4, 5], 3) =>
    (1, 2, 3), (1, 2, 4), (1, 2, 5), (1, 3, 4), (1, 3, 5),
    (2, 3, 4), (2, 3, 5), (2, 4, 5),
    (3, 4, 5)
```

The elements within each tuple remain in the same order as *iterable* returned them. For example, the number 1 is always before 2, 3, 4, or 5 in the examples above. A similar function, **`itertools.permutations(iterable, r=None)`**, removes this constraint on the order, returning all possible arrangements of length *r*:

```
itertools.permutations([1, 2, 3, 4, 5], 2) =>
    (1, 2), (1, 3), (1, 4), (1, 5),
```

```
(2, 1), (2, 3), (2, 4), (2, 5),  
(3, 1), (3, 2), (3, 4), (3, 5),  
(4, 1), (4, 2), (4, 3), (4, 5),  
(5, 1), (5, 2), (5, 3), (5, 4)
```

```
itertools.permutations([1, 2, 3, 4, 5]) =>  
    (1, 2, 3, 4, 5), (1, 2, 3, 5, 4), (1, 2, 4, 3, 5),  
    ...  
    (5, 4, 3, 2, 1)
```

If you don't supply a value for *r* the length of the iterable is used, meaning that all the elements are permuted.

Note that these functions produce all of the possible combinations by position and don't require that the contents of *iterable* are unique:

```
itertools.permutations('aba', 3) =>  
    ('a', 'b', 'a'), ('a', 'a', 'b'), ('b', 'a', 'a'),  
    ('b', 'a', 'a'), ('a', 'a', 'b'), ('a', 'b', 'a')
```

The identical tuple ('a', 'a', 'b') occurs twice, but the two 'a' strings came from different positions.

The

**`itertools.combinations_with_replacement(iterable, r)`** function relaxes a different constraint: elements can be repeated within a single tuple. Conceptually an element is selected for the first position of each tuple and then is replaced before the second element is selected.

```
itertools.combinations_with_replacement([1, 2, 3, 4, 5],  
    (1, 1), (1, 2), (1, 3), (1, 4), (1, 5),  
    (2, 2), (2, 3), (2, 4), (2, 5),  
    (3, 3), (3, 4), (3, 5),  
    (4, 4), (4, 5),  
    (5, 5))
```

## Grouping elements

The last function I'll discuss, `itertools.groupby(iter, key_func=None)`, is the most complicated. `key_func(elem)` is a function that can compute a key value for each element returned by the iterable. If you don't supply a key function, the key is simply each element itself.

`groupby()` collects all the consecutive elements from the underlying iterable that have the same key value, and returns a stream of 2-tuples containing a key value and an iterator for the elements with that key.

```
city_list = [('Decatur', 'AL'), ('Huntsville', 'AL'), ('Tuscaloosa', 'AL'),
             ('Anchorage', 'AK'), ('Nome', 'AK'),
             ('Flagstaff', 'AZ'), ('Phoenix', 'AZ'), ('Tucson', 'AZ'),
             ...
            ]
```

```
def get_state(city_state):
    return city_state[1]
```

```
itertools.groupby(city_list, get_state) =>
    ('AL', iterator-1),
    ('AK', iterator-2),
    ('AZ', iterator-3), ...
```

where

```
iterator-1 =>
    ('Decatur', 'AL'), ('Huntsville', 'AL'), ('Selma', 'AL'), ...
iterator-2 =>
    ('Anchorage', 'AK'), ('Nome', 'AK')
iterator-3 =>
    ('Flagstaff', 'AZ'), ('Phoenix', 'AZ'), ('Tucson', 'AZ'), ...
```

`groupby()` assumes that the underlying iterable's contents will already be sorted based on the key. Note that the returned iterators also use the underlying iterable, so you have to consume the results of iterator-1 before requesting iterator-2 and its corresponding key.

## The functools module

The `functools` module contains some higher-order functions. A **higher-order function** takes one or more functions as input and returns a new function. The most useful tool in this module is the `functools.partial()` function.

For programs written in a functional style, you'll sometimes want to construct variants of existing functions that have some of the parameters filled in. Consider a Python function `f(a, b, c)`; you may wish to create a new function `g(b, c)` that's equivalent to `f(1, b, c)`; you're filling in a value for one of `f()`'s parameters. This is called “partial function application”.

The constructor for `partial()` takes the arguments `(function, arg1, arg2, ..., kwarg1=value1, kwarg2=value2)`. The resulting object is callable, so you can just call it to invoke `function` with the filled-in arguments.

Here's a small but realistic example:

```
import functools

def log(message, subsystem):
    """Write the contents of 'message' to the specified
    print('%s: %s' % (subsystem, message))
    ...

server_log = functools.partial(log, subsystem='server')
server_log('Unable to open socket')
```

`functools.reduce(func, iter, [initial_value])` cumulatively performs an operation on all the iterable's elements and, therefore, can't be applied to infinite iterables. *func* must be a function that takes two elements and returns a single value. `functools.reduce()` takes the first two elements A and B returned by the iterator and calculates `func(A, B)`. It then requests the third element, C, calculates `func(func(A, B), C)`, combines this result with the fourth element returned, and continues until the iterable is exhausted. If the iterable returns no values at all, a `TypeError` exception is raised. If the initial value is supplied, it's used as a starting point and

`func(initial_value, A)` is the first calculation.

```
>>> import operator, functools
>>> functools.reduce(operator.concat, ['A', 'BB', 'C'])
'ABBC'
>>> functools.reduce(operator.concat, [])
Traceback (most recent call last):
...
TypeError: reduce() of empty sequence with no initial value
>>> functools.reduce(operator.mul, [1, 2, 3], 1)
6
>>> functools.reduce(operator.mul, [], 1)
1
```

If you use `operator.add()` with `functools.reduce()`, you'll add up all the elements of the iterable. This case is so common that there's a special built-in called `sum()` to compute it:

```
>>> import functools, operator
>>> functools.reduce(operator.add, [1, 2, 3, 4], 0)
10
>>> sum([1, 2, 3, 4])
10
>>> sum([])
0
```

For many uses of `functools.reduce()`, though, it can be clearer to just write the obvious `for` loop:

```
import functools
# Instead of:
product = functools.reduce(operator.mul, [1, 2, 3], 1)

# You can write:
product = 1
for i in [1, 2, 3]:
    product *= i
```

A related function is `itertools.accumulate(iterable, func=operator.add)`. It performs the same calculation, but

instead of returning only the final result, `accumulate()` returns an iterator that also yields each partial result:

```
itertools.accumulate([1, 2, 3, 4, 5]) =>  
1, 3, 6, 10, 15
```

```
itertools.accumulate([1, 2, 3, 4, 5], operator.mul) =>  
1, 2, 6, 24, 120
```

## The operator module

The `operator` module was mentioned earlier. It contains a set of functions corresponding to Python's operators. These functions are often useful in functional-style code because they save you from writing trivial functions that perform a single operation.

Some of the functions in this module are:

- Math operations: `add()`, `sub()`, `mul()`, `floordiv()`, `abs()`, ...
- Logical operations: `not_()`, `truth()`.
- Bitwise operations: `and_()`, `or_()`, `invert()`.
- Comparisons: `eq()`, `ne()`, `lt()`, `le()`, `gt()`, and `ge()`.
- Object identity: `is_()`, `is_not()`.

Consult the operator module's documentation for a complete list.

## Small functions and the lambda expression

When writing functional-style programs, you'll often need little functions that act as predicates or that combine elements in some way.

If there's a Python built-in or a module function that's suitable, you don't need to define a new function at all:

```
stripped_lines = [line.strip() for line in lines]  
existing_files = filter(os.path.exists, file_list)
```

If the function you need doesn't exist, you need to write it. One way to write small functions is to use the `lambda` expression. `lambda` takes a number of parameters and an expression combining these parameters, and creates an anonymous function that returns the value of the expression:

```
adder = lambda x, y: x+y
```

```
print_assign = lambda name, value: name + '=' + str(value)
```

An alternative is to just use the `def` statement and define a function in the usual way:

```
def adder(x, y):  
    return x + y
```

```
def print_assign(name, value):  
    return name + '=' + str(value)
```

Which alternative is preferable? That's a style question; my usual course is to avoid using `lambda`.

One reason for my preference is that `lambda` is quite limited in the functions it can define. The result has to be computable as a single expression, which means you can't have multiway `if...elif...else` comparisons or `try...except` statements. If

you try to do too much in a `lambda` statement, you'll end up with an overly complicated expression that's hard to read. Quick, what's the following code doing?

```
import functools  
total = functools.reduce(lambda a, b: (0, a[1] + b[1]),
```

You can figure it out, but it takes time to disentangle the expression to figure out what's going on. Using a short nested `def` statements makes things a little bit better:

```
import functools  
def combine(a, b):  
    return 0, a[1] + b[1]
```

```
total = functools.reduce(combine, items)[1]
```

But it would be best of all if I had simply used a `for` loop:

```
total = 0
for a, b in items:
    total += b
```

Or the `sum()` built-in and a generator expression:

```
total = sum(b for a, b in items)
```

Many uses of `functools.reduce()` are clearer when written as `for` loops.

Fredrik Lundh once suggested the following set of rules for refactoring uses of `lambda`:

1. Write a `lambda` function.
2. Write a comment explaining what the heck that `lambda` does.
3. Study the comment for a while, and think of a name that captures the essence of the comment.
4. Convert the `lambda` to a `def` statement, using that name.
5. Remove the comment.

I really like these rules, but you're free to disagree about whether this `lambda`-free style is better.

## Revision History and Acknowledgements

The author would like to thank the following people for offering suggestions, corrections and assistance with various drafts of this article: Ian Bicking, Nick Coghlan, Nick Efford, Raymond Hettinger, Jim Jewett, Mike Krell, Leandro Lameiro, Jussi Salmela, Collin Winter, Blake Winton.

Version 0.1: posted June 30 2006.

Version 0.11: posted July 1 2006. Typo fixes.

Version 0.2: posted July 10 2006. Merged `genexp` and `listcomp`

sections into one. Typo fixes.

Version 0.21: Added more references suggested on the tutor mailing list.

Version 0.30: Adds a section on the `functional` module written by Collin Winter; adds short section on the operator module; a few other edits.

# Logging HOWTO

Author

Vinay Sajip <vinay\_sajip at red-dove dot com>

## Basic Logging Tutorial

Logging is a means of tracking events that happen when some software runs. The software's developer adds logging calls to their code to indicate that certain events have occurred. An event is described by a descriptive message which can optionally contain variable data (i.e. data that is potentially different for each occurrence of the event). Events also have an importance which the developer ascribes to the event; the importance can also be called the *level* or *severity*.

## When to use logging

Logging provides a set of convenience functions for simple logging usage. These are `debug()`, `info()`, `warning()`, `error()` and `critical()`. To determine when to use logging, see the table below, which states, for each of a set of common tasks, the best tool to use for it.

### The best tool for the task

---

Task	Best tool
Display console output for ordinary usage of a command line script or program	<code>display()</code>

---

Report events that occur during normal operation of a program (e.g. for diagnostic purposes)	<code>logging.info()</code>
----------------------------------------------------------------------------------------------	-----------------------------

---

Issue a warning regarding a particular situation if the issue is avoidable and the client application should be modified to eliminate the warning	<code>logging.warning()</code>
---------------------------------------------------------------------------------------------------------------------------------------------------	--------------------------------

---

Report an exception regarding a particular runtime event	<code>logging.error()</code>
----------------------------------------------------------	------------------------------

---

Report suppression of an error without raising an exception (e.g. <code>error_handler_in_log()</code> using <code>suppress()</code> for the specific error and application domain)	<code>logging.error()</code>
------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------	------------------------------

---

The logging functions are named after the level or severity of the events they are used to track. The standard levels and their applicability are described below (in increasing order of severity):

### When it's used

---

Detailed information, typically of interest only when diagnosing problems.
----------------------------------------------------------------------------

---

Confirmation that things are working as expected.
---------------------------------------------------

---

A warning that something unexpected happened, or indicative of some problem in the near future (e.g. 'disk space low'). The software is still working as expected.
--------------------------------------------------------------------------------------------------------------------------------------------------------------------

---

Due to a more serious problem, the software has not been able to perform some function.
-----------------------------------------------------------------------------------------

---

A serious error, indicating that the program itself may be unable to continue running.
----------------------------------------------------------------------------------------

---

The default level is `WARNING`, which means that only events of this

level and above will be tracked, unless the logging package is configured to do otherwise.

Events that are tracked can be handled in different ways. The simplest way of handling tracked events is to print them to the console. Another common way is to write them to a disk file.

## A simple example

A very simple example is:

```
import logging
logging.warning('Watch out!') # will print a message to the console
logging.info('I told you so') # will not print anything
```

If you type these lines into a script and run it, you'll see:

```
WARNING:root:Watch out!
```

printed out on the console. The `INFO` message doesn't appear because the default level is `WARNING`. The printed message includes the indication of the level and the description of the event provided in the logging call, i.e. 'Watch out!'. Don't worry about the 'root' part for now: it will be explained later. The actual output can be formatted quite flexibly if you need that; formatting options will also be explained later.

## Logging to a file

A very common situation is that of recording logging events in a file, so let's look at that next. Be sure to try the following in a newly started Python interpreter, and don't just continue from the session described above:

```
import logging
logging.basicConfig(filename='example.log', encoding='utf-8')
logging.debug('This message should go to the log file')
logging.info('So should this')
logging.warning('And this, too')
logging.error('And non-ASCII stuff, too, like Øresund and Ælfric')
```

*Changed in version 3.9:* The *encoding* argument was added. In earlier Python versions, or if not specified, the encoding used is the default value used by `open()`. While not shown in the above example, an *errors* argument can also now be passed, which determines how encoding errors are handled. For available values and the default, see the documentation for `open()`.

And now if we open the file and look at what we have, we should find the log messages:

```
DEBUG:root:This message should go to the log file
INFO:root:So should this
WARNING:root:And this, too
ERROR:root:And non-ASCII stuff, too, like Øresund and Ma
```

This example also shows how you can set the logging level which acts as the threshold for tracking. In this case, because we set the threshold to `DEBUG`, all of the messages were printed.

If you want to set the logging level from a command-line option such as:

```
--log=INFO
```

and you have the value of the parameter passed for `--log` in some variable *loglevel*, you can use:

```
getattr(logging, loglevel.upper())
```

to get the value which you'll pass to `basicConfig()` via the *level* argument. You may want to error check any user input value, perhaps as in the following example:

```
# assuming loglevel is bound to the string value obtained
# command line argument. Convert to upper case to allow
# specify --log=DEBUG or --log=debug
numeric_level = getattr(logging, loglevel.upper(), None)
if not isinstance(numeric_level, int):
    raise ValueError('Invalid log level: %s' % loglevel)
logging.basicConfig(level=numeric_level, ...)
```

The call to `basicConfig()` should come *before* any calls to `debug()`, `info()`, etc. Otherwise, those functions will call `basicConfig()` for you with the default options. As it's intended as a one-off simple configuration facility, only the first call will actually do anything: subsequent calls are effectively no-ops.

If you run the above script several times, the messages from successive runs are appended to the file *example.log*. If you want each run to start afresh, not remembering the messages from earlier runs, you can specify the *filemode* argument, by changing the call in the above example to:

```
logging.basicConfig(filename='example.log', filemode='w')
```

The output will be the same as before, but the log file is no longer appended to, so the messages from earlier runs are lost.

## Logging from multiple modules

If your program consists of multiple modules, here's an example of how you could organize logging in it:

```
# myapp.py
import logging
import mylib

def main():
    logging.basicConfig(filename='myapp.log', level=logging.INFO)
    logging.info('Started')
    mylib.do_something()
    logging.info('Finished')

if __name__ == '__main__':
    main()

# mylib.py
import logging

def do_something():
    logging.info('Doing something')
```

If you run *myapp.py*, you should see this in *myapp.log*:

```
INFO:root:Started
INFO:root:Doing something
INFO:root:Finished
```

which is hopefully what you were expecting to see. You can generalize this to multiple modules, using the pattern in *mylib.py*. Note that for this simple usage pattern, you won't know, by looking in the log file, *where* in your application your messages came from, apart from looking at the event description. If you want to track the location of your messages, you'll need to refer to the documentation beyond the tutorial level – see [Advanced Logging Tutorial](#).

## Logging variable data

To log variable data, use a format string for the event description message and append the variable data as arguments. For example:

```
import logging
logging.warning('%s before you %s', 'Look', 'leap!')
```

will display:

```
WARNING:root:Look before you leap!
```

As you can see, merging of variable data into the event description message uses the old, %-style of string formatting. This is for backwards compatibility: the logging package pre-dates newer formatting options such as `str.format()` and `string.Template`. These newer formatting options *are* supported, but exploring them is outside the scope of this tutorial: see [Using particular formatting styles throughout your application](#) for more information.

## Changing the format of displayed messages

To change the format which is used to display messages, you need to specify the format you want to use:

```
import logging
```

```
logging.basicConfig(format='%(levelname)s:%(message)s',
logging.debug('This message should appear on the console')
logging.info('So should this')
logging.warning('And this, too')
```

which would print:

```
DEBUG:This message should appear on the console
INFO:So should this
WARNING:And this, too
```

Notice that the ‘root’ which appeared in earlier examples has disappeared. For a full set of things that can appear in format strings, you can refer to the documentation for [LogRecord attributes](#), but for simple usage, you just need the *levelname* (severity), *message* (event description, including variable data) and perhaps to display when the event occurred. This is described in the next section.

## Displaying the date/time in messages

To display the date and time of an event, you would place ‘%(asctime)s’ in your format string:

```
import logging
logging.basicConfig(format='%(asctime)s %(message)s')
logging.warning('is when this event was logged.')
```

which should print something like this:

```
2010-12-12 11:41:42,612 is when this event was logged.
```

The default format for date/time display (shown above) is like ISO8601 or [RFC 3339](https://datatracker.ietf.org/doc/html/rfc3339.html) [https://datatracker.ietf.org/doc/html/rfc3339.html]. If you need more control over the formatting of the date/time, provide a *datefmt* argument to `basicConfig`, as in this example:

```
import logging
logging.basicConfig(format='%(asctime)s %(message)s', datefmt='%Y-%m-%d %H:%M:%S',
logging.warning('is when this event was logged.')
```

which would display something like this:

```
12/12/2010 11:46:36 AM is when this event was logged.
```

The format of the *datefmt* argument is the same as supported by `time.strftime()`.

## Next Steps

That concludes the basic tutorial. It should be enough to get you up and running with logging. There's a lot more that the logging package offers, but to get the best out of it, you'll need to invest a little more of your time in reading the following sections. If you're ready for that, grab some of your favourite beverage and carry on.

If your logging needs are simple, then use the above examples to incorporate logging into your own scripts, and if you run into problems or don't understand something, please post a question on the comp.lang.python Usenet group (available at <https://groups.google.com/g/comp.lang.python>) and you should receive help before too long.

Still here? You can carry on reading the next few sections, which provide a slightly more advanced/in-depth tutorial than the basic one above. After that, you can take a look at the [Logging Cookbook](#).

## Advanced Logging Tutorial

The logging library takes a modular approach and offers several categories of components: loggers, handlers, filters, and formatters.

- Loggers expose the interface that application code directly uses.
- Handlers send the log records (created by loggers) to the appropriate destination.
- Filters provide a finer grained facility for determining which log records to output.
- Formatters specify the layout of log records in the final output.

Log event information is passed between loggers, handlers, filters and formatters in a `LogRecord` instance.

Logging is performed by calling methods on instances of the `Logger` class (hereafter called *loggers*). Each instance has a name, and they are conceptually arranged in a namespace hierarchy using dots (periods) as separators. For example, a logger named ‘scan’ is the parent of loggers ‘scan.text’, ‘scan.html’ and ‘scan.pdf’. Logger names can be anything you want, and indicate the area of an application in which a logged message originates.

A good convention to use when naming loggers is to use a module-level logger, in each module which uses logging, named as follows:

```
logger = logging.getLogger(__name__)
```

This means that logger names track the package/module hierarchy, and it’s intuitively obvious where events are logged just from the logger name.

The root of the hierarchy of loggers is called the root logger. That’s the logger used by the functions `debug()`, `info()`, `warning()`, `error()` and `critical()`, which just call the same-named method of the root logger. The functions and the methods have the same signatures. The root logger’s name is printed as ‘root’ in the logged output.

It is, of course, possible to log messages to different destinations. Support is included in the package for writing log messages to files, HTTP GET/POST locations, email via SMTP, generic sockets, queues, or OS-specific logging mechanisms such as syslog or the Windows NT event log. Destinations are served by *handler* classes. You can create your own log destination class if you have special requirements not met by any of the built-in handler classes.

By default, no destination is set for any logging messages. You can specify a destination (such as console or file) by using `basicConfig()` as in the tutorial examples. If you call the functions `debug()`, `info()`, `warning()`, `error()` and `critical()`, they will check to see if no destination is set; and if one is not set, they will set a destination of the console

(`sys.stderr`) and a default format for the displayed message before delegating to the root logger to do the actual message output.

The default format set by `basicConfig()` for messages is:

```
severity:logger name:message
```

You can change this by passing a format string to `basicConfig()` with the *format* keyword argument. For all options regarding how a format string is constructed, see [Formatter Objects](#).

## Logging Flow

The flow of log event information in loggers and handlers is illustrated in the following diagram.

## Loggers

**Logger** objects have a threefold job. First, they expose several methods to application code so that applications can log messages at runtime. Second, logger objects determine which log messages to act upon based upon severity (the default filtering facility) or filter objects. Third, logger objects pass along relevant log messages to all interested log handlers.

The most widely used methods on logger objects fall into two categories: configuration and message sending.

These are the most common configuration methods:

- `Logger.setLevel()` specifies the lowest-severity log message a logger will handle, where debug is the lowest built-in severity level and critical is the highest built-in severity. For example, if the severity level is INFO, the logger will handle only INFO, WARNING, ERROR, and CRITICAL messages and will ignore DEBUG messages.
- `Logger.addHandler()` and `Logger.removeHandler()` add and remove handler objects from the logger object. Handlers are covered in more detail in [Handlers](#).
- `Logger.addFilter()` and `Logger.removeFilter()`

add and remove filter objects from the logger object. Filters are covered in more detail in [Filter Objects](#).

You don't need to always call these methods on every logger you create. See the last two paragraphs in this section.

With the logger object configured, the following methods create log messages:

- `Logger.debug()`, `Logger.info()`, `Logger.warning()`, `Logger.error()`, and `Logger.critical()` all create log records with a message and a level that corresponds to their respective method names. The message is actually a format string, which may contain the standard string substitution syntax of `%s`, `%d`, `%f`, and so on. The rest of their arguments is a list of objects that correspond with the substitution fields in the message. With regard to `**kwargs`, the logging methods care only about a keyword of `exc_info` and use it to determine whether to log exception information.
- `Logger.exception()` creates a log message similar to `Logger.error()`. The difference is that `Logger.exception()` dumps a stack trace along with it. Call this method only from an exception handler.
- `Logger.log()` takes a log level as an explicit argument. This is a little more verbose for logging messages than using the log level convenience methods listed above, but this is how to log at custom log levels.

`getLogger()` returns a reference to a logger instance with the specified name if it is provided, or `root` if not. The names are period-separated hierarchical structures. Multiple calls to `getLogger()` with the same name will return a reference to the same logger object. Loggers that are further down in the hierarchical list are children of loggers higher up in the list. For example, given a logger with a name of `foo`, loggers with names of `foo.bar`, `foo.bar.baz`, and `foo.bam` are all descendants of `foo`.

Loggers have a concept of *effective level*. If a level is not explicitly set on a logger, the level of its parent is used instead as its effective

level. If the parent has no explicit level set, *its* parent is examined, and so on - all ancestors are searched until an explicitly set level is found. The root logger always has an explicit level set (`WARNING` by default). When deciding whether to process an event, the effective level of the logger is used to determine whether the event is passed to the logger's handlers.

Child loggers propagate messages up to the handlers associated with their ancestor loggers. Because of this, it is unnecessary to define and configure handlers for all the loggers an application uses. It is sufficient to configure handlers for a top-level logger and create child loggers as needed. (You can, however, turn off propagation by setting the *propagate* attribute of a logger to `False`.)

## Handlers

**Handler** objects are responsible for dispatching the appropriate log messages (based on the log messages' severity) to the handler's specified destination. **Logger** objects can add zero or more handler objects to themselves with an `addHandler()` method. As an example scenario, an application may want to send all log messages to a log file, all log messages of error or higher to stdout, and all messages of critical to an email address. This scenario requires three individual handlers where each handler is responsible for sending messages of a specific severity to a specific location.

The standard library includes quite a few handler types (see [Useful Handlers](#)); the tutorials use mainly **StreamHandler** and **FileHandler** in its examples.

There are very few methods in a handler for application developers to concern themselves with. The only handler methods that seem relevant for application developers who are using the built-in handler objects (that is, not creating custom handlers) are the following configuration methods:

- The `setLevel()` method, just as in logger objects, specifies the lowest severity that will be dispatched to the appropriate destination. Why are there two `setLevel()` methods? The level set in the logger determines which severity of messages

it will pass to its handlers. The level set in each handler determines which messages that handler will send on.

- `setFormatter()` selects a `Formatter` object for this handler to use.
- `addFilter()` and `removeFilter()` respectively configure and deconfigure filter objects on handlers.

Application code should not directly instantiate and use instances of `Handler`. Instead, the `Handler` class is a base class that defines the interface that all handlers should have and establishes some default behavior that child classes can use (or override).

## Formatters

`Formatter` objects configure the final order, structure, and contents of the log message. Unlike the base `logging.Handler` class, application code may instantiate formatter classes, although you could likely subclass the formatter if your application needs special behavior. The constructor takes three optional arguments – a message format string, a date format string and a style indicator.

```
logging.Formatter._init_(fmt=None, datefmt=None, style='%')
```

If there is no message format string, the default is to use the raw message. If there is no date format string, the default date format is:

```
%Y-%m-%d %H:%M:%S
```

with the milliseconds tacked on at the end. The `style` is one of `'%'`, `'{'`, or `'$'`. If one of these is not specified, then `'%'` will be used.

If the `style` is `'%'`, the message format string uses `%( <dictionary key> )s` styled string substitution; the possible keys are documented in [LogRecord attributes](#). If the style is `'{'`, the message format string is assumed to be compatible with `str.format()` (using keyword arguments), while if the style is `'$'` then the message format string should conform to what is expected by `string.Template.substitute()`.

*Changed in version 3.2:* Added the `style` parameter.

The following message format string will log the time in a human-readable format, the severity of the message, and the contents of the message, in that order:

```
'%(asctime)s - %(levelname)s - %(message)s'
```

Formatters use a user-configurable function to convert the creation time of a record to a tuple. By default, `time.localtime()` is used; to change this for a particular formatter instance, set the `converter` attribute of the instance to a function with the same signature as `time.localtime()` or `time.gmtime()`. To change it for all formatters, for example if you want all logging times to be shown in GMT, set the `converter` attribute in the `Formatter` class (to `time.gmtime` for GMT display).

## Configuring Logging

Programmers can configure logging in three ways:

1. Creating loggers, handlers, and formatters explicitly using Python code that calls the configuration methods listed above.
2. Creating a logging config file and reading it using the `fileConfig()` function.
3. Creating a dictionary of configuration information and passing it to the `dictConfig()` function.

For the reference documentation on the last two options, see [Configuration functions](#). The following example configures a very simple logger, a console handler, and a simple formatter using Python code:

```
import logging

# create logger
logger = logging.getLogger('simple_example')
logger.setLevel(logging.DEBUG)

# create console handler and set level to debug
```

```
ch = logging.StreamHandler()
ch.setLevel(logging.DEBUG)

# create formatter
formatter = logging.Formatter('%(asctime)s - %(name)s - %s')

# add formatter to ch
ch.setFormatter(formatter)

# add ch to logger
logger.addHandler(ch)

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warning('warn message')
logger.error('error message')
logger.critical('critical message')
```

Running this module from the command line produces the following output:

```
$ python simple_logging_module.py
2005-03-19 15:10:26,618 - simple_example - DEBUG - debug message
2005-03-19 15:10:26,620 - simple_example - INFO - info message
2005-03-19 15:10:26,695 - simple_example - WARNING - warn message
2005-03-19 15:10:26,697 - simple_example - ERROR - error message
2005-03-19 15:10:26,773 - simple_example - CRITICAL - critical message
```

The following Python module creates a logger, handler, and formatter nearly identical to those in the example listed above, with the only difference being the names of the objects:

```
import logging
import logging.config

logging.config.fileConfig('logging.conf')

# create logger
```

```
logger = logging.getLogger('simpleExample')

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warning('warn message')
logger.error('error message')
logger.critical('critical message')
```

Here is the logging.conf file:

```
[loggers]
keys=root,simpleExample

[handlers]
keys=consoleHandler

[formatters]
keys=simpleFormatter

[logger_root]
level=DEBUG
handlers=consoleHandler

[logger_simpleExample]
level=DEBUG
handlers=consoleHandler
qualname=simpleExample
propagate=0

[handler_consoleHandler]
class=StreamHandler
level=DEBUG
formatter=simpleFormatter
args=(sys.stdout,)

[formatter_simpleFormatter]
format=%(asctime)s - %(name)s - %(levelname)s - %(message)s
```

The output is nearly identical to that of the non-config-file-based example:

```
$ python simple_logging_config.py
2005-03-19 15:38:55,977 - simpleExample - DEBUG - debug
2005-03-19 15:38:55,979 - simpleExample - INFO - info me
2005-03-19 15:38:56,054 - simpleExample - WARNING - warn
2005-03-19 15:38:56,055 - simpleExample - ERROR - error
2005-03-19 15:38:56,130 - simpleExample - CRITICAL - cri
```

You can see that the config file approach has a few advantages over the Python code approach, mainly separation of configuration and code and the ability of noncoders to easily modify the logging properties.

## Warning

The `fileConfig()` function takes a default parameter, `disable_existing_loggers`, which defaults to `True` for reasons of backward compatibility. This may or may not be what you want, since it will cause any non-root loggers existing before the `fileConfig()` call to be disabled unless they (or an ancestor) are explicitly named in the configuration. Please refer to the reference documentation for more information, and specify `False` for this parameter if you wish.

The dictionary passed to `dictConfig()` can also specify a Boolean value with key `disable_existing_loggers`, which if not specified explicitly in the dictionary also defaults to being interpreted as `True`. This leads to the logger-disabling behaviour described above, which may not be what you want - in which case, provide the key explicitly with a value of `False`.

Note that the class names referenced in config files need to be either relative to the logging module, or absolute values which can be resolved using normal import mechanisms. Thus, you could use either `WatchedFileHandler` (relative to the logging module) or `mypackage.mymodule.MyHandler` (for a class defined in package `mypackage` and module `mymodule`, where `mypackage` is available on the Python import path).

In Python 3.2, a new means of configuring logging has been introduced, using dictionaries to hold configuration information. This provides a superset of the functionality of the config-file-based approach outlined above, and is the recommended configuration method for new applications and deployments. Because a Python dictionary is used to hold configuration information, and since you can populate that dictionary using different means, you have more options for configuration. For example, you can use a configuration file in JSON format, or, if you have access to YAML processing functionality, a file in YAML format, to populate the configuration dictionary. Or, of course, you can construct the dictionary in Python code, receive it in pickled form over a socket, or use whatever approach makes sense for your application.

Here's an example of the same configuration as above, in YAML format for the new dictionary-based approach:

```
version: 1
formatters:
  simple:
    format: '%(asctime)s - %(name)s - %(levelname)s - %'
handlers:
  console:
    class: logging.StreamHandler
    level: DEBUG
    formatter: simple
    stream: ext://sys.stdout
loggers:
  simpleExample:
    level: DEBUG
    handlers: [console]
    propagate: no
root:
  level: DEBUG
  handlers: [console]
```

For more information about logging using a dictionary, see [Configuration functions](#).

## What happens if no configuration is provided

If no logging configuration is provided, it is possible to have a situation where a logging event needs to be output, but no handlers can be found to output the event. The behaviour of the logging package in these circumstances is dependent on the Python version.

For versions of Python prior to 3.2, the behaviour is as follows:

- If `logging.raiseExceptions` is `False` (production mode), the event is silently dropped.
- If `logging.raiseExceptions` is `True` (development mode), a message ‘No handlers could be found for logger X.Y.Z’ is printed once.

In Python 3.2 and later, the behaviour is as follows:

- The event is output using a ‘handler of last resort’, stored in `logging.lastResort`. This internal handler is not associated with any logger, and acts like a `StreamHandler` which writes the event description message to the current value of `sys.stderr` (therefore respecting any redirections which may be in effect). No formatting is done on the message - just the bare event description message is printed. The handler’s level is set to `WARNING`, so all events at this and greater severities will be output.

To obtain the pre-3.2 behaviour, `logging.lastResort` can be set to `None`.

## Configuring Logging for a Library

When developing a library which uses logging, you should take care to document how the library uses logging - for example, the names of loggers used. Some consideration also needs to be given to its logging configuration. If the using application does not use logging, and library code makes logging calls, then (as described in the previous section) events of severity `WARNING` and greater will be printed to `sys.stderr`. This is regarded as the best default behaviour.

If for some reason you *don’t* want these messages printed in the absence of any logging configuration, you can attach a do-nothing

handler to the top-level logger for your library. This avoids the message being printed, since a handler will always be found for the library's events: it just doesn't produce any output. If the library user configures logging for application use, presumably that configuration will add some handlers, and if levels are suitably configured then logging calls made in library code will send output to those handlers, as normal.

A do-nothing handler is included in the logging package: **NullHandler** (since Python 3.1). An instance of this handler could be added to the top-level logger of the logging namespace used by the library (*if you want to prevent your library's logged events being output to `sys.stderr` in the absence of logging configuration*). If all logging by a library *foo* is done using loggers with names matching 'foo.x', 'foo.x.y', etc. then the code:

```
import logging
logging.getLogger('foo').addHandler(logging.NullHandler())
```

should have the desired effect. If an organisation produces a number of libraries, then the logger name specified can be 'orgname.foo' rather than just 'foo'.

## Note

It is strongly advised that you *do not log to the root logger* in your library. Instead, use a logger with a unique and easily identifiable name, such as the `__name__` for your library's top-level package or module. Logging to the root logger will make it difficult or impossible for the application developer to configure the logging verbosity or handlers of your library as they wish.

## Note

It is strongly advised that you *do not add any handlers other than **NullHandler** to your library's loggers*. This is because the configuration of handlers is the prerogative of the application developer who uses your library. The application developer knows their target audience and what handlers are most

appropriate for their application: if you add handlers ‘under the hood’, you might well interfere with their ability to carry out unit tests and deliver logs which suit their requirements.

## Logging Levels

The numeric values of logging levels are given in the following table. These are primarily of interest if you want to define your own levels, and need them to have specific values relative to the predefined levels. If you define a level with the same numeric value, it overwrites the predefined value; the predefined name is lost.

Numeric value
50
CRITICAL
40
ERROR
30
WARNING
20
INFO
10
DEBUG
0
NOTSET

Levels can also be associated with loggers, being set either by the developer or through loading a saved logging configuration. When a logging method is called on a logger, the logger compares its own level with the level associated with the method call. If the logger’s level is higher than the method call’s, no logging message is actually generated. This is the basic mechanism controlling the verbosity of logging output.

Logging messages are encoded as instances of the [LogRecord](#) class. When a logger decides to actually log an event, a [LogRecord](#) instance is created from the logging message.

Logging messages are subjected to a dispatch mechanism through the use of *handlers*, which are instances of subclasses of the [Handler](#) class. Handlers are responsible for ensuring that a logged message (in the form of a [LogRecord](#)) ends up in a particular location (or set of locations) which is useful for the target audience for that message (such as end users, support desk staff, system administrators, developers). Handlers are passed [LogRecord](#) instances intended for particular destinations. Each logger can have

zero, one or more handlers associated with it (via the `addHandler()` method of `Logger`). In addition to any handlers directly associated with a logger, *all handlers associated with all ancestors of the logger* are called to dispatch the message (unless the *propagate* flag for a logger is set to a false value, at which point the passing to ancestor handlers stops).

Just as for loggers, handlers can have levels associated with them. A handler's level acts as a filter in the same way as a logger's level does. If a handler decides to actually dispatch an event, the `emit()` method is used to send the message to its destination. Most user-defined subclasses of `Handler` will need to override this `emit()`.

## Custom Levels

Defining your own levels is possible, but should not be necessary, as the existing levels have been chosen on the basis of practical experience. However, if you are convinced that you need custom levels, great care should be exercised when doing this, and it is possibly *a very bad idea to define custom levels if you are developing a library*. That's because if multiple library authors all define their own custom levels, there is a chance that the logging output from such multiple libraries used together will be difficult for the using developer to control and/or interpret, because a given numeric value might mean different things for different libraries.

## Useful Handlers

In addition to the base `Handler` class, many useful subclasses are provided:

1. `StreamHandler` instances send messages to streams (file-like objects).
2. `FileHandler` instances send messages to disk files.
3. `BaseRotatingHandler` is the base class for handlers that rotate log files at a certain point. It is not meant to be instantiated directly. Instead, use `RotatingFileHandler` or `TimedRotatingFileHandler`.
4. `RotatingFileHandler` instances send messages to disk

files, with support for maximum log file sizes and log file rotation.

5. **TimedRotatingFileHandler** instances send messages to disk files, rotating the log file at certain timed intervals.
6. **SocketHandler** instances send messages to TCP/IP sockets. Since 3.4, Unix domain sockets are also supported.
7. **DatagramHandler** instances send messages to UDP sockets. Since 3.4, Unix domain sockets are also supported.
8. **SMTPHandler** instances send messages to a designated email address.
9. **SysLogHandler** instances send messages to a Unix syslog daemon, possibly on a remote machine.
10. **NTEventLogHandler** instances send messages to a Windows NT/2000/XP event log.
11. **MemoryHandler** instances send messages to a buffer in memory, which is flushed whenever specific criteria are met.
12. **HTTPHandler** instances send messages to an HTTP server using either `GET` or `POST` semantics.
13. **WatchedFileHandler** instances watch the file they are logging to. If the file changes, it is closed and reopened using the file name. This handler is only useful on Unix-like systems; Windows does not support the underlying mechanism used.
14. **QueueHandler** instances send messages to a queue, such as those implemented in the `queue` or `multiprocessing` modules.
15. **NullHandler** instances do nothing with error messages. They are used by library developers who want to use logging, but want to avoid the ‘No handlers could be found for logger XXX’ message which can be displayed if the library user has not configured logging. See [Configuring Logging for a Library](#) for more information.

*New in version 3.1:* The **NullHandler** class.

*New in version 3.2:* The **QueueHandler** class.

The **NullHandler**, **StreamHandler** and **FileHandler** classes are defined in the core logging package. The other handlers are defined in a sub-module, `logging.handlers`. (There is also

another sub-module, `logging.config`, for configuration functionality.)

Logged messages are formatted for presentation through instances of the `Formatter` class. They are initialized with a format string suitable for use with the `%` operator and a dictionary.

For formatting multiple messages in a batch, instances of `BufferingFormatter` can be used. In addition to the format string (which is applied to each message in the batch), there is provision for header and trailer format strings.

When filtering based on logger level and/or handler level is not enough, instances of `Filter` can be added to both `Logger` and `Handler` instances (through their `addFilter()` method). Before deciding to process a message further, both loggers and handlers consult all their filters for permission. If any filter returns a false value, the message is not processed further.

The basic `Filter` functionality allows filtering by specific logger name. If this feature is used, messages sent to the named logger and its children are allowed through the filter, and all others dropped.

## Exceptions raised during logging

The logging package is designed to swallow exceptions which occur while logging in production. This is so that errors which occur while handling logging events - such as logging misconfiguration, network or other similar errors - do not cause the application using logging to terminate prematurely.

`SystemExit` and `KeyboardInterrupt` exceptions are never swallowed. Other exceptions which occur during the `emit()` method of a `Handler` subclass are passed to its `handleError()` method.

The default implementation of `handleError()` in `Handler` checks to see if a module-level variable, `raiseExceptions`, is set. If set, a traceback is printed to `sys.stderr`. If not set, the exception is swallowed.

## Note

The default value of `raiseExceptions` is `True`. This is because during development, you typically want to be notified of any exceptions that occur. It's advised that you set `raiseExceptions` to `False` for production usage.

## Using arbitrary objects as messages

In the preceding sections and examples, it has been assumed that the message passed when logging the event is a string. However, this is not the only possibility. You can pass an arbitrary object as a message, and its `__str__()` method will be called when the logging system needs to convert it to a string representation. In fact, if you want to, you can avoid computing a string representation altogether - for example, the `SocketHandler` emits an event by pickling it and sending it over the wire.

## Optimization

Formatting of message arguments is deferred until it cannot be avoided. However, computing the arguments passed to the logging method can also be expensive, and you may want to avoid doing it if the logger will just throw away your event. To decide what to do, you can call the `isEnabledFor()` method which takes a level argument and returns true if the event would be created by the Logger for that level of call. You can write code like this:

```
if logger.isEnabledFor(logging.DEBUG):  
    logger.debug('Message with %s, %s', expensive_func1(),  
                expensive_func2())
```

so that if the logger's threshold is set above `DEBUG`, the calls to `expensive_func1()` and `expensive_func2()` are never made.

## Note

In some cases, `isEnabledFor()` can itself be more expensive

than you'd like (e.g. for deeply nested loggers where an explicit level is only set high up in the logger hierarchy). In such cases (or if you want to avoid calling a method in tight loops), you can cache the result of a call to `isEnabledFor()` in a local or instance variable, and use that instead of calling the method each time. Such a cached value would only need to be recomputed when the logging configuration changes dynamically while the application is running (which is not all that common).

There are other optimizations which can be made for specific applications which need more precise control over what logging information is collected. Here's a list of things you can do to avoid processing during logging which you don't need:

#### **What you don't want to collect**

---

**Information about where calls were made.** This avoids calling `sys._getframe()`, which may help to speed up your code in environments like PyPy (which can't speed up code that uses `sys._getframe()`).

---

**Threading information.** Leads to `False`.

---

**Current process ID (or `os.getpid()`).** `False`.

---

**Current process name when using `subprocess`.** Leads to managing multiple processes.

---

Also note that the core logging module only includes the basic handlers. If you don't import `logging.handlers` and `logging.config`, they won't take up any memory.

## Author

Vinay Sajip <vinay\_sajip at red-dove dot com>

This page contains a number of recipes related to logging, which have been found useful in the past. For links to tutorial and reference information, please see [Other resources](#).

## Using logging in multiple modules

Multiple calls to `logging.getLogger('someLogger')` return a reference to the same logger object. This is true not only within the same module, but also across modules as long as it is in the same Python interpreter process. It is true for references to the same object; additionally, application code can define and configure a parent logger in one module and create (but not configure) a child logger in a separate module, and all logger calls to the child will pass up to the parent. Here is a main module:

```
import logging
import auxiliary_module

# create logger with 'spam_application'
logger = logging.getLogger('spam_application')
logger.setLevel(logging.DEBUG)
# create file handler which logs even debug messages
fh = logging.FileHandler('spam.log')
fh.setLevel(logging.DEBUG)
# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)
# create formatter and add it to the handlers
formatter = logging.Formatter('%(asctime)s - %(name)s -
```

```

fh.setFormatter(formatter)
ch.setFormatter(formatter)
# add the handlers to the logger
logger.addHandler(fh)
logger.addHandler(ch)

logger.info('creating an instance of auxiliary_module.Auxiliary')
a = auxiliary_module.Auxiliary()
logger.info('created an instance of auxiliary_module.Auxiliary')
logger.info('calling auxiliary_module.Auxiliary.do_something()')
a.do_something()
logger.info('finished auxiliary_module.Auxiliary.do_something()')
logger.info('calling auxiliary_module.some_function()')
auxiliary_module.some_function()
logger.info('done with auxiliary_module.some_function()')

```

**Here is the auxiliary module:**

```

import logging

# create logger
module_logger = logging.getLogger('spam_application.auxiliary')

class Auxiliary:
    def __init__(self):
        self.logger = logging.getLogger('spam_application.auxiliary')
        self.logger.info('creating an instance of Auxiliary')

    def do_something(self):
        self.logger.info('doing something')
        a = 1 + 1
        self.logger.info('done doing something')

def some_function():
    module_logger.info('received a call to "some_function"')

```

**The output looks like this:**

```

2005-03-23 23:47:11,663 - spam_application - INFO -

```

```
    creating an instance of auxiliary_module.Auxiliary
2005-03-23 23:47:11,665 - spam_application.auxiliary.Auxiliary
    creating an instance of Auxiliary
2005-03-23 23:47:11,665 - spam_application - INFO -
    created an instance of auxiliary_module.Auxiliary
2005-03-23 23:47:11,668 - spam_application - INFO -
    calling auxiliary_module.Auxiliary.do_something
2005-03-23 23:47:11,668 - spam_application.auxiliary.Auxiliary
    doing something
2005-03-23 23:47:11,669 - spam_application.auxiliary.Auxiliary
    done doing something
2005-03-23 23:47:11,670 - spam_application - INFO -
    finished auxiliary_module.Auxiliary.do_something
2005-03-23 23:47:11,671 - spam_application - INFO -
    calling auxiliary_module.some_function()
2005-03-23 23:47:11,672 - spam_application.auxiliary - INFO -
    received a call to 'some_function'
2005-03-23 23:47:11,673 - spam_application - INFO -
    done with auxiliary_module.some_function()
```

## Logging from multiple threads

Logging from multiple threads requires no special effort. The following example shows logging from the main (initial) thread and another thread:

```
import logging
import threading
import time

def worker(arg):
    while not arg['stop']:
        logging.debug('Hi from myfunc')
        time.sleep(0.5)

def main():
    logging.basicConfig(level=logging.DEBUG, format='%(asctime)s')
    info = {'stop': False}
```

```

thread = threading.Thread(target=worker, args=(info,
thread.start()
while True:
    try:
        logging.debug('Hello from main')
        time.sleep(0.75)
    except KeyboardInterrupt:
        info['stop'] = True
        break
thread.join()

if __name__ == '__main__':
    main()

```

When run, the script should print something like the following:

```

0 Thread-1 Hi from myfunc
3 MainThread Hello from main

```

This shows the logging output interspersed as one might expect. This approach works for more threads than shown here, of course.

## Multiple handlers and formatters

Loggers are plain Python objects. The `addHandler()` method has no minimum or maximum quota for the number of handlers you may add. Sometimes it will be beneficial for an application to log all messages of all severities to a text file while simultaneously logging errors or above to the console. To set this up, simply configure the appropriate handlers. The logging calls in the application code will remain unchanged. Here is a slight modification to the previous simple module-based configuration example:

```
import logging

logger = logging.getLogger('simple_example')
logger.setLevel(logging.DEBUG)
# create file handler which logs even debug messages
fh = logging.FileHandler('spam.log')
fh.setLevel(logging.DEBUG)
# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)
# create formatter and add it to the handlers
formatter = logging.Formatter('%(asctime)s - %(name)s - %s')
ch.setFormatter(formatter)
fh.setFormatter(formatter)
# add the handlers to logger
logger.addHandler(ch)
logger.addHandler(fh)

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warning('warn message')
logger.error('error message')
logger.critical('critical message')
```

Notice that the ‘application’ code does not care about multiple handlers. All that changed was the addition and configuration of a new handler named *fh*.

The ability to create new handlers with higher- or lower-severity filters can be very helpful when writing and testing an application. Instead of using many `print` statements for debugging, use `logger.debug`: Unlike the `print` statements, which you will have to delete or comment out later, the `logger.debug` statements can remain intact in the source code and remain dormant until you need them again. At that time, the only change that needs to happen is to modify the severity level of the logger and/or handler to debug.

## Logging to multiple destinations

Let's say you want to log to console and file with different message formats and in differing circumstances. Say you want to log messages with levels of `DEBUG` and higher to file, and those messages at level `INFO` and higher to the console. Let's also assume that the file should contain timestamps, but the console messages should not. Here's how you can achieve this:

```
import logging

# set up logging to file - see previous section for more
logging.basicConfig(level=logging.DEBUG,
                    format='%(asctime)s %(name)-12s %(levelname)-8s',
                    datefmt='%m-%d %H:%M',
                    filename='/tmp/myapp.log',
                    filemode='w')

# define a Handler which writes INFO messages or higher to
console = logging.StreamHandler()
console.setLevel(logging.INFO)
# set a format which is simpler for console use
formatter = logging.Formatter('%(name)-12s: %(levelname)-8s: %(message)s')
# tell the handler to use this format
console.setFormatter(formatter)
# add the handler to the root logger
logging.getLogger('').addHandler(console)

# Now, we can log to the root logger, or any other logger
logging.info('Jackdaws love my big sphinx of quartz.')
```

```
# Now, define a couple of other loggers which might represent  
# application:
```

```
logger1 = logging.getLogger('myapp.area1')  
logger2 = logging.getLogger('myapp.area2')
```

```
logger1.debug('Quick zephyrs blow, vexing daft Jim.')  
logger1.info('How quickly daft jumping zebras vex.')  
logger2.warning('Jail zesty vixen who grabbed pay from quack.')  
logger2.error('The five boxing wizards jump quickly.')
```

When you run this, on the console you will see

```
root          : INFO          Jackdaws love my big sphinx of quartz.  
myapp.area1   : INFO          How quickly daft jumping zebras vex.  
myapp.area2   : WARNING       Jail zesty vixen who grabbed pay from quack.  
myapp.area2   : ERROR         The five boxing wizards jump quickly.
```

and in the file you will see something like

```
10-22 22:19 root          INFO          Jackdaws love my big sphinx of quartz.  
10-22 22:19 myapp.area1   DEBUG         Quick zephyrs blow, vexing daft Jim.  
10-22 22:19 myapp.area1   INFO          How quickly daft jumping zebras vex.  
10-22 22:19 myapp.area2   WARNING       Jail zesty vixen who grabbed pay from quack.  
10-22 22:19 myapp.area2   ERROR         The five boxing wizards jump quickly.
```

As you can see, the DEBUG message only shows up in the file. The other messages are sent to both destinations.

This example uses console and file handlers, but you can use any number and combination of handlers you choose.

Note that the above choice of log filename `/tmp/myapp.log` implies use of a standard location for temporary files on POSIX systems. On Windows, you may need to choose a different directory name for the log - just ensure that the directory exists and that you have the permissions to create and update files in it.

## Custom handling of levels

Sometimes, you might want to do something slightly different from the standard handling of levels in handlers, where all levels above a threshold get processed by a handler. To do this, you need to use filters. Let's look at a scenario where you want to arrange things as follows:

- Send messages of severity `INFO` and `WARNING` to `sys.stdout`
- Send messages of severity `ERROR` and above to `sys.stderr`
- Send messages of severity `DEBUG` and above to file `app.log`

Suppose you configure logging with the following JSON:

```
{
  "version": 1,
  "disable_existing_loggers": false,
  "formatters": {
    "simple": {
      "format": "%(levelname)-8s - %(message)s"
    }
  },
  "handlers": {
    "stdout": {
      "class": "logging.StreamHandler",
      "level": "INFO",
      "formatter": "simple",
      "stream": "ext://sys.stdout"
    },
    "stderr": {
      "class": "logging.StreamHandler",
      "level": "ERROR",
      "formatter": "simple",
      "stream": "ext://sys.stderr"
    },
    "file": {
      "class": "logging.FileHandler",
      "formatter": "simple",
      "filename": "app.log",
```

```

        "mode": "w"
    }
},
"root": {
    "level": "DEBUG",
    "handlers": [
        "stderr",
        "stdout",
        "file"
    ]
}
}

```

This configuration does *almost* what we want, except that `sys.stdout` would show messages of severity `ERROR` and above as well as `INFO` and `WARNING` messages. To prevent this, we can set up a filter which excludes those messages and add it to the relevant handler. This can be configured by adding a `filters` section parallel to `formatters` and `handlers`:

```

{
    "filters": {
        "warnings_and_below": {
            "()" : "__main__.filter_maker",
            "level": "WARNING"
        }
    }
}

```

and changing the section on the `stdout` handler to add it:

```

{
    "stdout": {
        "class": "logging.StreamHandler",
        "level": "INFO",
        "formatter": "simple",
        "stream": "ext://sys.stdout",
        "filters": ["warnings_and_below"]
    }
}

```

```
}
```

A filter is just a function, so we can define the `filter_maker` (a factory function) as follows:

```
def filter_maker(level):
    level = getattr(logging, level)

    def filter(record):
        return record.levelno <= level

    return filter
```

This converts the string argument passed in to a numeric level, and returns a function which only returns `True` if the level of the passed in record is at or below the specified level. Note that in this example I have defined the `filter_maker` in a test script `main.py` that I run from the command line, so its module will be `__main__` - hence the `__main__.filter_maker` in the filter configuration. You will need to change that if you define it in a different module.

With the filter added, we can run `main.py`, which in full is:

```
import json
import logging
import logging.config

CONFIG = '''
{
    "version": 1,
    "disable_existing_loggers": false,
    "formatters": {
        "simple": {
            "format": "%(levelname)-8s - %(message)s"
        }
    },
    "filters": {
        "warnings_and_below": {
            "()" : "__main__.filter_maker",
```

```

        "level": "WARNING"
    }
},
"handlers": {
    "stdout": {
        "class": "logging.StreamHandler",
        "level": "INFO",
        "formatter": "simple",
        "stream": "ext://sys.stdout",
        "filters": ["warnings_and_below"]
    },
    "stderr": {
        "class": "logging.StreamHandler",
        "level": "ERROR",
        "formatter": "simple",
        "stream": "ext://sys.stderr"
    },
    "file": {
        "class": "logging.FileHandler",
        "formatter": "simple",
        "filename": "app.log",
        "mode": "w"
    }
},
"root": {
    "level": "DEBUG",
    "handlers": [
        "stderr",
        "stdout",
        "file"
    ]
}
'''

```

```

def filter_maker(level):
    level = getattr(logging, level)

```

```
def filter(record):
    return record.levelno <= level

return filter
```

```
logging.config.dictConfig(json.loads(CONFIG))
logging.debug('A DEBUG message')
logging.info('An INFO message')
logging.warning('A WARNING message')
logging.error('An ERROR message')
logging.critical('A CRITICAL message')
```

And after running it like this:

```
python main.py 2>stderr.log >stdout.log
```

We can see the results are as expected:

```
$ more *.log
:::::::::::::
app.log
:::::::::::::
DEBUG      - A DEBUG message
INFO       - An INFO message
WARNING    - A WARNING message
ERROR      - An ERROR message
CRITICAL   - A CRITICAL message
:::::::::::::
stderr.log
:::::::::::::
ERROR      - An ERROR message
CRITICAL   - A CRITICAL message
:::::::::::::
stdout.log
:::::::::::::
INFO       - An INFO message
WARNING    - A WARNING message
```

## Configuration server example

Here is an example of a module using the logging configuration server:

```
import logging
import logging.config
import time
import os

# read initial config file
logging.config.fileConfig('logging.conf')

# create and start listener on port 9999
t = logging.config.listen(9999)
t.start()

logger = logging.getLogger('simpleExample')

try:
    # loop through logging calls to see the difference
    # new configurations make, until Ctrl+C is pressed
    while True:
        logger.debug('debug message')
        logger.info('info message')
        logger.warning('warn message')
        logger.error('error message')
        logger.critical('critical message')
        time.sleep(5)
except KeyboardInterrupt:
    # cleanup
    logging.config.stopListening()
    t.join()
```

And here is a script that takes a filename and sends that file to the server, properly preceded with the binary-encoded length, as the new logging configuration:

```
#!/usr/bin/env python
import socket, sys, struct
```

```
with open(sys.argv[1], 'rb') as f:
    data_to_send = f.read()

HOST = 'localhost'
PORT = 9999
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
print('connecting...')
s.connect((HOST, PORT))
print('sending config...')
s.send(struct.pack('>L', len(data_to_send)))
s.send(data_to_send)
s.close()
print('complete')
```

## Dealing with handlers that block

Sometimes you have to get your logging handlers to do their work without blocking the thread you're logging from. This is common in web applications, though of course it also occurs in other scenarios.

A common culprit which demonstrates sluggish behaviour is the **SMTPHandler**: sending emails can take a long time, for a number of reasons outside the developer's control (for example, a poorly performing mail or network infrastructure). But almost any network-based handler can block: Even a **SocketHandler** operation may do a DNS query under the hood which is too slow (and this query can be deep in the socket library code, below the Python layer, and outside your control).

One solution is to use a two-part approach. For the first part, attach only a **QueueHandler** to those loggers which are accessed from performance-critical threads. They simply write to their queue, which can be sized to a large enough capacity or initialized with no upper bound to their size. The write to the queue will typically be accepted quickly, though you will probably need to catch the **queue.Full** exception as a precaution in your code. If you are a library developer who has performance-critical threads in their code, be sure to document this (together with a suggestion to attach only **QueueHandlers** to your loggers) for the benefit of other

developers who will use your code.

The second part of the solution is `QueueListener`, which has been designed as the counterpart to `QueueHandler`. A `QueueListener` is very simple: it's passed a queue and some handlers, and it fires up an internal thread which listens to its queue for `LogRecords` sent from `QueueHandlers` (or any other source of `LogRecords`, for that matter). The `LogRecords` are removed from the queue and passed to the handlers for processing.

The advantage of having a separate `QueueListener` class is that you can use the same instance to service multiple `QueueHandlers`. This is more resource-friendly than, say, having threaded versions of the existing handler classes, which would eat up one thread per handler for no particular benefit.

An example of using these two classes follows (imports omitted):

```
que = queue.Queue(-1) # no limit on size
queue_handler = QueueHandler(que)
handler = logging.StreamHandler()
listener = QueueListener(que, handler)
root = logging.getLogger()
root.addHandler(queue_handler)
formatter = logging.Formatter('%(threadName)s: %(message)s')
handler.setFormatter(formatter)
listener.start()
# The log output will display the thread which generated
# the event (the main thread) rather than the internal
# thread which monitors the internal queue. This is what
# you want to happen.
root.warning('Look out!')
listener.stop()
```

which, when run, will produce:

```
MainThread: Look out!
```

## Note

Although the earlier discussion wasn't specifically talking about async code, but rather about slow logging handlers, it should be noted that when logging from async code, network and even file handlers could lead to problems (blocking the event loop) because some logging is done from `asyncio` internals. It might be best, if any async code is used in an application, to use the above approach for logging, so that any blocking code runs only in the `QueueListener` thread.

*Changed in version 3.5:* Prior to Python 3.5, the `QueueListener` always passed every message received from the queue to every handler it was initialized with. (This was because it was assumed that level filtering was all done on the other side, where the queue is filled.) From 3.5 onwards, this behaviour can be changed by passing a keyword argument `respect_handler_level=True` to the listener's constructor. When this is done, the listener compares the level of each message with the handler's level, and only passes a message to a handler if it's appropriate to do so.

## Sending and receiving logging events across a network

Let's say you want to send logging events across a network, and handle them at the receiving end. A simple way of doing this is attaching a `SocketHandler` instance to the root logger at the sending end:

```
import logging, logging.handlers

rootLogger = logging.getLogger('')
rootLogger.setLevel(logging.DEBUG)
socketHandler = logging.handlers.SocketHandler('localhost',
  logging.handlers.DEFAULT_TCP_LOGGING_PORT)
# don't bother with a formatter, since a socket handler
# an unformatted pickle
rootLogger.addHandler(socketHandler)

# Now, we can log to the root logger, or any other logger
```

```

logging.info('Jackdaws love my big sphinx of quartz.')

# Now, define a couple of other loggers which might represent
# application:

logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')

logger1.debug('Quick zephyrs blow, vexing daft Jim.')
logger1.info('How quickly daft jumping zebras vex.')
logger2.warning('Jail zesty vixen who grabbed pay from quack.')
logger2.error('The five boxing wizards jump quickly.')

```

At the receiving end, you can set up a receiver using the [socketserver](#) module. Here is a basic working example:

```

import pickle
import logging
import logging.handlers
import socketserver
import struct

class LogRecordStreamHandler(socketserver.StreamRequestHandler):
    """Handler for a streaming logging request.

    This basically logs the record using whatever logging
    configuration is locally.
    """

    def handle(self):
        """
        Handle multiple requests - each expected to be a
        LogRecord in pickle format. Logs each record
        according to whatever policy is configured locally.
        """
        while True:
            chunk = self.connection.recv(4)
            if len(chunk) < 4:

```

```

        break
    slen = struct.unpack('>L', chunk)[0]
    chunk = self.connection.recv(slen)
    while len(chunk) < slen:
        chunk = chunk + self.connection.recv(slen - len(chunk))
    obj = self.unPickle(chunk)
    record = logging.makeLogRecord(obj)
    self.handleLogRecord(record)

def unPickle(self, data):
    return pickle.loads(data)

def handleLogRecord(self, record):
    # if a name is specified, we use the named logger
    # implied by the record.
    if self.server.logname is not None:
        name = self.server.logname
    else:
        name = record.name
    logger = logging.getLogger(name)
    # N.B. EVERY record gets logged. This is because
    # is normally called AFTER logger-level filtering
    # to do filtering, do it at the client end to save
    # cycles and network bandwidth!
    logger.handle(record)

class LogRecordSocketReceiver(socketserver.ThreadingTCPServer):
    """
    Simple TCP socket-based logging receiver suitable for
    """

    allow_reuse_address = True

    def __init__(self, host='localhost',
                  port=logging.handlers.DEFAULT_TCP_LOGGING_PORT,
                  handler=LogRecordStreamHandler):
        socketserver.ThreadingTCPServer.__init__(self, (host, port))
        self.abort = 0

```

```

        self.timeout = 1
        self.logname = None

    def serve_until_stopped(self):
        import select
        abort = 0
        while not abort:
            rd, wr, ex = select.select([self.socket.file
  ], [], [],
  self.timeout)

            if rd:
                self.handle_request()
        abort = self.abort

def main():
    logging.basicConfig(
        format='%(relativeCreated)5d %(name)-15s %(levelname)s %s',
        tcpserver = LogRecordSocketReceiver()
    print('About to start TCP server...')
    tcpserver.serve_until_stopped()

if __name__ == '__main__':
    main()

```

First run the server, and then the client. On the client side, nothing is printed on the console; on the server side, you should see something like:

```

About to start TCP server...
59 root          INFO          Jackdaws love my big sph
59 myapp.area1   DEBUG          Quick zephyrs blow, vexir
69 myapp.area1   INFO          How quickly daft jumping
69 myapp.area2   WARNING       Jail zesty vixen who grab
69 myapp.area2   ERROR         The five boxing wizards j

```

Note that there are some security issues with pickle in some scenarios. If these affect you, you can use an alternative serialization scheme by overriding the **makePickle()** method and implementing your alternative there, as well as adapting the above

script to use your alternative serialization.

## Running a logging socket listener in production

To run a logging listener in production, you may need to use a process-management tool such as [Supervisor](http://supervisord.org/) [http://supervisord.org/].

[Here is a Gist](https://gist.github.com/vsajip/4b227ecec43817465ca835ca66f75e2b) [https://gist.github.com/vsajip/4b227ecec43817465ca835ca66f75e2b] which provides the bare-bones files to run the above functionality using Supervisor. It consists of the following files:

### File

---

A **Bash script** to prepare the environment for testing

---

The **Supervisor configuration file**, which has entries for the listener and a multi-process web application

---

A **Bash script** to ensure that Supervisor is running with the above configuration

---

The **socket listener program** which receives log events and records them to a file

---

A **simple web application** which performs logging via a socket connected to the listener

---

A **JSON configuration file** for the web application

---

A **Python script** to exercise the web application

---

The web application uses [Gunicorn](https://gunicorn.org/) [https://gunicorn.org/], which is a popular web application server that starts multiple worker processes to handle requests. This example setup shows how the workers can write to the same log file without conflicting with one another — they all go through the socket listener.

To test these files, do the following in a POSIX environment:

1. Download [the Gist](https://gist.github.com/vsajip/4b227ecec43817465ca835ca66f75e2b) [https://gist.github.com/vsajip/4b227ecec43817465ca835ca66f75e2b] as a ZIP archive using the *Download ZIP* button.
2. Unzip the above files from the archive into a scratch directory.
3. In the scratch directory, run `bash prepare.sh` to get things ready. This creates a `run` subdirectory to contain Supervisor-related and log files, and a `venv` subdirectory to contain a virtual environment into which `bottle`,

- unicorn and supervisor are installed.
4. Run `bash ensure_app.sh` to ensure that Supervisor is running with the above configuration.
  5. Run `venv/bin/python client.py` to exercise the web application, which will lead to records being written to the log.
  6. Inspect the log files in the `run` subdirectory. You should see the most recent log lines in files matching the pattern `app.log*`. They won't be in any particular order, since they have been handled concurrently by different worker processes in a non-deterministic way.
  7. You can shut down the listener and the web application by running `venv/bin/supervisorctl -c supervisor.conf shutdown`.

You may need to tweak the configuration files in the unlikely event that the configured ports clash with something else in your test environment.

## Adding contextual information to your logging output

Sometimes you want logging output to contain contextual information in addition to the parameters passed to the logging call. For example, in a networked application, it may be desirable to log client-specific information in the log (e.g. remote client's username, or IP address). Although you could use the *extra* parameter to achieve this, it's not always convenient to pass the information in this way. While it might be tempting to create **Logger** instances on a per-connection basis, this is not a good idea because these instances are not garbage collected. While this is not a problem in practice, when the number of **Logger** instances is dependent on the level of granularity you want to use in logging an application, it could be hard to manage if the number of **Logger** instances becomes effectively unbounded.

## Using LoggerAdapters to impart contextual information

An easy way in which you can pass contextual information to be output along with logging event information is to use the **LoggerAdapter** class. This class is designed to look like a **Logger**, so that you can call **debug()**, **info()**, **warning()**, **error()**, **exception()**, **critical()** and **log()**. These methods have the same signatures as their counterparts in **Logger**, so you can use the two types of instances interchangeably.

When you create an instance of **LoggerAdapter**, you pass it a **Logger** instance and a dict-like object which contains your contextual information. When you call one of the logging methods on an instance of **LoggerAdapter**, it delegates the call to the underlying instance of **Logger** passed to its constructor, and arranges to pass the contextual information in the delegated call. Here's a snippet from the code of **LoggerAdapter**:

```
def debug(self, msg, /, *args, **kwargs):
    """
    Delegate a debug call to the underlying logger, after
    contextual information from this adapter instance.
    """
    msg, kwargs = self.process(msg, kwargs)
    self.logger.debug(msg, *args, **kwargs)
```

The **process()** method of **LoggerAdapter** is where the contextual information is added to the logging output. It's passed the message and keyword arguments of the logging call, and it passes back (potentially) modified versions of these to use in the call to the underlying logger. The default implementation of this method leaves the message alone, but inserts an 'extra' key in the keyword argument whose value is the dict-like object passed to the constructor. Of course, if you had passed an 'extra' keyword argument in the call to the adapter, it will be silently overwritten.

The advantage of using 'extra' is that the values in the dict-like object are merged into the **LogRecord** instance's **\_dict\_**, allowing you to use customized strings with your **Formatter** instances which know about the keys of the dict-like object. If you need a different method, e.g. if you want to prepend or append the contextual information to the message string, you just need to

subclass **LoggerAdapter** and override **process()** to do what you need. Here is a simple example:

```
class CustomAdapter(logging.LoggerAdapter):
    """
    This example adapter expects the passed in dict-like
    'connid' key, whose value in brackets is prepended to
    """
    def process(self, msg, kwargs):
        return "[%s] %s" % (self.extra['connid'], msg),
```

which you can use like this:

```
logger = logging.getLogger(__name__)
adapter = CustomAdapter(logger, {'connid': some_conn_id})
```

Then any events that you log to the adapter will have the value of `some_conn_id` prepended to the log messages.

## Using objects other than dicts to pass contextual information

You don't need to pass an actual dict to a **LoggerAdapter** - you could pass an instance of a class which implements `__getitem__` and `__iter__` so that it looks like a dict to logging. This would be useful if you want to generate values dynamically (whereas the values in a dict would be constant).

## Using Filters to impart contextual information

You can also add contextual information to log output using a user-defined **Filter**. Filter instances are allowed to modify the LogRecords passed to them, including adding additional attributes which can then be output using a suitable format string, or if needed a custom **Formatter**.

For example in a web application, the request being processed (or at least, the interesting parts of it) can be stored in a threadlocal (`threading.local`) variable, and then accessed from a Filter to add, say, information from the request - say, the remote IP address and remote user's username - to the LogRecord, using the

attribute names 'ip' and 'user' as in the `LoggerAdapter` example above. In that case, the same format string can be used to get similar output to that shown above. Here's an example script:

```
import logging
from random import choice

class ContextFilter(logging.Filter):
    """
    This is a filter which injects contextual information into log messages.

    Rather than use actual contextual information, we just use random
    data in this demo.
    """

    USERS = ['jim', 'fred', 'sheila']
    IPS = ['123.231.231.123', '127.0.0.1', '192.168.0.1']

    def filter(self, record):

        record.ip = choice(ContextFilter.IPS)
        record.user = choice(ContextFilter.USERS)
        return True

if __name__ == '__main__':
    levels = (logging.DEBUG, logging.INFO, logging.WARNING, logging.ERROR)
    logging.basicConfig(level=logging.DEBUG,
                        format='%(asctime)-15s %(name)-5s %(levelname)-8s %(message)s')

    a1 = logging.getLogger('a.b.c')
    a2 = logging.getLogger('d.e.f')

    f = ContextFilter()
    a1.addFilter(f)
    a2.addFilter(f)
    a1.debug('A debug message')
    a1.info('An info message with %s', 'some parameters')
    for x in range(10):
        lvl = choice(levels)
        lvlname = logging.getLevelName(lvl)
```

```
a2.log(lvl, 'A message at %s level with %d %s',
```

which, when run, produces something like:

```
2010-09-06 22:38:15,292 a.b.c DEBUG      IP: 123.231.231.1
2010-09-06 22:38:15,300 a.b.c INFO       IP: 192.168.0.1

```

## Use of `contextvars`

Since Python 3.7, the `contextvars` module has provided context-local storage which works for both `threading` and `asyncio` processing needs. This type of storage may thus be generally preferable to thread-locals. The following example shows how, in a multi-threaded environment, logs can be populated with contextual information such as, for example, request attributes handled by web applications.

For the purposes of illustration, say that you have different web applications, each independent of the other but running in the same Python process and using a library common to them. How can each of these applications have their own log, where all logging messages from the library (and other request processing code) are directed to the appropriate application's log file, while including in the log additional contextual information such as client IP, HTTP request method and client username?

Let's assume that the library can be simulated by the following code:

```
# webapplib.py
```

```

import logging
import time

logger = logging.getLogger(__name__)

def useful():
    # Just a representative event logged from the library
    logger.debug('Hello from webapplib!')
    # Just sleep for a bit so other threads get to run
    time.sleep(0.01)

```

We can simulate the multiple web applications by means of two simple classes, `Request` and `WebApp`. These simulate how real threaded web applications work - each request is handled by a thread:

```

# main.py
import argparse
from contextvars import ContextVar
import logging
import os
from random import choice
import threading
import webapplib

logger = logging.getLogger(__name__)
root = logging.getLogger()
root.setLevel(logging.DEBUG)

class Request:
    """
    A simple dummy request class which just holds dummy
    client IP address and client username
    """
    def __init__(self, method, ip, user):
        self.method = method
        self.ip = ip
        self.user = user

```

```
# A dummy set of requests which will be used in the simulation
# from this list randomly. Note that all GET requests are from
# addresses, whereas POST requests are from 192.16.3.XXX
# are represented in the sample requests.
```

```
REQUESTS = [
    Request('GET', '192.168.2.20', 'jim'),
    Request('POST', '192.168.3.20', 'fred'),
    Request('GET', '192.168.2.21', 'sheila'),
    Request('POST', '192.168.3.21', 'jim'),
    Request('GET', '192.168.2.22', 'fred'),
    Request('POST', '192.168.3.22', 'sheila'),
]
```

```
# Note that the format string includes references to request
# such as HTTP method, client IP and username
```

```
formatter = logging.Formatter('%(threadName)-11s %(appname)s %(message)s')
```

```
# Create our context variables. These will be filled at the start of
# processing, and used in the logging that happens during processing.
```

```
ctx_request = ContextVar('request')
ctx_appname = ContextVar('appname')
```

```
class InjectingFilter(logging.Filter):
    """
    A filter which injects context-specific information into log records.
    that only information for a specific webapp is included.
    """
    def __init__(self, app):
        self.app = app

    def filter(self, record):
        request = ctx_request.get()
        record.method = request.method
        record.ip = request.ip
        record.user = request.user
```

```

        record.appName = appName = ctx_appname.get()
        return appName == self.app.name

```

```

class WebApp:

```

```

    """

```

```

    A dummy web application class which has its own hand
    webapp-specific log.

```

```

    """

```

```

    def __init__(self, name):

```

```

        self.name = name

```

```

        handler = logging.FileHandler(name + '.log', 'w')

```

```

        f = InjectingFilter(self)

```

```

        handler.setFormatter(formatter)

```

```

        handler.addFilter(f)

```

```

        root.addHandler(handler)

```

```

        self.num_requests = 0

```

```

    def process_request(self, request):

```

```

        """

```

```

        This is the dummy method for processing a request
        different thread for every request. We store the
        the context vars before doing anything else.

```

```

        """

```

```

        ctx_request.set(request)

```

```

        ctx_appname.set(self.name)

```

```

        self.num_requests += 1

```

```

        logger.debug('Request processing started')

```

```

        webapplib.useful()

```

```

        logger.debug('Request processing finished')

```

```

def main():

```

```

    fn = os.path.splitext(os.path.basename(__file__))[0]

```

```

    adhf = argparse.ArgumentDefaultsHelpFormatter

```

```

    ap = argparse.ArgumentParser(formatter_class=adhf, p

```

```

                                description='Simulate a

```

```

                                'applicatio

```

```

                                'requests,

```

```

                                'context ca

```

'populate 1

```
aa = ap.add_argument
aa('--count', '-c', type=int, default=100, help='How
options = ap.parse_args()

# Create the dummy webapps and put them in a list wh
# from randomly
app1 = WebApp('app1')
app2 = WebApp('app2')
apps = [app1, app2]
threads = []
# Add a common handler which will capture all events
handler = logging.FileHandler('app.log', 'w')
handler.setFormatter(formatter)
root.addHandler(handler)

# Generate calls to process requests
for i in range(options.count):
    try:
        # Pick an app at random and a request for it
        app = choice(apps)
        request = choice(REQUESTS)
        # Process the request in its own thread
        t = threading.Thread(target=app.process_requ
        threads.append(t)
        t.start()
    except KeyboardInterrupt:
        break

# Wait for the threads to terminate
for t in threads:
    t.join()

for app in apps:
    print('%s processed %s requests' % (app.name, ap

if __name__ == '__main__':
    main()
```

If you run the above, you should find that roughly half the requests go into `app1.log` and the rest into `app2.log`, and the all the requests are logged to `app.log`. Each webapp-specific log will contain only log entries for only that webapp, and the request information will be displayed consistently in the log (i.e. the information in each dummy request will always appear together in a log line). This is illustrated by the following shell output:

```
~/logging-contextual-webapp$ python main.py
app1 processed 51 requests
app2 processed 49 requests
~/logging-contextual-webapp$ wc -l *.log
 153 app1.log
 147 app2.log

```

## Imparting contextual information in handlers

Each **Handler** has its own chain of filters. If you want to add contextual information to a **LogRecord** without leaking it to other handlers, you can use a filter that returns a new **LogRecord** instead of modifying it in-place, as shown in the following script:

```
import copy
import logging

def filter(record: logging.LogRecord):
    record = copy.copy(record)
    record.user = 'jim'
    return record

if __name__ == '__main__':
    logger = logging.getLogger()
    logger.setLevel(logging.INFO)
    handler = logging.StreamHandler()
    formatter = logging.Formatter('%(message)s from %(user)s')
    handler.setFormatter(formatter)
    handler.addFilter(filter)
    logger.addHandler(handler)

    logger.info('A log message')
```

## Logging to a single file from multiple processes

Although logging is thread-safe, and logging to a single file from multiple threads in a single process is supported, logging to a single

file from *multiple processes* is *not* supported, because there is no standard way to serialize access to a single file across multiple processes in Python. If you need to log to a single file from multiple processes, one way of doing this is to have all the processes log to a **SocketHandler**, and have a separate process which implements a socket server which reads from the socket and logs to file. (If you prefer, you can dedicate one thread in one of the existing processes to perform this function.) [This section](#) documents this approach in more detail and includes a working socket receiver which can be used as a starting point for you to adapt in your own applications.

You could also write your own handler which uses the **Lock** class from the **multiprocessing** module to serialize access to the file from your processes. The existing **FileHandler** and subclasses do not make use of **multiprocessing** at present, though they may do so in the future. Note that at present, the **multiprocessing** module does not provide working lock functionality on all platforms (see <https://bugs.python.org/issue3770>).

Alternatively, you can use a **Queue** and a **QueueHandler** to send all logging events to one of the processes in your multi-process application. The following example script demonstrates how you can do this; in the example a separate listener process listens for events sent by other processes and logs them according to its own logging configuration. Although the example only demonstrates one way of doing it (for example, you may want to use a listener thread rather than a separate listener process – the implementation would be analogous) it does allow for completely different logging configurations for the listener and the other processes in your application, and can be used as the basis for code meeting your own specific requirements:

```
# You'll need these imports in your own code
import logging
import logging.handlers
import multiprocessing

# Next two import lines for this demo only
from random import choice, random
import time
```

```

#
# Because you'll want to define the logging configuration
# listener and worker process functions take a configured
# for configuring logging for that process. These functions
# which they use for communication.
#
# In practice, you can configure the listener however you want.
# simple example, the listener does not apply level or filter.
# In practice, you would probably want to do this logic in the
# sending events which would be filtered out between processes.
#
# The size of the rotated files is made small so you can rotate
def listener_configurer():
    root = logging.getLogger()
    h = logging.handlers.RotatingFileHandler('mptest.log')
    f = logging.Formatter('%(asctime)s %(processName)-10s %(message)s')
    h.setFormatter(f)
    root.addHandler(h)

# This is the listener process top-level loop: wait for
# (LogRecords) on the queue and handle them, quit when you get
# LogRecord.
def listener_process(queue, configurer):
    configurer()
    while True:
        try:
            record = queue.get()
            if record is None: # We send this as a sentinel
                break
            logger = logging.getLogger(record.name)
            logger.handle(record) # No level or filter
        except Exception:
            import sys, traceback
            print('Whoops! Problem:', file=sys.stderr)
            traceback.print_exc(file=sys.stderr)

# Arrays used for random selections in this demo

```

```
LEVELS = [logging.DEBUG, logging.INFO, logging.WARNING,
          logging.ERROR, logging.CRITICAL]
```

```
LOGGERS = ['a.b.c', 'd.e.f']
```

```
MESSAGES = [
    'Random message #1',
    'Random message #2',
    'Random message #3',
]
```

```
# The worker configuration is done at the start of the w
# Note that on Windows you can't rely on fork semantics,
# will run the logging configuration code when it starts
```

```
def worker_configurer(queue):
    h = logging.handlers.QueueHandler(queue) # Just the
    root = logging.getLogger()
    root.addHandler(h)
    # send all messages, for demo; no other level or fil
    root.setLevel(logging.DEBUG)
```

```
# This is the worker process top-level loop, which just
# random intervening delays before terminating.
# The print messages are just so you know it's doing som
```

```
def worker_process(queue, configurer):
    configurer(queue)
    name = multiprocessing.current_process().name
    print('Worker started: %s' % name)
    for i in range(10):
        time.sleep(random())
        logger = logging.getLogger(choice(LOGGERS))
        level = choice(LEVELS)
        message = choice(MESSAGES)
        logger.log(level, message)
    print('Worker finished: %s' % name)
```

```
# Here's where the demo gets orchestrated. Create the qu
```

```

# the listener, create ten workers and start them, wait
# then send a None to the queue to tell the listener to
def main():
    queue = multiprocessing.Queue(-1)
    listener = multiprocessing.Process(target=listener_p
                                     args=(queue, list

    listener.start()
    workers = []
    for i in range(10):
        worker = multiprocessing.Process(target=worker_p
                                     args=(queue, wo

        workers.append(worker)
        worker.start()
    for w in workers:
        w.join()
    queue.put_nowait(None)
    listener.join()

if __name__ == '__main__':
    main()

```

A variant of the above script keeps the logging in the main process, in a separate thread:

```

import logging
import logging.config
import logging.handlers
from multiprocessing import Process, Queue
import random
import threading
import time

def logger_thread(q):
    while True:
        record = q.get()
        if record is None:
            break
        logger = logging.getLogger(record.name)
        logger.handle(record)

```

```

def worker_process(q):
    qh = logging.handlers.QueueHandler(q)
    root = logging.getLogger()
    root.setLevel(logging.DEBUG)
    root.addHandler(qh)
    levels = [logging.DEBUG, logging.INFO, logging.WARNING,
              logging.CRITICAL]
    loggers = ['foo', 'foo.bar', 'foo.bar.baz',
               'spam', 'spam.ham', 'spam.ham.eggs']
    for i in range(100):
        lvl = random.choice(levels)
        logger = logging.getLogger(random.choice(loggers))
        logger.log(lvl, 'Message no. %d', i)

if __name__ == '__main__':
    q = Queue()
    d = {
        'version': 1,
        'formatters': {
            'detailed': {
                'class': 'logging.Formatter',
                'format': '%(asctime)s %(name)-15s %(levelname)s %(message)s'
            }
        },
        'handlers': {
            'console': {
                'class': 'logging.StreamHandler',
                'level': 'INFO',
            },
            'file': {
                'class': 'logging.FileHandler',
                'filename': 'mplog.log',
                'mode': 'w',
                'formatter': 'detailed',
            },
            'foofile': {

```

```

        'class': 'logging.FileHandler',
        'filename': 'mplog-foo.log',
        'mode': 'w',
        'formatter': 'detailed',
    },
    'errors': {
        'class': 'logging.FileHandler',
        'filename': 'mplog-errors.log',
        'mode': 'w',
        'level': 'ERROR',
        'formatter': 'detailed',
    },
},
'loggers': {
    'foo': {
        'handlers': ['foofile']
    }
},
'root': {
    'level': 'DEBUG',
    'handlers': ['console', 'file', 'errors']
},
}

workers = []
for i in range(5):
    wp = Process(target=worker_process, name='worker' + str(i))
    workers.append(wp)
    wp.start()

logging.config.dictConfig(d)
lp = threading.Thread(target=logger_thread, args=(q,))
lp.start()
# At this point, the main process could do some useful work
# Once it's done that, it can wait for the workers to finish
for wp in workers:
    wp.join()
# And now tell the logging thread to finish up, too
q.put(None)
lp.join()

```

This variant shows how you can e.g. apply configuration for particular loggers - e.g. the `foo` logger has a special handler which stores all events in the `foo` subsystem in a file `mplog-foo.log`. This will be used by the logging machinery in the main process (even though the logging events are generated in the worker processes) to direct the messages to the appropriate destinations.

## Using `concurrent.futures.ProcessPoolExecutor`

If you want to use

`concurrent.futures.ProcessPoolExecutor` to start your worker processes, you need to create the queue slightly differently. Instead of

```
queue = multiprocessing.Queue(-1)
```

you should use

```
queue = multiprocessing.Manager().Queue(-1) # also works
```

and you can then replace the worker creation from this:

```
workers = []
for i in range(10):
    worker = multiprocessing.Process(target=worker_process,
                                     args=(queue, worker_id))
    workers.append(worker)
    worker.start()
for w in workers:
    w.join()
```

to this (remembering to first import `concurrent.futures`):

```
with concurrent.futures.ProcessPoolExecutor(max_workers=10):
    for i in range(10):
        executor.submit(worker_process, queue, worker_id)
```

## Deploying Web applications using Gunicorn and uWSGI

When deploying Web applications using [Gunicorn](https://gunicorn.org/) [https://gunicorn.org/] or [uWSGI](https://uwsgi-docs.readthedocs.io/en/latest/) [https://uwsgi-docs.readthedocs.io/en/latest/] (or similar), multiple worker processes are created to handle client requests. In such environments, avoid creating file-based handlers directly in your web application. Instead, use a [SocketHandler](#) to log from the web application to a listener in a separate process. This can be set up using a process management tool such as Supervisor - see [Running a logging socket listener in production](#) for more details.

## Using file rotation

Sometimes you want to let a log file grow to a certain size, then open a new file and log to that. You may want to keep a certain number of these files, and when that many files have been created, rotate the files so that the number of files and the size of the files both remain bounded. For this usage pattern, the logging package provides a **RotatingFileHandler**:

```
import glob
import logging
import logging.handlers

LOG_FILENAME = 'logging_rotatingfile_example.out'

# Set up a specific logger with our desired output level
my_logger = logging.getLogger('MyLogger')
my_logger.setLevel(logging.DEBUG)

# Add the log message handler to the logger
handler = logging.handlers.RotatingFileHandler(
    LOG_FILENAME, maxBytes=20, backupCount=5)

my_logger.addHandler(handler)

# Log some messages
for i in range(20):
    my_logger.debug('i = %d' % i)
```

```
# See what files are created
logfiles = glob.glob('%s*' % LOG_FILENAME)

for filename in logfiles:
    print(filename)
```

The result should be 6 separate files, each with part of the log history for the application:

```
logging_rotatingfile_example.out
logging_rotatingfile_example.out.1
logging_rotatingfile_example.out.2
logging_rotatingfile_example.out.3
logging_rotatingfile_example.out.4
logging_rotatingfile_example.out.5
```

The most current file is always

`logging_rotatingfile_example.out`, and each time it reaches the size limit it is renamed with the suffix `.1`. Each of the existing backup files is renamed to increment the suffix (`.1` becomes `.2`, etc.) and the `.6` file is erased.

Obviously this example sets the log length much too small as an extreme example. You would want to set *maxBytes* to an appropriate value.

## Use of alternative formatting styles

When logging was added to the Python standard library, the only way of formatting messages with variable content was to use the %-formatting method. Since then, Python has gained two new formatting approaches: `string.Template` (added in Python 2.4) and `str.format()` (added in Python 2.6).

Logging (as of 3.2) provides improved support for these two additional formatting styles. The **Formatter** class been enhanced to take an additional, optional keyword parameter named `style`. This defaults to `'%'`, but other possible values are `'{'` and `'$'`, which correspond to the other two formatting styles. Backwards compatibility is maintained by default (as you would expect), but

by explicitly specifying a style parameter, you get the ability to specify format strings which work with `str.format()` or `string.Template`. Here's an example console session to show the possibilities:

```
>>> import logging
>>> root = logging.getLogger()
>>> root.setLevel(logging.DEBUG)
>>> handler = logging.StreamHandler()
>>> bf = logging.Formatter('{asctime} {name} {levelname}:
...                             style='{')
>>> handler.setFormatter(bf)
>>> root.addHandler(handler)
>>> logger = logging.getLogger('foo.bar')
>>> logger.debug('This is a DEBUG message')
2010-10-28 15:11:55,341 foo.bar DEBUG      This is a DEBUG
>>> logger.critical('This is a CRITICAL message')
2010-10-28 15:12:11,526 foo.bar CRITICAL This is a CRITI
>>> df = logging.Formatter('$asctime $name ${levelname}
...                             style='$')
>>> handler.setFormatter(df)
>>> logger.debug('This is a DEBUG message')
2010-10-28 15:13:06,924 foo.bar DEBUG This is a DEBUG me
>>> logger.critical('This is a CRITICAL message')
2010-10-28 15:13:11,494 foo.bar CRITICAL This is a CRITI
>>>
```

Note that the formatting of logging messages for final output to logs is completely independent of how an individual logging message is constructed. That can still use %-formatting, as shown here:

```
>>> logger.error('This is an%s %s %s', 'other,', 'ERROR,
2010-10-28 15:19:29,833 foo.bar ERROR This is another, E
>>>
```

Logging calls (`logger.debug()`, `logger.info()` etc.) only take positional parameters for the actual logging message itself, with keyword parameters used only for determining options for how to handle the actual logging call (e.g. the `exc_info` keyword parameter to indicate that traceback information should be logged,

or the `extra` keyword parameter to indicate additional contextual information to be added to the log). So you cannot directly make logging calls using `str.format()` or `string.Template` syntax, because internally the logging package uses %-formatting to merge the format string and the variable arguments. There would be no changing this while preserving backward compatibility, since all logging calls which are out there in existing code will be using %-format strings.

There is, however, a way that you can use {}- and \$- formatting to construct your individual log messages. Recall that for a message you can use an arbitrary object as a message format string, and that the logging package will call `str()` on that object to get the actual format string. Consider the following two classes:

```
class BraceMessage:
    def __init__(self, fmt, /, *args, **kwargs):
        self.fmt = fmt
        self.args = args
        self.kwargs = kwargs

    def __str__(self):
        return self.fmt.format(*self.args, **self.kwargs)

class DollarMessage:
    def __init__(self, fmt, /, **kwargs):
        self.fmt = fmt
        self.kwargs = kwargs

    def __str__(self):
        from string import Template
        return Template(self.fmt).substitute(**self.kwargs)
```

Either of these can be used in place of a format string, to allow {}- or \$-formatting to be used to build the actual “message” part which appears in the formatted log output in place of “%(message)s” or “{message}” or “\$message”. It’s a little unwieldy to use the class names whenever you want to log something, but it’s quite palatable if you use an alias such as `_` (double underscore — not to be confused with `_`, the single underscore used as a synonym/alias for

`gettext.gettext()` or its brethren).

The above classes are not included in Python, though they're easy enough to copy and paste into your own code. They can be used as follows (assuming that they're declared in a module called `wherever`):

```
>>> from wherever import BraceMessage as __
>>> print(__('Message with {0} {name}', 2, name='placeholder'))
Message with 2 placeholders
>>> class Point: pass
...
>>> p = Point()
>>> p.x = 0.5
>>> p.y = 0.5
>>> print(__('Message with coordinates: ({point.x:.2f}, {point.y:.2f})',
...         point=p))
Message with coordinates: (0.50, 0.50)
>>> from wherever import DollarMessage as __
>>> print(__('Message with $num $what', num=2, what='placeholder'))
Message with 2 placeholders
>>>
```

While the above examples use `print()` to show how the formatting works, you would of course use `logger.debug()` or similar to actually log using this approach.

One thing to note is that you pay no significant performance penalty with this approach: the actual formatting happens not when you make the logging call, but when (and if) the logged message is actually about to be output to a log by a handler. So the only slightly unusual thing which might trip you up is that the parentheses go around the format string and the arguments, not just the format string. That's because the `_` notation is just syntax sugar for a constructor call to one of the `XXXMessage` classes.

If you prefer, you can use a **LoggerAdapter** to achieve a similar effect to the above, as in the following example:

```
import logging
```

```

class Message:
    def __init__(self, fmt, args):
        self.fmt = fmt
        self.args = args

    def __str__(self):
        return self.fmt.format(*self.args)

class StyleAdapter(logging.LoggerAdapter):
    def __init__(self, logger, extra=None):
        super().__init__(logger, extra or {})

    def log(self, level, msg, /, *args, **kwargs):
        if self.isEnabledFor(level):
            msg, kwargs = self.process(msg, kwargs)
            self.logger._log(level, Message(msg, args),

logger = StyleAdapter(logging.getLogger(__name__))

def main():
    logger.debug('Hello, {}, 'world!')

if __name__ == '__main__':
    logging.basicConfig(level=logging.DEBUG)
    main()

```

The above script should log the message `Hello, world!` when run with Python 3.2 or later.

## Customizing LogRecord

Every logging event is represented by a [LogRecord](#) instance. When an event is logged and not filtered out by a logger's level, a [LogRecord](#) is created, populated with information about the event and then passed to the handlers for that logger (and its ancestors, up to and including the logger where further propagation up the hierarchy is disabled). Before Python 3.2, there were only two

places where this creation was done:

- `Logger.makeRecord()`, which is called in the normal process of logging an event. This invoked `LogRecord` directly to create an instance.
- `makeLogRecord()`, which is called with a dictionary containing attributes to be added to the `LogRecord`. This is typically invoked when a suitable dictionary has been received over the network (e.g. in pickle form via a `SocketHandler`, or in JSON form via an `HTTPHandler`).

This has usually meant that if you need to do anything special with a `LogRecord`, you've had to do one of the following.

- Create your own `Logger` subclass, which overrides `Logger.makeRecord()`, and set it using `setLoggerClass()` before any loggers that you care about are instantiated.
- Add a `Filter` to a logger or handler, which does the necessary special manipulation you need when its `filter()` method is called.

The first approach would be a little unwieldy in the scenario where (say) several different libraries wanted to do different things. Each would attempt to set its own `Logger` subclass, and the one which did this last would win.

The second approach works reasonably well for many cases, but does not allow you to e.g. use a specialized subclass of `LogRecord`. Library developers can set a suitable filter on their loggers, but they would have to remember to do this every time they introduced a new logger (which they would do simply by adding new packages or modules and doing

```
logger = logging.getLogger(__name__)
```

at module level). It's probably one too many things to think about. Developers could also add the filter to a `NullHandler` attached to their top-level logger, but this would not be invoked if an application developer attached a handler to a lower-level library logger — so output from that handler would not reflect the

intentions of the library developer.

In Python 3.2 and later, **LogRecord** creation is done through a factory, which you can specify. The factory is just a callable you can set with **setLogRecordFactory()**, and interrogate with **getLogRecordFactory()**. The factory is invoked with the same signature as the **LogRecord** constructor, as **LogRecord** is the default setting for the factory.

This approach allows a custom factory to control all aspects of **LogRecord** creation. For example, you could return a subclass, or just add some additional attributes to the record once created, using a pattern similar to this:

```
old_factory = logging.getLogRecordFactory()

def record_factory(*args, **kwargs):
    record = old_factory(*args, **kwargs)
    record.custom_attribute = 0xdeadbeef
    return record

logging.setLogRecordFactory(record_factory)
```

This pattern allows different libraries to chain factories together, and as long as they don't overwrite each other's attributes or unintentionally overwrite the attributes provided as standard, there should be no surprises. However, it should be borne in mind that each link in the chain adds run-time overhead to all logging operations, and the technique should only be used when the use of a **Filter** does not provide the desired result.

## Subclassing QueueHandler - a ZeroMQ example

You can use a **QueueHandler** subclass to send messages to other kinds of queues, for example a ZeroMQ 'publish' socket. In the example below, the socket is created separately and passed to the handler (as its 'queue'):

```

import zmq    # using pyzmq, the Python binding for ZeroMQ
import json   # for serializing records portably

ctx = zmq.Context()
sock = zmq.Socket(ctx, zmq.PUB)    # or zmq.PUSH, or other
sock.bind('tcp://*:5556')          # or wherever

class ZeroMQSocketHandler(QueueHandler):
    def enqueue(self, record):
        self.queue.send_json(record.__dict__)

handler = ZeroMQSocketHandler(sock)

```

Of course there are other ways of organizing this, for example passing in the data needed by the handler to create the socket:

```

class ZeroMQSocketHandler(QueueHandler):
    def __init__(self, uri, socktype=zmq.PUB, ctx=None):
        self.ctx = ctx or zmq.Context()
        socket = zmq.Socket(self.ctx, socktype)
        socket.bind(uri)
        super().__init__(socket)

    def enqueue(self, record):
        self.queue.send_json(record.__dict__)

    def close(self):
        self.queue.close()

```

## Subclassing QueueListener - a ZeroMQ example

You can also subclass **QueueListener** to get messages from other kinds of queues, for example a ZeroMQ ‘subscribe’ socket. Here’s an example:

```

class ZeroMQSocketListener(QueueListener):

```

```
def __init__(self, uri, /, *handlers, **kwargs):
    self.ctx = kwargs.get('ctx') or zmq.Context()
    socket = zmq.Socket(self.ctx, zmq.SUB)
    socket.setsockopt_string(zmq.SUBSCRIBE, '') # s
    socket.connect(uri)
    super().__init__(socket, *handlers, **kwargs)

def dequeue(self):
    msg = self.queue.recv_json()
    return logging.makeLogRecord(msg)
```

## An example dictionary-based configuration

Below is an example of a logging configuration dictionary - it's taken from the [documentation on the Django project](https://docs.djangoproject.com/en/stable/topics/logging/#configuring-logging) [https://docs.djangoproject.com/en/stable/topics/logging/#configuring-logging]. This dictionary is passed to [dictConfig\(\)](#) to put the configuration into effect:

```
LOGGING = {
    'version': 1,
    'disable_existing_loggers': True,
```

```

'formatters': {
    'verbose': {
        'format': '%(levelname)s %(asctime)s %(module)s',
    },
    'simple': {
        'format': '%(levelname)s %(message)s'
    },
},
'filters': {
    'special': {
        '()': 'project.logging.SpecialFilter',
        'foo': 'bar',
    }
},
'handlers': {
    'null': {
        'level': 'DEBUG',
        'class': 'django.utils.log.NullHandler',
    },
    'console': {
        'level': 'DEBUG',
        'class': 'logging.StreamHandler',
        'formatter': 'simple'
    },
    'mail_admins': {
        'level': 'ERROR',
        'class': 'django.utils.log.AdminEmailHandler',
        'filters': ['special']
    }
},
'loggers': {
    'django': {
        'handlers': ['null'],
        'propagate': True,
        'level': 'INFO',
    },
    'django.request': {
        'handlers': ['mail_admins'],

```

```

        'level': 'ERROR',
        'propagate': False,
    },
    'myproject.custom': {
        'handlers': ['console', 'mail_admins'],
        'level': 'INFO',
        'filters': ['special']
    }
}

```

For more information about this configuration, you can see the [relevant section](https://docs.djangoproject.com/en/stable/topics/logging/#configuring-logging) [https://docs.djangoproject.com/en/stable/topics/logging/#configuring-logging] of the Django documentation.

## Using a rotator and namer to customize log rotation processing

An example of how you can define a namer and rotator is given in the following runnable script, which shows gzip compression of the log file:

```

import gzip
import logging
import logging.handlers
import os
import shutil

def namer(name):
    return name + ".gz"

def rotator(source, dest):
    with open(source, 'rb') as f_in:
        with gzip.open(dest, 'wb') as f_out:
            shutil.copyfileobj(f_in, f_out)
    os.remove(source)

```

```
rh = logging.handlers.RotatingFileHandler('rotated.log',
rh.rotator = rotator
rh.namer = namer

root = logging.getLogger()
root.setLevel(logging.INFO)
root.addHandler(rh)
f = logging.Formatter('%(asctime)s %(message)s')
rh.setFormatter(f)
for i in range(1000):
    root.info(f'Message no. {i + 1}')
```

After running this, you will see six new files, five of which are compressed:

```
$ ls rotated.log*
rotated.log      rotated.log.2.gz  rotated.log.4.gz
rotated.log.1.gz rotated.log.3.gz  rotated.log.5.gz
$ zcat rotated.log.1.gz
2023-01-20 02:28:17,767 Message no. 996
2023-01-20 02:28:17,767 Message no. 997
2023-01-20 02:28:17,767 Message no. 998
```

## A more elaborate multiprocessing example

The following working example shows how logging can be used with multiprocessing using configuration files. The configurations are fairly simple, but serve to illustrate how more complex ones could be implemented in a real multiprocessing scenario.

In the example, the main process spawns a listener process and some worker processes. Each of the main process, the listener and the workers have three separate configurations (the workers all share the same configuration). We can see logging in the main process, how the workers log to a QueueHandler and how the listener implements a QueueListener and a more complex logging configuration, and arranges to dispatch events received via the queue to the handlers specified in the configuration. Note that these

configurations are purely illustrative, but you should be able to adapt this example to your own scenario.

Here's the script - the docstrings and the comments hopefully explain how it works:

```
import logging
import logging.config
import logging.handlers
from multiprocessing import Process, Queue, Event, current_process
import os
import random
import time

class MyHandler:
    """
    A simple handler for logging events. It runs in the
    dispatches events to loggers based on the name in the
    which then get dispatched, by the logging system, to
    configured for those loggers.
    """

    def handle(self, record):
        if record.name == "root":
            logger = logging.getLogger()
        else:
            logger = logging.getLogger(record.name)

        if logger.isEnabledFor(record.levelno):
            # The process name is transformed just to show
            # doing the logging to files and console
            record.processName = '%s (for %s)' % (current_process().name, record.name)
            logger.handle(record)

def listener_process(q, stop_event, config):
    """
    This could be done in the main process, but is just
    process for illustrative purposes.
    """
```

This initialises logging according to the specified  
starts the listener and waits for the main process t  
via the event. The listener is then stopped, and the  
"""

```
logging.config.dictConfig(config)
listener = logging.handlers.QueueListener(q, MyHandler)
listener.start()
if os.name == 'posix':
    # On POSIX, the setup logger will have been confi
    # parent process, but should have been disabled
    # dictConfig call.
    # On Windows, since fork isn't used, the setup l
    # exist in the child, so it would be created and
    # would appear - hence the "if posix" clause.
    logger = logging.getLogger('setup')
    logger.critical('Should not appear, because of o
stop_event.wait()
listener.stop()
```

```
def worker_process(config):
    """
    A number of these are spawned for the purpose of ill
    practice, they could be a heterogeneous bunch of pro
    ones which are identical to each other.
```

This initialises logging according to the specified  
and logs a hundred messages with random levels to ra  
loggers.

A small sleep is added to allow other processes a ch  
is not strictly needed, but it mixes the output from  
processes a bit more than if it's left out.

```
"""
logging.config.dictConfig(config)
levels = [logging.DEBUG, logging.INFO, logging.WARNI
          logging.CRITICAL]
loggers = ['foo', 'foo.bar', 'foo.bar.baz',
           'spam', 'spam.ham', 'spam.ham.eggs']
```

```

if os.name == 'posix':
    # On POSIX, the setup logger will have been conf
    # parent process, but should have been disabled
    # dictConfig call.
    # On Windows, since fork isn't used, the setup l
    # exist in the child, so it would be created and
    # would appear - hence the "if posix" clause.
    logger = logging.getLogger('setup')
    logger.critical('Should not appear, because of o
for i in range(100):
    lvl = random.choice(levels)
    logger = logging.getLogger(random.choice(loggers
    logger.log(lvl, 'Message no. %d', i)
    time.sleep(0.01)

```

```

def main():
    q = Queue()
    # The main process gets a simple configuration which
    config_initial = {
        'version': 1,
        'handlers': {
            'console': {
                'class': 'logging.StreamHandler',
                'level': 'INFO'
            }
        },
        'root': {
            'handlers': ['console'],
            'level': 'DEBUG'
        }
    }
    # The worker process configuration is just a QueueHa
    # root logger, which allows all messages to be sent
    # We disable existing loggers to disable the "setup"
    # parent process. This is needed on POSIX because th
    # be there in the child following a fork().
    config_worker = {
        'version': 1,

```

```

'disable_existing_loggers': True,

# Log some initial events, just to show that logging
# normally.
logging.config.dictConfig(config_initial)
logger = logging.getLogger('setup')
logger.info('About to create workers ...')
workers = []
for i in range(5):
    wp = Process(target=worker_process, name='worker'
                 args=(config_worker,))

```

```

        workers.append(wp)
        wp.start()
        logger.info('Started worker: %s', wp.name)
    logger.info('About to create listener ...')
    stop_event = Event()
    lp = Process(target=listener_process, name='listener',
                 args=(q, stop_event, config_listener))
    lp.start()
    logger.info('Started listener')
    # We now hang around for the workers to finish their
    for wp in workers:
        wp.join()
    # Workers all done, listening can now stop.
    # Logging in the parent still works normally.
    logger.info('Telling listener to stop ...')
    stop_event.set()
    lp.join()
    logger.info('All done.')

if __name__ == '__main__':
    main()

```

## Inserting a BOM into messages sent to a SysLogHandler

**RFC 5424** [<https://datatracker.ietf.org/doc/html/rfc5424.html>] requires that a Unicode message be sent to a syslog daemon as a set of bytes which have the following structure: an optional pure-ASCII component, followed by a UTF-8 Byte Order Mark (BOM), followed by Unicode encoded using UTF-8. (See the [relevant section of the specification](https://datatracker.ietf.org/doc/html/rfc5424.html#section-6) [<https://datatracker.ietf.org/doc/html/rfc5424.html#section-6>].)

In Python 3.1, code was added to **SysLogHandler** to insert a BOM into the message, but unfortunately, it was implemented incorrectly, with the BOM appearing at the beginning of the message and hence not allowing any pure-ASCII component to appear before it.

As this behaviour is broken, the incorrect BOM insertion code is being removed from Python 3.2.4 and later. However, it is not being replaced, and if you want to produce [RFC 5424](https://datatracker.ietf.org/doc/html/rfc5424.html) [https://datatracker.ietf.org/doc/html/rfc5424.html]-compliant messages which include a BOM, an optional pure-ASCII sequence before it and arbitrary Unicode after it, encoded using UTF-8, then you need to do the following:

1. Attach a **Formatter** instance to your **SysLogHandler** instance, with a format string such as:

```
'ASCII section\ufeffUnicode section'
```

The Unicode code point U+FEFF, when encoded using UTF-8, will be encoded as a UTF-8 BOM – the byte-string `b'\xef\xbb\xbf'`.

2. Replace the ASCII section with whatever placeholders you like, but make sure that the data that appears in there after substitution is always ASCII (that way, it will remain unchanged after UTF-8 encoding).
3. Replace the Unicode section with whatever placeholders you like; if the data which appears there after substitution contains characters outside the ASCII range, that's fine – it will be encoded using UTF-8.
